Introduction Critical torque is suggested as a demarcation point, above which fatigue develops and exercise termination will occur (Burnley, 2009). Distinct profiles of neuromuscular fatigue have been demonstrated above and below critical torque (Burnley, Vanhatalo & Jones 2012), however the neuromuscular processes underpinning fatigue development at intensities exceeding critical torque have not been investigated. Therefore, the aim of the study was to investigate fatigue development during repeated maximal isometric knee extensor contractions (MVC) at two intensities exceeding critical torque, employing electrical stimulation of the femoral nerve. Methods Young healthy individuals ($n=10$, 4 males, MVC 132 ± 13 Nm, height 1.69 ± 0.12 m, body mass 67.2 ± 15.2 kg) completed intermittent isometric knee extensor exercise to exhaustion at 90% (H) and 55% (M) MVC. Performance variables (time to fatigue, peak torque) were measured. Electrical stimulation of the femoral nerve was applied during knee extension MVCs and at rest, pre and post intermittent exercise to quantify voluntary activation (VA), peripheral (M-wave) evoked responses in m. vastus medialis as well as electromechanical delay and twitch responses. Results Time to fatigue was significantly longer (M: 1412 ± 195 vs H: 144 ± 25 s, interaction effect $p<0.001$) and change in peak torque was significantly greater in the 55% than 90% condition (M: $-81.4 \pm 3.6\%$, H: $-25.3 \pm 4.6\%$; interaction effect $p<0.05$) after fatiguing exercise. Peripheral excitability significantly decreased in the 55% but not 90% condition (M-Wave area/MVC, M: $-29.5 \pm 5.5\%$, H: $-3.9 \pm 7.4\%$, interaction effect $p = 0.006$), whereas electromechanical delay significantly decreased in the 90% but not 55% condition (M: $3.97 \pm 8.74\%$, H: $-28.1 \pm 5.76\%$, interaction effect $p=0.03$). Voluntary activation was decreased after fatiguing exercise ($p=0.004$), but the change was not significantly different between conditions. Discussion Fatigue profiles above critical torque were intensity dependent, unsurprisingly, with extended exercise duration at the lower contraction intensity. Termination of exercise occurred after a similar magnitude decline in voluntary activation in both conditions; yet peripheral excitability was not reduced in the shorter duration, but higher intensity protocol. Differences in the rate and magnitude of extracellular potassium and hydrogen ion accumulation, resulting changes in membrane potentials, as well as altered excitation-contraction coupling are likely to be implicated. RECOVERY OF NEUROPHYSIOLOGICAL FACTORS AFTER AN INTERMITTENT FATIGUE PROTOCOL DESIGNED FOR MOTORCYCLE RIDERS

TORRADO, P.1, MORALES, M.2, VALLS-SOLÉ, J.2, MARINA, M.1

1: INEFC (Barcelona, Spain), 2: Hospital clinic (Barcelona, Spain)

Introduction The neuromuscular system is highly demanded during a motorcycle race and fatigue levels are high especially in their forearms. The purpose is to describe the time course of recovery of different neurophysiological parameters on the exerted and contralateral extensor digitorum (ED) following an intermittent fatigue protocol (IFP). Methods Twelve males (31.3 ± 7.5 years) participated in this study. The IFP was performed in a specially designed road race motorcycle simulator (Marina, et al., 2013) with subjects operating both the braking and gas handle. Subjects performed work/rest cycles until exhaustion consisting of 6 brakes of 6s duration at 30% of the maximal voluntary contraction (MVC), and 4s in which they turned the throttle twice. Pre- and Post-exercise we (1) stimulated the radial nerve to obtain the maximal M-wave in the ED muscle of the fatigued limb; (2) stimulated the ED cortical motor area with transcranial magnetic stimulation to elicit motor evoked potentials at rest (MEPR) and facilitated (MEPF) and the cortical silence period (CSP) in both the exercised and contralateral limb. The recovery period consisted of 20 minutes and the assessment was taken at 0, 3, 5, 10 and 20 min (T0, T3, T5, T10 and T20) after the IFP. Results There was significant difference in MVC values of exercised limb at the end of the IFP which remained depressed after 20 min. Regarding the M-wave, there was a significant depression at T0 and an early recovery between the first 3 minutes. We observe a prolongation of the CSP at T0 and again a depression in MEPR and MEPF of the fatigued limb. While CSP recovered early in the first 3 min, MEPF recovered in the first 5 min, MEPR needed more than 10 minutes to recover the baseline. Although M-wave values recovered faster than MEPs, we may not overestimate inhibition of cortical excitability because changes in muscle electrophysiological properties could alter MEP amplitude (Gruet et al., 2013). There was no difference neither MVC values nor in any of the neurophysiological variables of the non-exercised limb. Conclusion Despite the recovery of the neurophysiological parameters, the MVC values of the exercised limb remained depressed after 20 min. Although the absence of cross-over effects in the non-exercised limb suggested that local factors have a major role in MVC depression, we cannot conclude this as an absence of central fatigue because other central fatigue indicators are needed. EFFECTS OF ANODAL TRANSCRANIAL DIRECT CURRENT STIMULATION ON CORTICOSPINAL EXCITABILITY AND TIME TO FAILURE OF A SUBMAXIMAL CONTRACTION

ABDELMOLA, A., BAUDRY, S., DUCHATEAU, J.

Université libre de Bruxelles

Introduction Anodal transcranial direct current stimulation (α -tDCS) consists of a low-intensity electrical stimulation that can increase corticospinal excitability when applied over the motor cortex (3). Previous work reported that α -tDCS increased time to failure of a sustained submaximal isometric contraction of elbow flexors performed 60 min after a similar contraction (1). Furthermore, it has been shown that during this type of fatiguing contraction, corticospinal excitability changes differently between agonist and antagonist muscles during sustained contractions (2). The aim of this work was to study the effects of α -tDCS on time to failure in relation with changes in excitability of the corticospinal pathway of two agonist [biceps brachii (BB), brachioradialis (BRD)] and one antagonist triceps brachii (TB) muscles during a sustained isometric contraction performed with the elbow flexors. Methods Eleven young adults performed 2 isometric contractions until failure at an intensity of 35% of maximal voluntary force separated by one hour in 2 separate sessions. During one session, α -tDCS was applied over the motor cortex for 10 min at the end of the rest period between the 2 fatiguing contractions whereas during the other session, sham stimulation was applied. Surface electromyogramme (EMG) was recorded for BB, BRD and TB during the first (C1) and second (C2) fatiguing contraction. Changes in corticospinal excitability during C1 and C2 were assessed by recording, in the same muscles, motor evoked potential (MEP) elicited by transcranial magnetic stimulation of the motor cortex. Results Time to failure was briefer for C2 than C1 in both experimental sessions, but the reduction was less pronounced ($p = 0.04$) after α -tDCS ($-14.4 \pm 12.7\%$) than sham stimulation ($-23.3 \pm 11.9\%$). In contrast, changes in MEP amplitude and EMG activity in both agonist and antagonist muscles were similar between C1 and C2, and did not differ between sessions ($p>0.05$). Similarly co-activation did not change during the different contractions ($p>0.05$). Discussion In agreement with previous work (1), time to failure of C2 was increased following α -tDCS. However, α -tDCS did not influence muscle activity (EMG) and corticospinal excitability (MEP) during C2, neither in agonist nor antagonist muscles. These results suggest that the effect of α -tDCS on time to task failure should rely on other neural structures than the corticospinal pathway or on cognitive functions involved during sustained isometric contractions. PERFORMANCE IMPROVEMENT DURING A DECEPTIVE CYCLING TIME-TRIAL IS ASSOCIATED WITH GREATER CENTRAL FATIGUE BUT SIMILAR PERIPHERAL FATIGUE

DUCROCQ, G.P.1, HUREAU, T.J.1, MESTE, O.2, BLAIN, G.M.1

University Nice Sophia Antipolis, Toulon, LAMHESS, EA 6312, Nice, France ; CNRS – University Nice Sophia Antipolis, I3S, Sophia Antipolis, France

Time to task failure during high-intensity, exhaustive cycling exercise might coincide with a severe degree of peripheral fatigue, which is never voluntarily exceeded by the exercising human (i.e. a "critical threshold"). However, data showed that it is possible to improve performance time during cycling time trial (TT), by misleading participants into believing they are racing against a virtual avatar reproducing a previous TT when, in fact, power output was greater (i.e. deceptive TT). The neuromuscular consequences underpinning this performance improvement remains to be determined. Therefore, the present study aimed to investigate the influence of deceptive TTs on end-exercise peripheral and central fatigue. Ten participants performed, on separate days, one maximal 5km TT (5KCTRL) and three deceptive 5km TTs, during which they had to strictly adjust their pace to match the one of a virtual pacer. Whilst participants were informed that the virtual pacer reproduced the pattern of power output measured during 5KCTRL, which was true in only one session (5K100%), power output was in fact 5% (5K105%) and 10% (5K110%) greater in two other sessions. Maximal voluntary contraction (MVC) and peripheral fatigue were quantified via changes in pre- to post-exercise isometric quadriceps force and potentiated quadriceps twitch force (QTW) as evoked by supramaximal electrical stimulation of the femoral nerve, respectively. Central fatigue was estimated via changes in pre- to post-exercise quadriceps voluntary activation (VA). Power output ($229 \pm 64\text{W}$ vs $219 \pm 61\text{W}$, $P<0.001$) and performance time ($9.03 \pm 1.2\text{min}$ vs $9.16 \pm 1.2\text{min}$, $P<0.001$) were improved by $5 \pm 2\%$ and $2 \pm 1\%$ in 5K105% compared to 5K100%, respectively. These improvements were associated with a $14 \pm 6\%$ and $28 \pm 9\%$ greater reduction in MVC ($-41 \pm 14\%$ vs $-36 \pm 14\%$, $P<0.01$) and VA ($-19 \pm 10\%$ vs $-15 \pm 9\%$, $P<0.01$) but unchanged QTW ($-51 \pm 8\%$ vs $-50 \pm 9\%$, $P=0.55$) in 5K105% vs 5K100%, respectively. During 5K110%, participants failed ($P>0.25$) to improve power output ($223 \pm 60\text{W}$) and performance time ($9.12 \pm 1.1\text{min}$) compared to 5K100%. Following 5K110%, reduction in MVC ($-40 \pm 14\%$), VA ($-16 \pm 9\%$) and QTW ($-51 \pm 8\%$) were not different compared to 5K100% ($P>0.23$). Our data showed that performance improvement during a deceptive TT is limited to small increments in power output and occurred at the expense of a centrally-mediated reduction in the muscle force generating capacity. This rise in central fatigue might assure that muscle activation does not surpass a level that would cause a further accumulation of peripheral fatigue beyond an invariable level.

NEUROMUSCULAR FATIGUE DEPENDS ON RELATIVE BLOOD-FLOW RESTRICTION LEVELS

FATELA, P., REIS, J., MENDONÇA, G., AVELA, J., MIL-HOMENS, P.

Universidade de Lisboa - Faculdade de Motricidade Humana

Introduction: The acute neuromuscular response to blood flow restriction exercise (BFRE) is yet to be understood, particularly with different relative levels of BFR. This study aimed to resolve methodological limitations reported in literature (Loenneke, 2015), and to extent the findings of past research on the neuromuscular adaptations to BFRE performed at different levels of pressure (Loenneke, 2015; Yasuda, 2008). We examined the acute effects of low-intensity knee extensions (20% 1RM) with BFR, on neuromuscular fatigue and torque of the rectus femoris (RF) and vastus medialis (VM) muscles. Methods: Fourteen young men (24.8 ± 5.4 yrs; height: 175.2 ± 4.4 cm; body mass: 71.1 ± 6.9 kg) were tested on 3 different conditions of unilateral knee extension exercise (20% 1RM: 4 sets of $30+15+15+15$ reps) with BFR. Conditions were determined by various BFR levels normalized to the pressure value of absolute vascular occlusion, determined at rest (40, 60 and 80% BFR). Torque was collected from a Biodex System 3 (Shirley, NY), during pre and post-exercise MVCs. Neuromuscular fatigue was determined through EMG signal - median frequency (MF); using Trigno™ wireless system (Delsys, USA). MF was calculated through 3 sustained isometric contractions (20% MVC), at 4 time-points: pre 1 – baseline; pre 2 – 1 min after cuff inflation; post 1 – immediately after exercise; post 2 – 1 min after cuff release. Paired t tests were used to explore differences in torque and MF parameters, for

each condition (40, 60 and 80%BFR). A two-way repeated measures ANOVA [condition (40 vs. 60 vs. 80%BFR) x time (pre1 vs. pre2 vs. post1 vs. post2)] was conducted to determine the effects pre to post-exercise on MF. Results: Torque only decreased (-5.2%) in the 80%BFR condition ($p<0.01$). One minute after cuff inflation (pre1 to pre2), MF was only significantly different in the 80% BFR condition for the RF muscle (-7.8%, $p<0.01$). After exercise with various levels of BFR (pre2 to post1), MF decreased significantly in the RF muscle (40%BFR: -8.4%, 60%BFR: -15.2%, 80%BFR: -21.2%, $p<0.01$) and in the VM muscle (60%BFR: -3.2%, 80%BFR: -7.5%, $p<0.01$). After cuff release (post1 to post2), MF increased significantly in both muscles for all conditions, although MF of the RF was still significantly different between pre1 and post 2 (-11.8%, $p<0.01$), after the 80%BFR condition. Discussion: This study demonstrated that the magnitude and duration of neuromuscular fatigue is dependent on the relative level of vascular restriction. Accordingly, within resistance training context, BFR should not be prescribed using standardized values of occlusion pressure, as the relationship between relative and absolute values of BFR pressure can be very different. OP-BN08 Sport Technology: Movement Monitors

RELIABILITY OF A LASER SYSTEM WITH AN AUTOMATIC CONTROL TRACKING FOR MONITORING THE RUNNING OF ATHLETES USING COMPUTER VISION

VILLACIEROS, J.1, MENDOZA, D.2, DOMÍNGUEZ, S.2, GARRIDO, G.1, GRAMS, L.1, FERRO, A.1

1: Faculty of Physical Activity and Sports Science-INEF. Universidad Politécnica de Madrid. Spain 2: Technical School of Industrial Engineering. Universidad Politécnica de Madrid. Spain

Introduction Laser sensors for analyzing velocity in real-time is adequate (Ferro et al, 2014) although its use has been limited to placing them on tripods (Graubner and Nixdorf, 2011) or to guide them manually, being easy to lose the bean contact with the athletes' backs. The purpose was to analyze the reliability test re-test of a laser system (BioLaserSport®) equipped with an automatic tracking which is controlled by computer vision for monitoring the athletes in order to obtain their running velocity. Methods Eighteen male, recreationally active healthy students (age=20.18 ± 1.56 years, height= 1.77 ± 0.05 m, body mass=69.19 ± 5.34 kg) took part in two series of 30 m sprint during two days in the same week. Distances were measured in real time by a laser system Biolasersport® (Ferro, 2012; Ferro and Floria, 2010) using a LD301-Jenoptik-type1-laser at 2000 Hz. For to develop an algorithm that allows tracking clearly and concise of the location of the marker used by the athlete, we use the open library Open Computer Vision-open CV. It allows to apply techniques of computer vision. Calchist function, to select the region of interest (the color reference) for calculating the histogram was used. The center of region or center of mass provides x,y coordinates into the image analyzed. This coordinates were used to make the control of the positions and orientations of Biolasersport®. An integral proportional control (IP) to calculate the error between the center of the frame and center visual reference for provide the correction signal required on the system was used.. Average velocities (Vm) and maximum velocities (Vmax), over sections 0-10, 10-20 and 20-30 m were analyzed. Intraclass correlation coefficient (ICC) with confidence interval (CI) of 95%, standard error of measurement (SEM) and the minimum difference (MD) to be considered "real" were used to analyses Intrasession and intersession reliability. Results The ICC intrasession and intersession values obtained were 0.85-0.93 for Vmax and 0.85-0.97 forVm. SEM was lower than 0.14 m/s for Vmax and 0.09 m/s for Vm. MD was lower than 0.28 m/s for Vmax and 0.24 m/s for Vm. Discussion The ICC intrassession was excellent being higher in Vm than in Vmax and better than ICC intersession. The minimum value at which a change in performance would be considered would exceed 4.67%. The automatic control implemented in the laser system by computer vision can improve reliability in the analysis of the velocity in real time, eliminating human error produced when aiming the laser sensor manually. Also, it can be used in competition conditions without the colours or shapes the environment affect their measure. References 1. R. Graubner, R. Nixdorf, E. (2011). New Stud. Athlet. 26, 19-53. 2. 2. RELIABILITY OF WEARABLE MICROSSENSORS TO MEASURE PHYSICAL ACTIVITY IN HANDBALL

SPENCER, M., HOLME, B.R., LUTEBERGET, L.S.

Norwegian School of Sports Sciences

Introduction In recent years, there has been an increased use of wearable tracking technology to measure the physical activity in elite team sports. However, there is currently limited published information on the reliability of these devices (Chambers et al., 2015). Therefore, the aim of this study was to assess the reliability and sensitivity of a commercially available microsensor technology to measure the specific physical activity demands in handball. Methods A total of twenty-two, male and female, elite and highly-trained handball players (age, 22.6 ± 3.7 years; body mass, 84.0 ± 14.2 kg; height, 184.4 ± 12.0 cm; mean ± SD) participated in the study. The subjects were instrumented with two devices (Optimeye S5, Catapult Sports, Melbourne, Australia), and partook either in a laboratory assessment ($n = 10$) or field assessment ($n = 12$). The laboratory assessment consisted of seven different handball specific movement tasks. The field assessment consisted of twelve handball-training sessions. Selected inertial movement analysis (IMA) variables were extracted from the manufacturer's software (Catapult Sprint, Catapult Sports, Melbourne, Australia), including IMA magnitude and counts, in addition to PlayerLoad™. The reliability and sensitivity was estimated using typical error ± 90% CI (expressed as coefficient of variation [CV]) and smallest worthwhile different (SWD) (Hopkins, 2015). Results Laboratory assessment: IMA magnitude showed good reliability (CV 2.9%) in well-controlled movement tasks. The CV increased (4.4 to 8.2%) in more chaotic movement tasks. Field assessment: IMA counts showed a good reliability (CV 2.4%) when displayed as total counts. However, the CV increased when categorized into low (1.5-2.5 m.s-1; 2.9%), medium (2.5-3.5 m.s-1; 5.5%) and high (>3.5 m.s-1; 5.6%) intensity bands. Medium/high band (combined) showed a CV of 3.9%. The CV for low, medium/high and total counts was less than the SWD. Furthermore, it was observed a good reliability (CV 0.9%) for PlayerLoad™, which was less than the SWD. Discussion The reliability of IMA counts was acceptable, given that data were expressed as low, medium/high and total counts. PlayerLoad™ also demonstrated acceptable reliability. As the CV of the aforementioned variables were below the SWD, this suggests that the Optimeye S5 microsensors and its software are sensitive to detect "real and worthwhile" differences in

typical handball activity. References Chambers, R., Gabbett, T.J., Cole, M.H., & Beard, A. (2015). Sports Med., 45: 1065-1081. Hopkins, W.G. (2015). Sportscience 19, 36-42 (sportsci.org/2015/ValidRely.htm). Contact: matt.spencer@nih.no

DEVELOPMENT OF A MULTI-AXIAL MECHATRONIC STRENGTH TRAINING AND TESTING DEVICE

RASCHNER, C.1, PATTERSON, C.1, BARTH, M.2, BARTH, A.1

1 University Innsbruck, Austria; 2 University Jena, Germany

Introduction Strength and power are very important in elite sport so high quality training and testing is imperative. Mechatronic systems utilizing mechanical, electronic and software components are commonplace in industry. Published documentation of robotic applications in elite sport is rare, with the exception of isokinetic devices (Haddadina et al., 2009). The aim of this project was to develop a multi-axial mechatronic-based leg strength training and testing device. Methods The following demands in the development process of the new device must be met: linear and curvilinear movements, variable speeds, bilateral and unilateral training, concentric and eccentric as well as sport-specific training. The athlete should have force and position visual feedback and a test mode should be available for all movements. Results The developed device (Evo) is constructed as a right/left leg independent system, each consisting of two synchronized servomotors for the horizontal and vertical plane connected to spindles and servo controllers. The Evo operates with a programmable logic controller (PLC) used for automation of electromechanical input and output processes. Training and testing software are downloaded onto the PLC. The coach operates the Evo with a handheld terminal with a 6.5" VGA TFT display. The prototype allows for both single axis (horizontal and vertical linear movement) and for two coordinated axes (curves, circles and ellipses) training and testing. The maximum speeds of horizontal and vertical movements are 2.5m/s and 3.3m/s, respectively. Maximum load capacities are 4.8kN horizontally and 1.6kN vertically. The form of the ellipse (steeper or flatter angle) or circle as well as the repetitions per minute (up to 100) can be chosen on the handheld control. Additionally several stretch shortening cycles or stochastic shocks can be included. To measure the force values two 3-dimensional force plates were integrated into the foot plates. Discussion The Evo utilizes mechatronics allowing a multitude of general and sport-specific movement combinations of concentric and eccentric exercises for leg/hip extension and flexion muscles with visual force and position feedback. Training and testing on the Evo offer basic research opportunities such as the analysis of stretch-shortening cycles and stochastic shocks in the different training modes and speeds. Additionally eccentric hamstring training on the Evo in the vertical plane and with curves could have potential for injury prevention. Mechatronics can transform training conceptions into reality for high performance athletes. References Haddadina S, Laue T, Frese U, Wolfa S, Albu-Schäffer A, Hirzinger G. (2009). RECOGNITION OF DYNAMIC AND STATIONARY ACTIVITY TYPES IN OUT-OF-LAB CONDITIONS USING HEART RATE AND ACCELEROMETERS DATA FUSION

ABDULRAHMAN, H.1,2,3, LEFAUCHEUR, A.1,4, GE, D.2,3, CARRAULT, G.2,3, PRIOUX, J.1,4

Ecole Normale Supérieure - Rennes

Introduction Of particular interest in healthcare monitoring, automatic recognition of human activity has become an extensively researched topic. Unlike the majority of recognition systems, our study focuses on the classification of dynamic and stationary activities extended to natural out-of-lab conditions, with a two-fold purpose: (i) find the optimal sensors placements on the body and (ii) assess the effect of combining the heart rate (HR) information to the acceleration. Methods The dataset was established on 8 volunteers freely performing 5 activities: run, walk, cycle, car ride, and rest (stand or sit). 4 nodes manufactured by the SHIMMER Company (Dublin, Ireland) recording 3D raw acceleration signals (in gravity unit: g) were attached to the ankle, chest, wrist and hip of the subjects and 6 electrodes were placed on the chest to extract the HR measures from the RR waves of the recorded Electrocardiogram (ECG) signals. The recognition model is based on a previously developed method (AbdulRahman et al., 2015) that extracts the spectral distances features from acceleration data. These features are then used as input for 3 commonly used classifiers: the K-Nearest neighbors (KNN), the Naive Bayes (NB) and the Decision Tree (DT) for activity prediction (Lara et al. 2013). Results With the 4-position accelerometers, an overall classification rate of $99.0\% \pm 0.4$ was achieved by the KNN classifier, while the NB and the DT classifiers marked $87.8\% \pm 1.1$ and $95.9\% \pm 1.1$ respectively. $89.8\% \pm 1.0$, $94.5\% \pm 0.8$, $95.4\% \pm 0.7$ and $95.7\% \pm 0.7$ are the system responses when considering the single node on the chest, the wrist, the hip and the ankle respectively. These accuracies raise to $94.1\% \pm 1.1$, $97.9\% \pm 0.6$, $98.7\% \pm 0.5$, and $98.7\% \pm 0.3$ when coupling the HR information to each corresponding position. Discussion The lower limbs sensors hold the most valuable information for the prediction of the dynamic and stationary activity types. Unlike the 'rest' and 'car ride' activities, 'run' and 'walk' are correctly detected, which support the idea that ambulation behaviors involve quasi-periodic movement of the body (Altun et al. 2010). Combining acceleration and HR data enhance the accuracy of the identification. Thus, with an HR monitor and only a single unit accelerometer, it is accurately sufficient to classify dynamic and stationary activities (mean accuracy higher than 97%). MOBILITY PERFORMANCE MEASUREMENT IN WHEELCHAIR BASKETBALL

VAN DER SLIKKE, R., BERGER, M., BREGMAN, D., VEEGER, H.

The Hague University of Applied Sciences

Introduction The current level of play in wheelchair basketball requires a professional approach in optimizing overall game performance, including the mobility performance of each individual athlete. This mobility performance describes the kinematics of the wheelchair-athlete combination. The goal of this research was to evaluate a mobility performance measurement method by measuring athletes of different competition level and classification in wheelchair basketball. Given the level of impairment, kinematic based mobility performance was expected to differ between classification groups. Differences due to competition level or gender, were expected to be more subtle and with differences mainly in the strength and skill related (rotational) acceleration. Methods Using a three inertial measurement unit configuration (Van Der Slikke et al. 2015), wheelchair kinematics of 29 national and international level athletes were measured during a match. The following wheelchair kinematics were measured: displacement, speed, acceleration, rotation, rotational speed and rotational acceleration. The new measurement method was rated as accurate, if expected differences in kinematics showed significant with large Cohen's d effect sizes. Results All calculated kinematics differed significantly between classification groups, with less impaired athletes being faster, with higher accelerations. National level players rotated significantly slower than international players and with significantly lower rotational acceleration from standstill. All significant differences uncovered also showed large (> 0.8) Cohen's d effect

sizes. Discussion The method was concluded to be accurate, since it was able to detect all expected differences in mobility performance between groups. The true value of the new method showed in picking up differences in (rotational) acceleration between competition level or gender groups, something to our knowledge was not measured before. The application of the inertial measurement unit configuration allowed for a more detailed and more accurately quantified measure of wheelchair mobility performance. The method proved to be able to discriminate well between expected differences of aspects of mobility performance, between athletes of different classification, competition level or gender. The measured between-group differences in higher order outcomes, mark the need for including (rotational) acceleration in the quantification of mobility performance. Consequently, the new method measures important aspects of mobility performance and it enables individual athlete evaluation. In such way, it is a crucial tool in professionalizing wheelchair sports, since it supports evaluation of interventions in wheelchair settings or athlete training. References Van Der Slikke, R. M. OP-PM19 Soccer & Rugby Performance

DEVELOPMENT OF PHYSICAL AND SPORTS SPECIFIC PERFORMANCE OF YOUTH SOCCER PLAYERS FOR THE PERIOD OF ONE SEASON.

HOFER, C., WIRTH, K., HALLER, A.

Fachhochschule Wiener Neustadt

Introduction The purpose of this study is to reveal possible developments between two performance groups within the same team for the period of one season. It has already been shown that jumping and sprinting abilities can be increased through strength training interventions (Wirth et al., 2011). The aim of this study is to disclose how one different training session influences sports motoric and soccer specific performance parameters although training and match volume keeps the same. **Methods** The subjects (n=15; age= 9.17 ± 0.28; sex= 14 m, 1 w) played all for the same team, but participated in different training sessions (2 groups). Once a week the training of the high performance group members was replaced by a session at a performance centre (LAZ) and they were selected by talent scouts of the Austrian Football Association (OEFB). Performance parameters were analysed for Drop Jumps (DJ) from various heights (16, 24 and 32 cm), Squat Jumps (SJ), Countermovement Jumps (CMJ), Sprints (10 and 30 Meters), a soccer specific version of the Illinois Agility Tests (IA) and for the Loughborough soccer passing test (LSPT) over 12 weeks (autumn season). Data was analysed with a two-way analysis of variance (ANOVA) with post hoc Test Bonferroni by using the statistics software SPSS (Version 20.0). **Results** The study indicated a significant ($p<0.05$) decrease in sprint performance of both groups over 10 and 30 meters. Regarding repeated measurement factors no interactions for any parameter between the groups has been found over the period of the season. **Discussion** Due to no significant varying development of both groups, the one different training session of the high performance group has no influence on the development of the measured performance parameters. Regarding declining sprint times, environmental influences like variable temperature, minimal discrepancies of the light barrier system positioning or the possible error created by the design of the light barrier system (one sensor system) can not be ruled out. PHYSICAL AND TECHNICAL PERFORMANCE OF ELITE YOUTH SOCCER PLAYERS DURING INTERNATIONAL TOURNAMENTS: INFLUENCE OF OPPONENT QUALITY AND TEAM SUCCESS

VARLEY, M., GREGSON, W., McMILLAN, K., BONNANO, D., STAFFORD, K., MODONUTTI, M., DI SALVO, V.

Aspire Academy

Introduction: This study investigated the positional differences in physical performance of elite youth footballers across two international club tournaments and the influence of team success and opponent quality on team physical and technical performance. **Method:** Match performance observations were collected using a semi-automated multi-camera tracking system across two elite under-17 international club tournaments from all players and teams (n=1,457 individual cases). To investigate if the exclusion of substituted players influenced the physical performance profile, data of only players who completed a full game and data of all players were analysed in relative (m·min⁻¹) terms. Teams were classified based on their final tournament rank as top (1-4 rank), middle (5-8 rank) and bottom (9-12 rank). Technical performance measures were expressed in absolute terms and relative to the time the team was in possession of the ball. Positional differences in physical performance and the influence of team success and opponent quality on team match performance were identified using a generalized linear mixed model. **Results:** Positional differences were similar to that observed in elite senior players. Full game players experienced a clear reduction in relative very-high speed running distance in the 2nd half, however when all players were analysed there were no clear reductions. Top ranked teams performed a greater number of absolute and relative shots and shots on target than bottom teams (Effect Size = 0.67 to 0.82). Passing and organising variables had unclear effects between team rankings. Top ranking teams performed a greater number of relative tackles than bottom and middle teams (ES; 0.44 to 0.70). When playing against top ranking opponents the number of absolute shots and shots on target, shot conversion and passing accuracy were lowest compared to playing against middle and bottom opponents (ES; -0.86 to -0.31). **Discussion:** In an elite youth tournament setting, opponent quality has a greater influence on match performance than team success. Practitioners should account for these contextual factors when analysing match performance data to assist in their match preparation. Finally, match analysis should include full game players and all players to avoid to understand the influence of substitutes on team physical performance.

PLAYER'S SUCCESS PREDICTION IN RUGBY UNION: FROM YOUTH PERFORMANCE TO SENIOR LEVEL PLACING

COLOSIO, A., FONTANA, F.Y., DA LOZZO, G., POGLIAGHI, S.

University of Verona

Union Rugby National federations and clubs regularly engage in youth draft camps, where anthropometric and functional characteristics are evaluated towards early talent identification and selection of the potentially elite athletes. Yet the relative predictive power of single characteristics in future career development remains to be determined. PURPOSE: this study aims at determining if and to what extent specific anthropometric and functional characteristics can accurately predict subsequent career progression. METHODS: Anthropometric and functional characteristics of 531 male players in the U16 age category, as recorded during 2006-09 Italian National Draft Camps, were retrospectively analysed in relation to senior level placing at age 21-24. Players were classified as International (I, National team and international clubs) or National (N, 1st, 2nd and other divisions, dropout). Multivariate analysis of variance (One-way MANOVA) tested the difference between I and N along a combination of anthropometric (weight, height, body fat, fat-free mass) and functional variables (SJ, CMU, t15m, t30m, VO2max). A Discriminant function (DF) was determined to predict group assignment based on a linear combination of variables and corresponding coefficients. Correct level assignment was expressed as % hit rate. RESULTS: The youth players enrolled in draft camps represent a very selected sample that does not reflect the anthropometric characteristics of the reference population (> 95th percentile for weight and height). 39 players (7%) were classified as I, while 492 (93%) were classified as N. The results of MANOVA analysis indicate that a combination of anthropometric and functional characteristics reflects future level assignment (I vs. N) ($V = 0.27$, $F(28, 1356) = 3.45$, $p < 0.05$). Furthermore, players' success can be accurately predicted (hit rate = 81% and 77% for I and N respectively) by a DF ($\Lambda = 0.88$, $\chi^2 = 45.1$, $p < 0.05$) that combines anthropometric and functional variables as measured at ~15 years of age. Among these, % body fat and speed appear to be the most influent predictors of group stratification within the discriminant function. CONCLUSIONS: Within a group of 15 year-olds with exceptional physical characteristics, future player's success can be predicted using a linear combination of anthropometric and functional variables, among which a lower % body fat and higher speed over a 15m sprint provide the most important predictors of the highest career success. The early identification of the athlete's potential allows to "customise" the development programme based on the individual's needs and deficits and to maximise the overall efficiency of the formation process. alessandro.colosio@univr.it

TAPERING IN TEAM SPORTS: PHYSICAL PERFORMANCE RESPONSE IN ELITE RUGBY SEVENS PLAYERS

MARRIER, B., ROBINEAU, J., PISCIONE, J., PEETERS, A., HAUSWIRTH, C., MORIN, J.B., LE MEUR, Y.

French Rugby Federation

Introduction As for endurance sports, appropriate tapering is considered critical for maximizing team sports performance. However, there is little scientific information available to guide coaches in prescribing efficient tapering strategies for team sports players. The aim of this study was to monitor the changes in physical performance in elite rugby sevens players during a 3-week taper immediately following the pre-season training camp. Methods 10 male international rugby sevens players were tested before (Pre) and after (Post) a 4-week pre-season training camp, and each week during a subsequent 3-week taper (T1, T2, T3). During each testing session, maximal lower limb strength and explosiveness, sprint acceleration mechanical outputs and performance, and repeated sprint ability were assessed. Results At Post, both sprint performance and maximal isometric force output remained unchanged, while an almost certain small increase in both mean (MPO) and peak cycling power output (PPO) was reported ($+6.0 \pm 1.7\%$ with a 100/0/0 % chance to observe a positive/trivial/negative change in performance and $+4.5 \pm 2.1\%$, 99/1/0 % for MPO and PPO, respectively). During the taper, the 30-meter sprint time improved almost certainly ($-3.1 \pm 0.9\%$, 0/0/100 %, large). A moderate negative correlation ($r = -0.50 \pm 0.45$) between change in sprint running performance and change in Pmax was reported. Maximal force output during the mid-thigh pull improved very likely during the taper ($+7.3 \pm 6.4\%$, 95/3/2 %, small). Both MPO and PPO also improved almost certainly during the same period ($+9.0 \pm 2.6\%$, 100/0/0 %, moderate; $8.6 \pm 2.7\%$, 100/0/0 %, moderate, respectively). For all variables tested, peak performance occurred on average between 9th and 16th day of taper. Discussion Although maximal strength, sprint performance and repeated sprint ability kinetics differed, a 2-week tapering timeframe seems optimal to maximize the overall physical performance response in elite rugby sevens players. We also found a substantial inter-individual variability, which supports the importance of an individualized training load during the tapering period.

NEUROMUSCULAR, BIOCHEMICAL, PERFORMANCE AND PERCEPTUAL RESPONSES FOLLOWING A SELF-PACED SOCCER MATCH SIMULATION

TOFARI, P., KEMP, J., CORMACK, S.

Australian Catholic University

Aim: A soccer match is characterised by high-intensity, intermittent running, including directional changes, rapid accelerations and decelerations, resulting in both biological and psychological disturbance. Match simulations used to assess responses in a controlled environment lack ecologically validity due to external pacing. Recently, an ecologically valid and reliable self-paced protocol has been developed using a non-motorised treadmill (NMT). The aim was to assess the neuromuscular, biochemical, performance and perceptual responses to that protocol. Method: Twelve male team-sport athletes (24.5 ± 3.9 y, 76.8 ± 5.1 kg, $VO2peak 52.3 \pm 4.0 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) performed a self-paced 90-min match simulation on a NMT. Match running performance and the following variables were collected Pre-, Half-time (except blood), Post-, 2-h post-, and 1-4 days post-match: - Quadriceps function via a maximal voluntary contraction and magnetic stimulation assessing central (voluntary activation) and peripheral (potentiated twitch torque) fatigue - Endocrine response (testosterone and cortisol), oxidative stress (uric acid) and muscle damage [creatinine kinase (CK)] - Countermovement jump, squat jump (SJ) and isometric mid-thigh pull (IMTP) performance - Rating of perceived exertion and self-report wellness questionnaire Statistical analysis included magnitude of change calculations between time points compared to pre-match using effect size statistics ($\pm 90\%$ CL) and regression analysis. Results: Participants covered 12445.8 ± 768.7 m at $87.1 \pm 3.2\%$ maximal HR, similar to actual match observations. Central and peripheral fatigue was evident at Half-time (-0.38 ± 0.46 and -0.79 ± 0.30 , respectively) and persisted post-match. SJ height was reduced at Half-time (-0.42 ± 0.31) and persisted until Day 4. Perceptual fatigue and soreness peaked at Day 1 (-0.92 ± 0.88 and -1.49 ± 0.76 , respectively), as did CK ($123.4 \pm 70.8\%$). Significant relationships arose between numerous variables, including high speed running and soreness ($r=0.65$), very high speed running and potentiated twitch torque ($r=-0.78$) and IMTP $F \cdot \text{kg}^{-1}$ Pre with change in CK ($r=-0.58$ to -0.81). Discussion: The current protocol allowed detection of central and peripheral fatigue at half time, which has not been previously reported, and this magnitude of change was not increased post-match. Similar to previous work, there was disturbance to

numerous systems, generally returning to baseline in 3 days. Relationships exist between activity profile and perceptual and neuromuscular variables, and higher maximal lower-body strength resulted in less muscle damage post-match. The findings warrant further investigation into the role of central and peripheral fatigue in regulating second half performance and potential interventions to minimise any negative impacts.

ANTHROPOMETRIC CHARACTERISTICS, BODY COMPOSITION AND SOMATOTYPE OF FEMALE PLAYERS OF THE SECOND DIVISION OF THE NATIONAL RUGBY LEAGUE.

BARRIOS, C.1, ESCRIVÁ, D.2, PABLOS, C.3

Valencia Catholic University

Introduction Several studies have described the somatotype and anthropometric characteristics in female team sports like soccer, basketball, handball, volleyball, and also in female individual sports such as tennis and gymnastics. However, there is very little information on the morphometric characteristics of female rugby players. There are only two studies describing anthropometric data of a total of 51 females players from Australia and France (Gabbett, 2007; Bru et al., 2011). The objective of this study is to analyze the anthropometric characteristics of 55 female players from the second division of the national league rugby. **Methods** Anthropometric measurements were performed according to standardized techniques adopted by the International Society for the Advancement of Kinanthropometry (ISAK). Height, weight, body mass index, and sum of 6 skinfold were measured. Three different methods were used to calculate the percentage of body fat (%BF): Faulkner (only 4 skinfolds of the upper extremity and trunk), Reilly et al. (skinfolds of the thighs, legs, triceps and abdomen) and Yuhasz (sum of 6 skinfolds). The somatotype was assessed using the equations of Carter and Heath. **Results** The characteristics of the players were: body mass 66.0 ± 10.0 kg; height 163.3 ± 7.1 cm; body fat $14.5 \pm 4.2\%$ (Yuhasz), $16.1 \pm 4.2\%$ (Faulkner), $17.3 \pm 4.0\%$ (Reilly) and muscle mass 54.6 ± 6.2 kg. The sum of skinfolds was: $\Sigma 6$ folds, 121.7 ± 44.4 mm; $\Sigma 4$ (Reilly), 83.2 ± 27.0 mm. The average somatotype was: Endomorphy 4.47 ± 1.74 ; Mesomorphy 2.65 ± 0.95 ; Ectomorphy 1.74 ± 0.1 . There were significant differences ($p < 0.05$) in some anthropometric parameters (body mass and skinfold thickness) between players of different positions: the 'forwards' were heavier and had higher skinfold thickness than the 'backwards'. **Discussion** The results of this study show that female players from the Spanish 2nd League are away from the internationally recommended body composition for female athletes. These sample of rugby league players have a higher body mass and skinfold thickness greater than previously published in other female team sports. These results show the need to analyze and planify interventions on anthropometric parameters to allow players from the second division league rugby tolerate more effectively the physiological demands of competition. **References** Gabbett TM. OP-SH11 Psychology: Motivation 2

ANALYSING THE STATE OF OPTIMAL MOTIVATION IN ENDURANCE SPORTS UNDER CONTROLLED CONDITIONS

KOPP, P., JANTA, M., LICHTENBERG, C., SENNER, V.

Technical University of Munich

Introduction Previous studies showed, that flow experience will occur even if there is no required balance of challenge and skills. Neither subjectively perceived fit nor objective measurements confirmed this assumption regarding a congruence of both influencing factors as a requirement for the occurrence of flow. Therefore, the aim of this study is to test whether the optimal adaption of abilities and demands will be precondition for the development of flow experiences in racing cyclists, even if it's examined under laboratory conditions. Furthermore, it is the target to document the individual dynamics of flow during continuous cycling performances and their correlations with physiological variables. **Methods** The four- week investigation ($N = 10$) was conducted in a climate chamber under controlled conditions ($T: 18^\circ$ Celsius; relative humidity: 50%; air velocity: 1m/s; uniform clothing). Therefore, flow experience should be impaired less as possible since the parameters were selected by insuring physical wellbeing independent of low or high physical stress. The individual predetermined physical strain to pass was examined by using a bicycle ergometer. Physical demands were based on an existing maximal incremental cycling test for each test subject. This allowed an individual setting of load intensity according to usual training zones (KB, GA1, GA2, EB) in cycling. The adjustment was related to the individual anaerobic threshold (IAT) as follows: KB: 55,2%; GA1: 76,7%; GA2: 92,4%; EB: 104,4. Continuous recording of physiological parameters (heart rate; pedaling frequency; wattage; power range) could be ensured at each point of time. Flow was measured with the Flow Short Scale (Rheinberg et al., 2003) close to the desired situation of optimal motivation without interrupting the applied activity at an interval of ten minutes by a verbal query (Schattke et al., 2009). Participants had an achievement-related affinity towards cycling to make flow experience more likely to occur. **Results** Positive correlation between total flow score and pedaling frequency ($r = 0,90$) as well as heart rate ($r = 0,65$). The stated balance between task difficulty and skills ($M = 6,60$) at the end of the EB area (high physical demands) with recognizable incongruent relationship of both factors has a higher Flow score ($M = 5,75$) than any stated fit in the areas EB, GA1 and GA2 with low or moderate strain. **Discussion** It is possible to create Flow on a bicycle ergometer under controlled conditions within the predefined performance areas independent of any perceived balance concerning challenge and skill. Nevertheless test subjects were acquired with an imputed high implicit achievement motive and perceived importance towards cycling. Occurrence of flow however is also motivated due to more influencing intrapsychic factors we didn't measure at all (Kehr, 2004). Physical demand were matched with the individual threshold (IAT). Results are not generalizable caused by the small sample size. Therefore Flow experience among controlled circumstances is no predictor for real terms.

DIFFERENCES IN MOTIVES FOR RUNNING AND PARTICIPATION IN RUNNING EVENTS BETWEEN RUNNERS WITH DIFFERENT RACE PACE

CZAJKA, K., PLUTA, B.

Eugeniusz Piasecki University School of Physical Education, Poznań

Introduction For several years it is seen that more and more people participate in recreational sport, which includes running events. It is not only in marathon events but also on shorter races e.g 10K. Recreational running, as a form of physical activity is still gaining popularity (von Bottenburg et al., 2010). It is important to learn more about various factors that encourage people to run and participate in recreational road races. Due to that need, profile of runners in different countries was established (Forsberg, 2012; Petridis, 2013). The purpose of this study was to analyze the profile of three groups of runners with different race pace, who participated in 10K running events, and to analyze the factors related to their perception about their running activity. **Methods** An online questionnaire was used to collect data, which was based on the questionnaire about running from the Danish Institute for Sport Studies. Questionnaire was sent to runners taking part in two 10K running events in Poland. Total of 635 runners questionnaires were analyzed (61% males and 39% females). Runners were categorized in 3 groups regarding they race pace (<4:30min/km, 4:30–5:30min/km, >5:30min/km). Five-point Likert scale was used for answers. Results Slower runners (>5:30min/km) see this form of recreation as way of socializing with others, in oppose to faster runners (<4:30min/km). Also slower runners see running as a boring activity. Moderate runners (4:30–5:30min/km) thinks running carries high risk of injuries. It's easier for faster runners to find time for practice and also those runners agree that running is for everyone. Faster runners take part in running events mostly to compete against others and set those events as a training goal. Moderate runners are taking part in running races to set personal best on measured course. **Discussion** Different race pace influence motivation to running. Runners see difference between running everyday and running in road races. Even though slower runners agree that running is a great way to socialize with others but at the same time they don't get easily attached to other runners, but they also run in road races because they like to spend time with friends and family. Faster runners are more proud of their activity than other runner groups. Also they see all runners as a specific group, different than groups in other sports. References Forsberg, P. (2012). MOTIVATION CONTAGION IN FITNESS SETTINGS: HOW EXERCISERS' PERCEIVED MOTIVATION AND WEIGHT STATUS INFLUENCE INSTRUCTOR MOTIVATION AND THEIR INTERPERSONAL STYLE TOWARD EXERCISERS

THOGERSEN-NTOUMANI, C., NTOUMANIS, N., GADEKE, C.

Curtin University

Introduction The effect of perceptions of another individual's motivation on the perceiver's own motivation is referred to as motivation contagion. This present study represents the first experimental test of this concept in a fitness setting. Specifically, the aim of the study was to examine if perceptions of novice exercisers' motivation and weight status influence fitness instructors' own motivation to instruct, their perceptions of the exerciser's efficacy beliefs, and the interpersonal behaviours the fitness instructors would use when interacting with exercisers. **Methods** A randomised, factorial 2 (new exerciser motivation: autonomous, controlled) x 3 (new exerciser weight: average weight, overweight, formerly overweight) between-subjects experimental design. Qualified fitness-instructors ($n = 199$; Mage (SD)=25.90 (5.55); 57.10% male) were randomly assigned to conditions and presented with an image and cover story of a hypothetical male exerciser. Subsequently they completed a questionnaire pack measuring perceptions of the exerciser's motivation and exercise efficacy and their own motivation to instruct, plus the degree to which they would employ autonomy supportive and controlling interpersonal behaviours when instructing the target exerciser. The questionnaires were completed online. Factorial ANOVA and MANOVAs were employed to analyse the data. **Results** The instructors reported higher levels of autonomous motivation to instruct, more autonomous supportive behaviours, and perceived the exercisers to be more efficacious, when exercisers were portrayed as being autonomously motivated to exercise, compared to when they had controlled motivation. Further, instructors reported more controlled motivation to instruct and more controlling interpersonal behaviours with an overweight exerciser, compared to the average weight or formerly overweight exercisers, reflecting a potential weight bias. **Discussion** The results suggest that the motivation to instruct and interpersonal behaviours of fitness instructors are influenced by their perceptions of exercisers' quality of motivation to exercise and exercisers' weight status. This can have important implications for exercise adherence, and ultimately health, of novice exercisers. The findings suggest that fitness instructors should be made more aware of how cues about exercise clients may affect their own motivation (including behaviours) and how their own weight bias may negatively influence exerciser outcomes.

A FIGHTER'S LIFE-ATHLETIC CAREER DEVELOPMENT IN PROFESSIONAL CHINESE MARTIAL ARTS ATHLETES

CHENG, W., KUHN, P.

Bayreuth University

Background: 1. It is meaningful to develop theoretical frame in oriental cultural context. ; 2. Few knowledge of the athletic career in Martial arts and combat athletes has been known. ; 3. For young Fighters, especially for Chinese athletes, they have not been consulted through their professional career for their development and the problems they experienced. **Purpose:** Explore the characteristics of professional development of Chinese martial artists (before, during, termination and post-career). **Method:** 1. Questionnaire. The Athletic and Post Athletic Questionnaire (APAQ) is employed in this study. APAQ was invented and developed by Schmidt and Si based on the three theoretical frameworks mentioned above. In this instrument, four parts of questions of before, during, athletic termination and after the professional career are included. 2. Interview guidelines. According to the statistical analysis work and the interview, APAQ interview guidelines was invented and developed. It can be used in this study. It is also based on the three theoretical frameworks including multilevel and different sets of questions and takes the life-span development as the main time line. The whole process usually takes 40-60 minutes in different cases. **Sampling:** forty five ex-martial arts athletes (42 males, 4 females) were invited into questionnaire survey and five of them took into the section of interview who came from Beijing and Tianjin sport university. They are ranging in age from 19 to 31 years ($M=22.22$, $SD=3.23$). Before joining the universities, they were totally active Chinese martial arts athletes (Taolu and Fighting) for several years during which, they were all supported in finance and living by local sport system of government. Up to now, they have already retired more than 2 years. **Result:** Throughout the professional career, family is the strongest support for athletes to counter and solve the problems which is very different from the previous studies of coach influence; throughout the professional career, athletes have

no clear future plan for their life development and have little right and space to decide for themselves; when they join the professional team, their social circle becomes narrow; during the professional phase and termination transition phase, they get little help from government, social organization and sport team for the future development; they encounter serious problems during the retirement transition; they adapt the post-career life and opposite even though they have still high athletic identity which is totally different from previous studies; compared with Chinese sport system, European sport system (France and Sweden) help athletes throughout their professional career to independent decide. The cross cultural and comparison study between European countries and China athletes would be conducted next year.

OP-PM04 Rehabilitation & Training

WHAT IS THE EFFECT ON INDEPENDENT RECOVERY OF USING Pedometers AS A TOOL TO PRESCRIBE EXERCISE FOLLOWING TOTAL HIP REPLACEMENT?

WITHERS, T.M., CLARK, A., SACKLEY, C., SMITH, T.

University of East Anglia

Introduction It has been previously shown that following total hip replacements (THR) patients are less active compared to age-matched controls and that interventions to increase post-operative physical activity (PA) have little success (Lowe et al. 2015). There is a need to increase PA in this population using a relatively inexpensive measure, pedometry, to take into account the current strains that national health systems are under. A two arm-randomised control trial (RCT) was undertaken to assess this hypothesis. Methods Patients on the waiting list for primary unilateral THR were recruited. Both groups received treatment as usual with the intervention group additionally receiving a target number of steps for two days a week for the first 24 weeks post-operatively and a pedometer to record this. Outcome measures were taken pre-operatively and at four, 12 and 24 weeks post-operatively. Physical activity was measured using the Physical Activity Score for the Elderly (PASE), hip outcome using the Oxford Hip Score (OHS), a two-way repeated measures analysis of variance was used to analyse the PASE and OHS data. Results Thirty-three participants were recruited between December 2014 to December 2015 two participants are excluded from the analysis, one due to THR being indefinitely cancelled and one as a bilateral THR was performed. A total of 15 participants were in the control group, mean age=71.3+10.4, three males and 12 females and 16 in the intervention, mean age=67.8+11.0, 10 male and six female. There was no significant difference ($p>0.05$) in baseline pre-operative measures. For the PASE sphericity was assumed ($W=0.61$, $p=0.58$) there was a significant within subject effect ($F_{3,27}=3.90$, $p=0.019$) and non-significant between group effect ($F_{1,9}=0.02$ $p=0.886$), the change preoperatively to week 24 was 39.4+51.1. For the OHS sphericity was assumed ($W=0.20$, $p=0.06$) there was a significant within subject effect ($F_{3,24}=21$, $p<0.001$) and non-significant between group effect ($F_{1,8}=2.9$ $p=0.13$), the mean change for OHS pre-op to week 24 was 22.6+10.6. Conclusion This research follows the common theme of exercise interventions not showing a significant effect in this population. Though equally it is surprising as this intervention has worked previously in clinical populations (Bravata et al. 2007). This RCT adds to the complex picture in respect to physical activity following THR. There is still a need to find an intervention that works within this population. References Bravata D. PERFORMANCE AND PHYSIOLOGICAL EFFECTS OF DIFFERENT DESCENDING STRATEGIES FOR CROSS-COUNTRY MOUNTAIN BIKE PERFORMANCE

MILLER, M., MACDERMID, P., FINK, P., STANNARD, S.

Massey University

Introduction Physiological variables measured during cross-country mountain bike racing remain steady despite highly intermittent propulsive work demanded by variable terrain (Macdermid and Stannard, 2012), which may be due to musculo-tendonous damping of vibrations that are translated from the riding surface (Macdermid et al., 2014). Reports that descending performance is independent of mechanical propulsive work (Hurst and Atkins, 2006) suggest it may be possible to reduce pedaling on descents and better recover for subsequent ascents. This study investigated the vibrations, metabolic benefits and performance-related feasibility of eliminating pedaling while descending and compared these values to those measured on a road surface. Methods Eight nationally competitive mountain bikers took part in this study. 24 hours after a laboratory fitness test, participants completed a field trial consisting of three descending conditions (off-road pedaling (DHP); off-road coasting (DHC), both 1.01 km, -16.3%; road (DHR), 1.03 km, -15.7%). After familiarization with the track used and practicing the coasting strategy, participants cycled uphill at race pace before randomly commencing DHC or DHP. DHR was completed at the mean velocity of the off-road trials. Power, heart rate, VO₂, and tri-axial accelerations were recorded. Results VO₂ was significantly increased during DHP when compared with DHC (35.2 ± 4.8 vs $31.7 \pm 3.9 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$, respectively) despite no difference in vibrations and relatively low average power output ($18.8 \pm 11.6 \text{ W}$). Pedaling did not elicit a performance benefit (DHC=142.5 ±29.2, DHP=139.9 ± 29.2 s) on the descent used in this study. Lower heart rate and oxygen uptake were observed in DHR versus both off-road trials, likely caused by the decrease in vibrations. Discussion Despite relatively low power output, metabolic demand is exacerbated when pedaling on off-road descents compared with coasting. Elimination of propulsive work does not change vibration exposure but decreases oxygen cost, and importantly has no negative effect on performance. Vibrations experienced during road descending are relatively low, and accompany further reduce physiological demand. It is recommended that athletes focus on skills to increase descending speed without the addition of pedaling, and that equipment be used to decrease vibrations nearer to those seen on the road. INTENSITY OF GAME-BASED TRAINING DRILLS IN FEMALE TEAM HANDBALL

LUTEBERGET, L.S., TROLLERUD, H.P., SPENCER, M.

Norwegian School of Sport Sciences

Introduction The use of game-based training drills is a recommended training modality that promotes physical performance enhancement and training efficiency via a combination of the different components of the game (Corvino et al, 2014) The aim of this study was to compare the intensity and quantity of high intensity events (HIE) of game-based training drills to official matches. Method Player movements were observed from two female handball teams, from the first and second level in Norway. The study consisted of monitoring ten sessions, where participants completed game-based training (3vs3 and 6vs6, randomized order) with a duration of 5 min each. In addition, ten official matches were monitored. Twenty-seven players (backs, pivots, and wings) were included in the study. Inertial movement units (Catapult Optimeye S5, Australia) were used for data collection. PlayerLoad™ (PL) and HIE (>2.5 m·s⁻¹) were extracted from the raw-files. Magnitude based inferences were used to describe probabilities of substantial differences between conditions. Differences were deemed substantial when there was a likelihood of >75% of the difference exceeding an effect size (ES) of 0.2. Results 3vs3 condition: When compared to average match intensity, the 3vs3 condition was substantially higher in PL for backs (100%, ES:4.3), wings (100%, ES:5.0), and pivots (100%, ES:3.6). Substantially higher values were also found when comparing PL against the highest 5-min period in match play (H5-min) for all positions. HIE was higher compared to average match for backs (97.2%, ES:0.6), wings (100%, ES:2.2) and pivots (96.8%, ES:1.2). Wings and pivots showed substantially higher values for HIE compared to H5-min. 6vs6 condition: Higher PL values was found for backs (100%, ES:1.6), wings (100%, ES:1.8), and pivots (95.9%, ES:1.1) compared to average match intensity. Only wings showed substantially higher values (83.5%, ES:0.5) when compared to H5-min. HIE in 6vs6 was not different from average match, however, when compared to H5-min HIE was substantially lower for all playing positions. **Discussion** An overload in general intensity (PL) is evident in both game-based training conditions compared to average match intensity. HIE values show a smaller difference from average match data than for PL, and thus suggests that the increased intensity is mostly due to an increase in lower-intensity accelerative actions e.g. running at a steady velocity. This is especially apparent in the 6vs6 condition. Thus, game-based training drills might not overload the important physical components (Karcher et al. 2014) of team handball. References 1. QUANTIFYING THE MOST INTENSE PERIODS OF MATCH-PLAY IN RUGBY UNION

HOWE, S.T.1,2, AUGHEY, R.1, HOPKINS, W.G.1, CAVANAGH, B.2, DUTHIE, G.1, STEWART, A.1

Victoria University

Affiliations: 1. Institute of Sport, Exercise and Active Living, Victoria University. 2. Melbourne Rebels **INTRODUCTION:** Understanding match activity profiles may guide training prescription and in-game decision making. Peak periods of activity can be quantified via the mean value in a moving window of a given duration. This approach was applied here to National rugby union matches. **METHODS:** Movement data were collected via global positioning system and accelerometry for the 30 players of an Australian National Rugby Championship team across the eight matches of a season. Mean running speed (m·min⁻¹), external load (PlayerLoad (TM)) and metabolic power were analysed using a rolling average method to identify the maximum mean values for periods ranging from 5 s to 10 min. General linear mixed modelling was used to predict these measures, with fixed effects for positional differences (backs, forwards), match half (1st, 2nd), and within-season trend (date as linear numeric), and with random effects for between-player differences, within-player variabilities, and between-match differences. The random effects were combined into intraclass correlation coefficients representing reproducibility of each measure. Effects were quantified using standardization and interpreted with magnitude-based inferences. **RESULTS:** There was an approximately six-fold reduction in mean running speed for the longest window duration compared with the shortest. Backs achieved clearly faster speeds than forwards by 21% (90% confidence limits ±9%) for the 5-s window down to 1.5% (±7.5%; unclear) for the 10-min window. Mean running speed declined clearly by up to 11% in the second half for forwards and backs for most windows of ≥1 min. Mean running speed declined clearly by ~7% over the season for windows of ≥5 min for backs and by 9–14% for windows ≥30 s for forwards. The reproducibility of mean running speed between halves and between matches was poor for the 10-min window ($IICC=0.54$) and very poor for the shorter windows ($IICC <0.50$). External load and metabolic power showed effects generally similar to those of mean running speed, but external load was clearly higher for forwards over the 10-min window, and reproducibility of external load was impractical ($IICC <0.20$) for all but the 10-min window ($IICC=0.51$). **DISCUSSION:** The differences and changes in the mean measures of maximum-intensity match play have direct implications for design of training and for substitution decisions of professional rugby union players. The low reproducibility of the measures implies that players will have to be monitored across many games to obtain adequate precision for assessing physical performance of individual players.

EXAMINING THE RELIABILITY OF THE 100 POINT FUNCTIONAL MOVEMENT SCREEN SCORING SYSTEM

EVERARD, E., HARRISON, A., LYONS, M., ELWELL, S.

University of Limerick, Limerick Institute of Technology

Introduction The Functional Movement Screen (FMS) is one of the most widely used movement screens in both research and practical settings. The FMS comprises of seven tests that are traditionally graded from 0 to 3, providing a composite score out of 21. A 100 point scoring system has been developed in order to improve the ability of the FMS to detect variations in movement quality between participants. The reliability of the 100 point system has yet to be fully investigated, with currently no published studies reporting intra-rater reliability and only one study examining the inter-rater reliability of the 100 point scoring system. Therefore, the primary aim of this investigation was to examine both inter- and intra-rater reliability of the 100 point FMS scoring system using two chartered physiotherapists who are both certified and experienced with the FMS (>1000 screens conducted). Methods 110 physically active collegiate males (mean \pm SD 21.43 ± 3.2 years; body mass = 77.27 ± 8.7 kg; height = 177.5 ± 6.8 cm) were videotaped undertaking the seven FMS tests: Squat, lunge, hurdle, rotary stability, press up, active straight leg raise (ASLR) and shoulder mobility (Shld). Thirty participants were randomly chosen and their videos were re-scored 6 weeks later by the second rater and again by the first rater. Inter- and intra-rater reliability of both the final scores and component tests were analysed using Intra-Class Coefficients (ICC) and kappa statistics with associated 95% Confidence Intervals (CI) respectively. Results Inter- and intra-rater ICC values for the total scores were .97 (.95-.98) and .98 (.97-.99) for the 100 point and .98 (.96-.99) and .99 (.96-.99) for the 21 point scoring system, indicating that both scales had almost perfect inter- and intra-rater reliability. All the component tests using both scoring systems had between perfect and substantial agreement for both inter- and intra-rater reliability. For intra-rater reliability, the 100 point scale had seven measures that were perfect or almost perfect (Shld, ASLR, squat,

right rotary stability) and five measures had substantial agreement (lunge, left rotary stability, hurdle). For inter-rater reliability, the 100 point scale had 10 of the tests that were either perfect or near-perfect agreement and 2 (Right Lunge and Hurdle) with substantial agreement. Every measure using the 21 point scale had perfect or almost perfect inter- and intra-rater agreement with the exception of the rotary stability test, which had substantial agreement. Conclusion Both the 100 point and 21 point scoring systems had substantial to excellent levels of inter- and intra-rater reliability for both the total score and component scores. Experienced practitioners should feel confident using the 100 point scoring system, which may help distinguish athletes of different movement abilities more effectively than the 21 point scoring system.

THE RELATIONSHIP BETWEEN WALKING CAPACITY AND PREVIOUS STOP DURATION IN PATIENTS WITH PERIPHERAL ARTERY DISEASE

DE MÜLLENHEIM, P.Y.¹, CHAUDRU, S.², EMILY, M.^{3,4}, FRANCONNET, M.³, MOREAU, R.³, PRIOUX, J.¹, MAHÉ, G.^{2,5}, LE FAUCHEUR, A.^{1,2}

1: M2S, ENS Rennes (Rennes, France), 2: INSERM, CIC 1414 (Rennes, France), 3: Agrocampus Ouest (Rennes, France), 4: IRMAR (Rennes, France), 5: University Hospital of Rennes (Rennes, France)

Introduction Walking capacity is a key outcome in the management of lower extremity peripheral artery disease (PAD) patients limited by ischemic pain during walking. While the walking pattern of these patients is characterized by repeated walking and stopping bouts due to ischemia, it is likely that walking capacity is not maximized throughout repeated walks/stops. Indeed, during recovery from a maximal walking test (MWT), patients' pain dissipates whereas ischemia is still present (Gardner, 1993). The aim of this study was to prospectively determine how maximal treadmill walking time is influenced by previous stop duration. **Methods** This study presents preliminary results of the CLASH protocol (NCT02041169) for 13 PAD (ABI ≤ 0.90) patients. The included patients had a maximal walking distance < 500 m with limitations due to lower-limb pain during a treadmill test. Using a Strandness protocol, patients performed 10 "walking blocks" in a random order on 4 different days. A block was composed of: i) a MWT1; ii) a recovery bout of a given duration; iii) a MWT2. Ten recovery durations were tested: from 0.5 to 9.5 min with 1.0-min increments. Maximal walking time was measured during MWT1 and MWT2. Individual linear and logarithmic models were tested for the relationship between change in maximal walking time ($(\text{MWT2} / \text{MWT1}) \times 100$) and recovery duration. A general (group-based) linear mixed model was also tested. **Results** Individual linear and logarithmic models were significant ($p < 0.05$) in 9 and 11 patients, respectively. R² coefficients ranged from 0.50 to 0.78 (linear models), and from 0.43 to 0.93 (logarithmic models). Greater R² values were obtained using logarithmic (vs. linear) models in most patients ($n = 9$). In 2 patients, no model reached statistical significance. The R² coefficient for the general mixed model was 0.50 ($p < 0.05$). **Discussion** While the relationship between maximal walking time and previous stop duration seems to mainly be logarithmic, it remains an important inter-individual variability. Further analyses of our data are needed to determine which factors, such as pathophysiological responses to walking, could improve the prediction offered by both individual- and group-based models. Such a prediction could be tested in free-living conditions (Le Faucheur, 2010) and likely be used to optimize walking exercise programs. **References** Gardner A W (1993). OP-PM68 Health & Fitness

PROLONGED SITTING, POSTURE AND PHYSICAL INACTIVITY - A MODERN EPIDEMIC IN SCHOOL CHILDREN

ADAR, B., ROTH, V., WEINBERG, H.

Hebrew university Jerusalem & Kay academic college

During childhood and adolescence growth, the development of bones and muscles should be coordinated, because muscular forces influence the growth and function of bones and joints. The alignment and posture of the spine is related to the length and balance of muscles attached to the spine and pelvis. Despite great care dedicated to proper motor function in children, shortness of muscles is common among them. This may be due to the modern lifestyle related epidemic of inactivity, which is one of the factors of back pain among school children. Adult back pain became to be one of the most important of medical and socio-economic problems today. 437 pupils (225 boys and 212 girls) were randomly selected from 10 primary schools in six different Israeli cities. The research population was divided into three age groups according to age and sex. Straight leg Raising (SLR), Pelvic Rotation (PR), Hip Extension (HE), Lumbar Lordosis (LL), Thoracic Kyphosis angles (TK) and postural deformities were measured. Past complaints of Back pain noted, 'Physical activity parameters' and 'Sitting parameters' were recorded. The average of out-of-school sitting was 3.2 hours/day. The commonest leisure activity was watching television, 12.4 hrs/week in boys and using a computer 10.3 hrs/week. Among the girls watching television occupied 13.7 hrs/week and using a computer 9.6 hours/week. There was a reduction in the range of all motion parameters as the number of sitting hours increased ($P < 0.05$). A significant negative correlation was found between all motion parameters, SLR, PR, HE and the LL angle ($P < 0.05$). With the TK angle only PR and SLR were found significantly correlated ($P = 0.05$). Tight hamstrings were found as a predicting value for Back pain only amongst girls ($P = 0.05$). Better ranges of motion, both with regard to SLR and PR were noted in those involved in physical activity ($P = 0.06$) and here there were also less postural deformities ($P = 0.00$). Both prolonged sitting and excessive physical activity were associated with back pain. Significant differences were found with regard to the frequency of computer use in relation to back pain ($P = 0.007$). Great importance must be attached to revising physical education and sports programs as an inseparable part of our cultural life. This situation, already considered to be one of the most dangerous, chronic epidemics of the modern era, will, probably, become worse, in the future, because the amount of sitting hours and inactivity will increase as modern high technology continues to develop. This research was supported by research foundation of Hadassah Hospital, Orthopedics Dep. By the late Prof. Haim Veinberg until the year of 2012, and it is a continuation of original papers presented in different international conferences.

RESULTS OF A HEALTH AND FITNESS PROMOTION CAMPAIGN IN A MILITARY SETTING: EXPLORATION OF DIFFERENCES BETWEEN SUCCESSFUL PARTICIPANTS AND DROPOUTS.

WITZKI, A.1, ROHDE, U.1, KRAPICK, M.1, HARTMANN, N.1, LEYK, D.1,2

1: Central Institute of the Bundeswehr Medical Service Koblenz; 2: German Sport University Cologne

Introduction Sustained participation of personnel in workplace health promotion campaigns is even under optimal conditions a challenging problem (Leyk et al. 2014). In order to minimize dropout rates of health and fitness programs, it is important to explore in detail differences between sustaining participants and those who drop out. 203 persons participated in a health and fitness campaign at an international military agency in Strasbourg. Given the physical requirements in a military setting most participants did previously exercise. We hypothesized that low and medium exercisers who dropped out of the program would differ from sustained participants in their perception of the importance of physical performance, motivation, and motives to exercise. Methods In order to reduce intercultural, age, and gender related influences only data from German males in the range of 25-50 years of age were analyzed. Of the 123 Germans participating 48 qualified as low and medium exercisers (training frequency < 3 times a week). This sample was split into two groups (31 drop-outs and 17 sustainers). Dropouts were defined as persons that participated only at the onset of the six months study period. Data collection included questionnaire data on lifestyle, motives to exercise (Motives for Physical Activity Measure revised) and motivation (Behavioural Regulation in Exercise Questionnaire 2), as well as anthropometric measurements. Analyses were conducted using Chi-Square and t-tests (U-tests). Results At the onset of the program the two groups did not differ in respect to their motivation, motives, and importance of physical performance to themselves as individuals. However, sustainers considered physical performance to be less important to their prior assignments. Sustainers were less satisfied with their own body weight and did weigh significantly more than drop-outs. At the end of the program sustainers significantly reduced their body weight, BMI, waist circumference, and body fat. Discussion Results show that participation in the program was worth the effort. Nevertheless, less than 20% of eligible personnel participated in the health promotion campaign. In addition almost 2/3 of the low and medium exercisers that choose to take part in the health program did not finish it six months later. These findings underscore the urgent need for a better understanding of the individual motives to participate and incentives to stay with health and fitness programs. References Leyk D et al (2014). INFLUENCE OF INCREASED PHYSICAL ACTIVITY ON APPETITE AND MOOD STATE IN YOUNG ADULT WOMEN USING VARIOUS PHYSICAL ACTIVITY INDICATORS

KUMAHARA, H.1, AYABE, M.2, AKAGI, H.1, DOI, M.1, YOKOO, S.1, KIKUGAWA, E.1

1: Nakamura Gakuen University (Fukuoka, Japan), 2: Okayama Prefectural University (Soja, Japan)

Introduction Engaging in regular physical activity (PA) with moderate-to-vigorous PA (MVPA) or PA at or above the lactate threshold intensity (LT) would improve health outcomes. Increasing the daily step count (SC) is often promoted as an alternative indicator for achieving a target PA level. However, our understanding of how such PA indicators influence the quality of PA and how appetite and psychological stress are affected remains limited. This study aimed to assess the effects of acutely increased habitual PA on the quality of PA, appetite and mood state using various PA indicators. Methods Twenty-seven healthy young adult women participated in this randomized, crossover study. All subjects completed a 1-day protocol under three different conditions. For the LT trial, subjects were instructed to increase PA to a level that was equivalent to or exceeded LT for at least baseline plus 30 min. For the STEP trial, subjects were instructed to increase their SC by at least baseline plus an equivalent amount of SC, which was estimated as increasing SC during the LT trial. For the MVPA trial, subjects were instructed to increase their MVPA for at least baseline plus 30 min. For each trial, all subjects used the 100-mm VAS to record their subjective feelings regarding hunger, fullness, desire to eat and estimated quantity of food they desired. These assessments were conducted at the following three time-points: on waking up on the morning of the trial, immediately prior to eating evening dinner and on the morning following the trial. Each subject was additionally asked to complete a Profile of Mood States-Brief Form (POMS) at the similar three time-points. Results While there were no significant differences in SC when compared across the three different trials, the duration of PA conducted at LT during the LT trial was significantly longer than that in the STEP or MVPA trials. Significant time effects, in which all subjective appetite parameters increased from the morning to a time-point immediately before evening dinner, were found in all trials. However, no significant trial effects or time x trial interactions were observed for any of these parameters or with regard to the data provided in the POMS's scales. Discussion The present data indicated that the quality of PA can fluctuate according to the PA indicator used when individuals attempt to increase their PA. Moreover, a strenuous PA, such as increasing the duration of PA at or above LT, is not likely to cause deleterious effects on appetite or induce psychological stress. EVALUATION OF A 2-YEAR PEDOMETER-BASED INTERVENTION PROGRAM USING APPRECIATIVE INQUIRY: STEP INTO HEALTH IN CAMPUSES

SALIH KHIDIR, D., SAYEGH, S., AL KUWARI, M.

Aspetar - Orthopaedic and Sports Medicine Hospital, Doha, Qatar

Introduction: In Arab countries, physical inactivity among adults fluctuated from 33% to 86%; Qatar shows a prevalence rate of 46% [1]. This study evaluates the effectiveness of a 2-year community intervention based program on increasing the physical activity levels through pedometer measures and appreciative inquiry (AI) within 11 universities in Qatar. **Methods:** SIH in Campuses, Qatar, is a community-based program to increase physical activity levels through walking amongst universities [2]. This study involved 1,299 students and staff (aged 18-64 years), males and females of different nationalities. The intervention was implemented in 2 phases and launched as a 4-month walking competition. The 2nd phase included awareness sessions about physical activity and the program itself. Pedometers are linked to a web-database allowing physical activity level follow up. Daily steps were categorized as: ≤5,000, sedentary; 5,000-7,499, low active; ≥7,500, physically active [3]. AI evaluation used the 4-D model and involved 30 universities' stakeholders. **Results:** Out of total population: 800 were females (62%) and 499 males (38%); 86% were non-Qataris, 14% Qatari nationals. Mean age was 31.3 ± 12.9 years and BMI averaged 26.6 ± 5.1 kg/m². Daily step count was 5,681 steps. The age groups 18-24 and 25-34 years (n=841; 68%) represent students, while age groups 35-44 (n=201; 15.5%), 45-54 (n=162; 12.5%) and 55-64 (n=95; 7.3%) are staff. Results show 38% were low active, 37% physically active and 25% sedentary. The AI main themes that engaged stakeholders the most were awareness/ education - 5 points (100%), competition, multi levels of involvement with SIH, sense of community, community-based program, and motivation - 4 points each (80%). The AI points represent themes' repetition accrued within stakeholders' discussions. **Discussion:** This intervention engaged more students, categorized as low active. Participants tend to become more active with age, as staff was categorized as physi-

cally active. Both phases confirm an increase of average steps engaging the community in physical activity. The 2nd phase shows a greater increase due to the awareness session and continuity of the program. All outcomes confirm that this intervention would focus more on spreading physical activity/health awareness and education within universities community. References: [1] Musaiger AO, et. al. OP-SH17 PE in School & other Pedagogical Settings

VOLUNTEER MOVEMENT AS A MEANS OF HEALTHY LIFESTYLE PROMOTION.

IONKINA, V.

Moscow City University

The issue of establishing a well-organized Physical Education system is one of the most essential problems that modern education faces. Its urgency arises from the fact that only duly organized Physical Education process can contribute to improving schoolchildren's health and encourage children to develop physically and spiritually [1]. The student volunteer movement at Pedagogical University of Physical Culture and Sports is aimed at raising popularity of PE and sports activities among children and teenagers, including children with deviant behavior, at attracting their attention to the idea that healthy living is within their reach and equipping them with all the qualities needed for an active, healthy and achievement-oriented lifestyle. Researchers have concluded that one of the prospective trends in Theory and Methodology of Physical Education is the trend of optimizing the integral process of physical and mental development of schoolchildren. It means that both physical training and auto-training techniques should be integrated into the PE system [2]. The aim of cooperation between students of MSU Pedagogical University of Physical Culture and Sports and the Khimki basketball team is «to raise students' interest in their future professional activity by means of the University extracurricular activities» [3]. MSU students and the Khimki basketball team take part in "One team" project. "One team" is a corporate programme of social responsibility and an integrated marketing program developed by Euroleague in partnership with several sports clubs. MSU students and members of the basketball team arrange sports activities for children in cooperation with secondary school teachers. They arrange meetings with pupils, teach master classes at PE lessons, and organize basketball games to develop team spirit, tolerance and the ability to interact among schoolchildren. During the first year with "One team" MSU students had teaching practice at secondary schools in Khimki. It was a good opportunity for students to get involved into the professional basketball club activities, learn about the latest basketball Euroleague sports and teaching techniques, put their knowledge into practice. Multiple activities were aimed at helping students develop new education programs and manuals for PE teachers and coaches. By the end of the first year students achieved significant results: pupils became much more involved and interested in PE lessons, trainings and master-classes arranged by students, Khimki team players and world class athletes. Children with deviant behavior took part in most of these activities and games. As a result of team work with Khimki basketball club students got a lot of experience that may help them make a long-term plan of actions aimed at bringing PE teaching system up to standard.

SAVORING DANCE IN A LIFE: A CASE STUDY ON THE DANCE EXPERIENCE OF MIDDLE-AGED KOREAN WOMEN PARTICIPATING IN A DANCE EDUCATION PROGRAM

KWON, S., CHOI, E.

Seoul National University

Introduction This study aims to understand the dance experience of middle-aged Korean women in the context of their lives. In particular, Korean women in middle age experience a time of many changes when they are given free from child-rearing and household chores. They encounter a turning point in their lives re-illuminating their own identities, roles and so on. In this regards, experiencing dance in middle age can make their lives happier. Therefore, this study focused on the stories from middle-aged women, who participate in a dance education program, and explored the way they savor dance and the meaning of dance in their lives. **Methods** Through the case study based on qualitative research method, this study took 2 participants, of whom one participated in a dance education program for 2 years and the other in the same program for 5 years. The program was to provide middle-aged women opportunities of arts education and was supported by a Foundation for Arts and Culture in Seoul. The data were collected through in-depth interview, non-participation observation, researcher's field note, and the materials from the program, and analyzed in the inductive method. **Findings** Three ways of savoring dance experience - physical, cognitive, and affective way - were identified; and each ways were all divided into two aspects again – external aspect (EA) and internal aspect (IA). First, the physical way that the participants savored dance included 'doing dance movement and skills' (EA) and 'lived experience during movement' (IA). Second, the cognitive way included 'acquiring information around dance' (EA) and 'cultivating phronesis' (IA). Third, the affective way included 'promoting attitude to dance' (EA) and 'building character through dance experience' (IA). These dance experiences meant to the participants as 'fulfilling their lives', 'communicating with the world', and 'encountering the self as a new existence'. **Conclusion** This study was to explore the meaning of savoring dance in a life of middle-aged women, and identified that the experience of savoring dance had the possibilities to make their lives happier. Based on the findings, the following further researches were suggested. Firstly, it should be discussed how the experience of savoring dance relates to the concepts; lived experience, aesthetic experience, and embodied experience, etc. Secondly, we should study on what and how to teach to make learners savor dance constantly. COMMUNICATION ACTIVITIES IN LIFESAVING TEAM RESCUE: FOR DEVELOPING THE METHODOLOGY OF LIFESAVER TRAINING

TACHIKAWA, K.

Ryutsu Keizai University

Introduction Whether someone is struggling at the local pool or has gone overboard out at sea, communication is an indispensable duty for lifesavers. Their day-to-day activities are unique and vary from other sports in terms of communication styles. Unfortunately there are not enough studies about communication skills in the field of lifesaving. This study shows the specific characteristics of communication styles in lifesaving and suggests the effective training in lifesaving skills from an educational perspective. Method Data concerning lifesaving communication was taken by observing the R University's lifesaving club's simulation training. As for gathering data, both verbal and non-verbal activities of lifesaving has been recorded by an IC recorder and a videotape. Transcript of recording data was processed by the way of Szatrowski (2010) and analyzed by the method of text linguistics (Brown and Yule 1983). Furthermore subjects were interviewed right after the simulation training to examine the purpose, meaning of their utterance and their emotions during lifesaving activities. Result 1. Using a nickname for each member of the team at lifesaving activities is essential to strengthen their sense of unity as a team and form friendships. 2. The leader of the lifesaving team uses at most three simple words at rescue, and manages communications easily and smoothly. 3. Each member of the team can understand and communicate with teammates by minimal words and signs. The communication system in an emergency is naturally formed through their rigorous routine exercise regimens and frequent small talk. Discussion Communicating with teammates not only at the lifesaving exercises but on daily basis is paramount. Having everyday conversations and knowing each member's characteristics and habits contribute toward developing the team's communication skills and competence to cope with a problem as a cohesive unit. It is not isolated individual activity but a team working in unison in order to save a life. In addition, active and spontaneous association with other people seems to be crucial for lifesavers to develop an attitude toward saving life in an emergency. References Brown, G. & Yule, G. (1983) Discourse Analysis. Cambridge: Cambridge University Press. Szatrowski, P. (ed.) (2010) Storytelling across Japanese Conversational Genre. Amsterdam: John Benjamins. TALENT UNDERSTANDING AND TALENT DEVELOPMENT AMONG HANDBALL COACHES IN NORWEGIAN AND DANISH SPORT SCHOOLS

RISBERG, U., NILSEN, A.K., DANIELSEN, A.G.

Bergen University College

Introduction: There is little consensus among researchers and scholars regarding the term talent (Baker, Schorer & Cobley, 2012), as well as among coaches (Ellingsen & Danielsen). The first aim of this study is to analyse how coaches at sport schools for athletes in the age of 15 to 19 understand the term "talent". The second aim is to determine how male handball players skills are developed at these selected schools. Methods: Qualitative in-depth interviews were conducted in autumn 2015. Two sport schools in Norway and two sport schools in Denmark were included in the study. Coaches with daily contact with the students were interviewed, and their working experience ranged from 3.5 to 10 years. They also had experience as coaches at elite-club level. Some were former elite-level players. Results: The understanding of talent seems to be different among the coaches. The schools aim for the players seemed to vary between countries. The coaches understanding of talent ranged from finding the "right types", to technical and tactical skills, physical abilities, will to work hard over time and prioritize, handling of adversity and the role of the environment. The findings indicate further that the Norwegian schools have a clear objective to develop a certain number of national and international players. The Danish schools tend to be more directed towards ensuring the students academic career and helping the students reach the objectives they set for themselves. Discussion: The Norwegian coaches both stressed "reading of the game" as an important aspect of a talent among physical abilities such as height, speed and size, supporting Howe, Davidson og Sloboda (1998) focus on the inherently characteristics in an athlete. The Danish coaches combination on focusing on both innate abilities and the environments role corresponds with Baker et al. (2012) work regarding talent. Gagné (2004) model "The Differentiated Model of Giftedness and Talent" and Bronfenbrenners (1979) ecological developmental model will be used to get a further understanding of talent and talent development in the schools. PE LESSONS IN HUNGARIAN SCHOOLS IN THE LIGHT OF THE INTRODUCTION OF DAILY PE LESSONS

HAMAR, P.1, KARSAI, I.2, CSIRKÉS, ZS.1, CSEPELA, Y.1, SOÓS, I.3

1University of Physical Education, HU, 2University of Pécs, HU, 3University of Sunderland, UK

PE lessons in Hungarian schools in the light of the introduction of daily PE lessons Hamar, P.1, Karsai, I.2, Csirkés, Zs.1, Csepela, Y.1, Soós, I.3 1University of Physical Education, HU, 2University of Pécs, HU, 3University of Sunderland, UK Introduction After the transformation of the political regime, the majority of teachers in Hungary agreed, or at least acknowledged the fact that the essential reform of education must go forward (Halász, 2003). Physical Education and Sport is one of the key areas that play an indispensable role in the cultural domain system (Hamar et al., 2006). From the beginning of the 2012/13 school year, five physical education lessons have to be held in Hungarian primary and secondary schools in the first, fifth and ninth grades and then in other grades in an ascending order, as well. In this presentation the position of physical education and physical education teachers is examined, for example, the status of physical education in relation to other subjects, the position of physical education teachers compared to other teachers, and if there are such central measures that ensure the transition between compulsory physical education and extracurricular sports activities. Methods A cross-sectional questionnaire-based survey method was taken place in Hungary. The original version of the questionnaire translated into Hungarian was used by Ken Hardman and Joe Marshall in an international investigation (Hardman & Marshall, 2009). In the interest of the representativeness of the data, the stratified sampling procedure for groups was used (N=1.161). Data collection was carried out in the 2013/14 school year. Besides performing descriptive statistics (frequencies), the Chi-square test was applied to examine the association and independence of nominal variables, and the Fisher Exact test for smaller number of samples. Results and discussion About one-third of the teachers questioned believe that physical education has the same status as the other subjects. In the period of the introduction of daily physical education, more than a quarter of the PE teachers said that the PE teachers' position was worse compared to other teach-

ers. This feedback primarily comes from those teachers who are more highly qualified and have a university degree. The main explanation for this can be the different approach and content in terms of teacher training. Although the introduction of five physical education lessons a week is welcomed, at the same time it causes concerns because of the lack of infrastructure and/or sufficient qualified staff. THE PREVALENCE OF UNDERWEIGHT AND OBESITY AMONG HIGH SCHOOL GIRLS AND THE ROLE OF PARENTAL EDUCATION ON THE SPORT PRIORITY OF THEM

RASHIDI ZAFAR, R., GHAFOURI, F.

organization of education

Introduction Sport participation in children and adults allow multiple health benefits such as increased physical activity and physical fitness (Sepúlveda & Calado, 2012). Family, school, coaches and society are mainly responsible of the consequences that sport participation would have in physical and psychological development of children (Marcen et al, 2013). In addition, socioeconomic status (SES) can affects intention to participate in physical activity (Eime et al, 2015). This study aimed to discover the prevalence of obesity and underweight among high school girl students and effect of the sport type (individual sport and team sport) in body satisfaction and leisure time physical activity. Also tried to find the role of parental education in sport priorities of their children (individual sport and team sport). Methods Our sample consisted of 8000 high school girl students of Shahryar and according to Morgan table, we recruited 307 students with (age: 16.36 ± 2.23 years, height: 160 ± 21.04 cm, weight: 58.30 ± 24.07 kg). Sampling used in the survey was Cluster sampling. In order to collect data, we prepared an adapted and modified questionnaire based on literatures and standard questionnaire (PAQ-A). Spearman rank correlation was used to compute the relationship between parental education and sport participation in children. Results According to the results, those who participate in team sports had better body satisfaction ($Z = -2.64$, $P = 0.49$). Results revealed that there is a positive significant relationship between father educations with the time spending in leisure time physical activity while there were not significant relationship between mother education and the type of the sport in the students. Discussion Although when we speak about SES, it comes the educational level by itself; researchers didn't find any study conducted the effect of parental education on type of the sport chosen by children. In most cases, education especially in father as a basic part of a family, affect the economic situation of the family. Well educated parents especially father, would be able to get along with their children and encourage them to be more socialize. Maybe children with an educated father are more self-confidence and are more willing to be exposed as a member of team sport and subsequently give more verbal and nonverbal encouragement. OP-PM67 Interval Training

MICROPAUSES IMPROVE THE PALATABILITY OF RUNNING.

WALSH, A., DELAHUNT, E., BOREHAM, C.

University College Dublin

Introduction Despite the well-established health benefits accruing from regular exercise such as running. Barriers including lack of time and unpalatability of vigorous effort deter large sections of the population from taking part. This pilot study was conducted, therefore to investigate the palatability of running interspersed with regular micropauses of 30 seconds. Methods Following institutional ethics approval, eight recreationally active male volunteers (age = 21 ± 2 years; body mass = 70 ± 8 kg; height = $1.72 \pm .03$ m) were tested under controlled laboratory conditions on two occasions, at least one week apart. On day one participants performed continuous running for 18 minutes at 85% of previously determined VO₂ max. Participants' rate of perceived exertion (RPE) was monitored at regular intervals during the run. Upon completion of the run, participants' blood lactate concentration was assessed as well as their score on the Physical Activity Enjoyment Scale (PACES). On day two, participants performed the same running protocol interspersed at regular intervals with five micropauses of 30s passive rest. All other aspects of the protocol were identical to those of day one. A Shapiro-Wilk test was run to test normality of distribution, following which, paired t-tests were used to compare the measured responses to the exercise. Results The primary finding was that the micropause running protocol was associated with a significantly higher score ($p < 0.01$) on the PACES (5.10 ± 0.23) compared to the continuous running protocol (3.24 ± 0.23). Additionally, the average RPE was significantly lower ($p < 0.01$) for the micropause running (12.83 ± 1.72) compared to continuous running ($16.97 \pm .69$). Maximum heart rate did not differ between the two running protocols, but post-exercise lactate level was significantly higher ($p < 0.01$) following continuous running (14.2 ± 2.52 mmol/l) compared with the micropause protocol (10.6 ± 2.97 mmol/l). Discussion The results from this study show that the introduction of short micropauses significantly reduces both subjective and metabolic stress during running. Further research is warranted to explore the practical implications of these findings for physical activity promotion.

IS SPRINT INTERVAL TRAINING EFFICIENT ALTERNATIVE TO IMPROVE HEALTH AND FITNESS IN SEDENTARY OBESE MEN?

KEBSI, W.1,5, LEMOINE-MOREL, S.1, RAUT LE GALIC, L.1, ADELA, H.2, HAMBLI, M.2, BEN ABDERRAHMAN, A.3, AHMAIDI, S.4, AMRI, M.5, ZOUHAL, H.1

INTRODUCTION Sprint Interval Training (SIT) has been proposed to be a time-efficient alternative for reducing metabolic disorders in obese people (Gillen and Gibala, 2014). So far, there is no data about its impact on physical fitness. Therefore, we aim to investigate the effect of SIT on metabolic, respiratory and fitness factors in obese sedentary men. **METHODS** Thirteen participants (age, 24±0.74 years; Body mass index (BMI), 33.38±4.30 kg.m⁻²) underwent 10 weeks of SIT (3-4 sessions/wk; 3/3-4 x 8s sprints at 75%-95% peak power (Ppeak)). Body composition, anthropometric, fasting blood markers (glucose, insulin, HbA1c, HDL- and LDL-cholesterol, triglycerides) and fitness measurements: peak oxygen uptake (VO₂peak) (from maximal incremental test), Ppeak (from force-velocity test), maximal power (Pmax) and mean power (Pmean) (from cycling sprint test: 7 x 6s of 'all out' sprints interspersed with 90s of recovery) were assessed at baseline and post-intervention. **RESULTS** Our results showed a trend of weight drop (-5.68%, p=0.052), a significant reduce in waist circumference (-7%, p=0.001) and fat mass (-5.98%, p=0.036). Despite no change in fat free mass (FFM), there was an important trend of leg free fatty mass increase (+500g, p=0.055) in response to SIT. No changes in metabolic blood markers were observed. No significant changes in VO₂peak, breathing frequency, tidal volume and minute ventilation at rest and during cycling stages were observed. However, SIT induced a trend of decrease rest heart rate (-16.58%, p=0.06) and a significant increase in aerobic peak power output (170W vs. 210W, p<0.05) through increase in cycling loads. Moreover, anaerobic power output was enhanced significantly (p<0.05) through increase in cycling loads (+22.25%, p<0.05). **DISCUSSION** This study have shown, for the first time, that 10 weeks of SIT induced aerobic and anaerobic power output enhancement in obese sedentary male. These fitness increases showed a growing evidence of better mechanical efficiency which can be explained, at least in part, by muscle structural and neural adaptations (Vincent et al. 2003). Thus, SIT has a positive effect on health and fitness that translated into increased functional capacity and better quality of life in obese people. **REFERENCES** Gillen JB, Gibala MJ. BETA-ALANINE SUPPLEMENTATION PROVIDES ADDED BENEFITS TO THE EFFECT OF SPRINT-INTERVAL TRAINING ON CYCLING PERFORMANCE

BELLINGER, P., MINAHAN, C.

Griffith University

Introduction: Beta-alanine supplementation and sprint-interval training (SIT) have been independently shown to have positive effects on cycling time trial (TT) performance (Rønnestad et al., 2014; Bellinger et al., 2015). SIT following beta-alanine supplementation may lead to added benefits compared to SIT alone by allowing athletes to train at a higher intensity. The present study investigated the effects of beta-alanine supplementation only, and in combination with SIT, on training capacity, and energy provision and performance during exhaustive supramaximal cycling and a 4-km TT. **Methods** Trained cyclists (VO₂max=4.5±0.6 L/min) performed a supramaximal cycling test to exhaustion (equivalent to 120% VO₂max), a 4-km TT and 4 x 1-km sprints at 3 time points: before and after 4 wk of supplementation loading (6.4 g/day) with beta-alanine (BA=7) or a placebo (PL=7), and after 5-wk of supervised SIT (repeated 1-km maximal efforts) performed 2/wk whilst maintaining supplementation (1.2 g/day). Data was compared using a two-way ANOVA and contemporary magnitude-based inferences (Hopkins et al., 2009). **Results** Beta-alanine supplementation alone increased anaerobic capacity (4.0±3.0%; P=0.03), supramaximal cycling TTE (8.9±8.4%; P=0.03), 4-km TT (1.7±1.7%; P=0.05) and sprint 3 and 4 of the 4 x 1-km sprints (2.1±2.0% and 1.9±1.2%; P<0.05, respectively) with no change in PL. Power output during the 1-km cycling sprints increased from the first to the last training session to a greater extent in BA compared to PL (BA: 12.9±6.4%; PL: 6.6±4.2; P=0.04). Following SIT, there were greater improvements in supramaximal cycling TTE (BA: 14.9±7.6%; PL: 9.0±6.9; P=0.04) and further worthwhile enhancements in 4-km TT performance (BA: 4.0±1.5%; PL: 2.9±1.5; P=0.28) in BA compared to PL, but this did not reach statistical significance. Anaerobic capacity (5.5±4.2%; P=0.04) and VO₂ after 60-s of supramaximal cycling (2.9±1.9%; P=0.05) was higher in BA following training, but remained unchanged in PL, whilst VO₂peak increased similarly in each group (BA: 3.1±2.9%; PL: 3.5±2.8; P=0.48). **Discussion:** These findings indicate that beta-alanine supplementation allowed for better maintenance of cycling performance during repeated bouts of cycling sprint intervals, thereby allowing cyclists to consistently train at a higher intensity during a SIT program. Furthermore, this provided additional worthwhile benefits to exhaustive supramaximal cycling and 4-km TT performance compared to training alone. The additive benefits to performance following beta-alanine supplementation, in combination with SIT, appear to be related to superior aerobic and anaerobic adaptations. **References:** Rønnestad B., et al. HIGH INTENSITY INTERVAL TRAINING DURING WINTER TIME IN SUBJECTS WITH INCREASED CARDIOVASCULAR RISK: IS ALPINE SKIING A SOLUTION?

STÖGGL, T., SCHWARZL, C., MÜLLER, E.E., NAGASAKI, M., STÖGGL, J., SCHÖNFELDER, M., NIEBAUER, J.

University of Salzburg; Paracelsus Medical University; Aichi Gakuin University, TU Munich

Introduction Physical inactivity is a strong predictor of cardiovascular morbidity and is decreased up to 40% during winter (e.g. Merchant et al., 2007). High intensity interval training (HIIT) revealed great improvements in key variables of endurance performance in both trained and untrained (Laursen & Jenkins, 2002) and was found to be a potent stimulus to induce physiological adaptations similar to traditional endurance training despite lower training time commitment (Gibala et al., 2012). Alpine and Nordic sports have a long standing tradition in alpine and Scandinavian countries with alpine skiing (AS) being seen as the best way to experience nature and freedom in winter (Bachleitner, 1998). It is open to debate whether AS – besides being a popular leisure time activity - might provide sufficient cardiovascular and metabolic response for HIIT. **Methods** Nineteen volunteers proficient in AS and cross-country skiing (XCS) were included in the study and performed a complete medical examination including cycle ergometry ramp protocol and AS, XCS, and indoor cycling (IC) sessions in randomized order on three separate days. During each session after a standardized warm-up a heart rate (HR) (XCS, IC) or skiing technique (AS)-controlled 4-min continuous session at high intensity (HIGH: 90% HRmax) and a 10-min HIIT (5x1' at >90% HRmax, with 1' low) were carried out. Results in all three exercises subjects were able to attain HR>90% HRmax, with highest values during XCS (100%) and higher HR during HIIT compared with HIGH (99 vs 94%, P<.05). No difference in VO₂peak was found between the three exercises

(84–97% VO_{2max}), while energy expenditure (EE) was lower ($P<.05$) during AS for both situations compared with XCS and IC. With AS, when using HIIT the estimated EE for 1 hr (including standing and lift) was increased 22% compared with HIGH (314 vs 384 kcal/h). Discussion All three exercise modes induced pronounced physiological response (>91% HRmax, >84% VO_{2max}) and participants were able to maintain continuous 4-min HIGH, or 10-min HIIT. When applying short turn skiing and the terrain allows steady skiing over a longer period, AS might provide sufficient stimulus for the cardiologic and metabolic system to enhance fitness and reduce cardiovascular risk. Consequently, besides a popular leisure activity, AS might serve as a fitness workout including HIIT (e.g. "cardio-skiing"). References Bachleitner R (1998). AN ACUTE BOUT OF HIGH INTENSITY INTERVAL TRAINING REDUCES THE AUTOPHAGOSOME CONTENT IN TYPE I AND TYPE II MUSCLE FIBRES

SHAW, C.S., ZACHAREWICZ, E., TREWIN, A.J., PARKER, L., GARNHAM, A., STEPTO, N.K., MURPHY, R.M.

Deakin University

Introduction Autophagy is a dynamic intracellular degradation process which can target old or damaged organelles and provide substrate for cellular regeneration. Activation of autophagy during exercise has been implicated in the improvements in glucose homeostasis with training. The aim of this study was to investigate the muscle fibre type specific autophagy response to an acute bout of moderate intensity continuous (MICT) and high intensity interval training (HIT). Methods Eight recreationally active individuals (aged 25±6 years, BMI 24.8±1.0, VO_{2max} 48.4±4.0 ml/min/kg) completed two exercise bouts on a cycle ergometer in a randomised order separated by ≥7 days. HIT sessions involved 5 x 4 min bouts performed at 75% peak power output whereas MICT was performed at 50% of peak power output, work matched to the HIT session. Muscle biopsies were collected after an overnight fast prior to exercise, immediately post-exercise and 3 h post-exercise. Single muscle fibres were immediately isolated and muscle fibre type was assessed using immunoblotting. Single muscle fibres of the same fibre type were pooled before analysis of the autophagy markers LC3-I/II, GABARAP and p62. Results Basal LC3-II abundance ($P=0.08$) and the LC3-II/I ratio ($P<0.05$) was higher in type I muscle fibres, which is indicative of greater autophagosome content. There was no significant change in LC3-II abundance or LC3-II/I ratio in response to MICT immediately or 3 hours post-exercise. In contrast, there was a reduction in the LC3-II abundance in type I ($P=0.02$) and type II muscle fibres ($P=0.02$) immediately post-HIT which returned to baseline values at 3 hours post-exercise. These changes were reflected in the LC3-II/I ratio which were also reduced in both muscle fibre types immediately following HIT ($P<0.05$). There were no significant differences in GABARAP or p62 abundance ($P>0.05$) following either exercise mode ($P>0.05$). Discussion These results demonstrate that HIT induces a transient reduction in autophagosome content in both type I and type II muscle fibres which does not occur following a work matched bout of MICT. This enhanced clearance of autophagosomes may contribute to the superior metabolic benefits observed following HIT. Furthermore, these results indicate that type I muscle fibres have a higher autophagosome content in the basal state, therefore fibre type differences should be considered when assessing autophagy in human skeletal muscle. chris.shaw@deakin.edu.au

GASTROCNEMIUS CONTRACTILE BEHAVIOR IN CHILDREN WITH CEREBRAL PALSY DURING FLAT, UPHILL AND BACKWARD-DOWNHILL GAIT

HÖSL, M.1,2, BÖHM, H.1, ARAMPATZIS, A.2, KEYMER, A.3, DÖDERLEIN, L.1

Behandlungszentrum Aschau GmbH

Introduction Patients with Cerebral Palsy (CP) develop joint contractures and the ankle is severely affected. For the Gastrocnemius, degenerations in passive morphometrics have been documented (e.g. 1-3) but the contractile behavior during gait is unclear. Especially adaptability of muscle contractions on slopes could be relevant during therapy. Our aim was to compare Gastrocnemius contractions in patients and controls during flat and sloped walking. Methods Med. Gastrocnemius contractions were measured during flat, uphill (+12%) and backward-downhill (-12%) treadmill gait in 15 children with bilateral CP and 17 controls (aged: 7-16 years). CP patients displayed passive dorsiflexion of only 1±8° and naturally walked in mild to moderate crouch. They were analyzed using an Echoblastar ultrasound (Teledyne) to image fascicles at 60-Hz. Vicon Nexus was used to capture lower limb kinematics. Ultrasound of 6 strides was analyzed and a seated rest measurement was performed. Fascicle length was tracked, muscle-tendon unit and series-elastic element length were calculated. All values were normalized on seated rest length. Additionally, EMG (Noraxon) of the Med. Gastrocnemius, Soleus and Tibialis ant. was collected. Results Key findings were that during flat gait, spastic gastrocnemii maximally reached 10% shorter relative fascicle length, 5% shorter series-elastic element length and also showed 37% less fascicle shortening during stance than controls. No difference in fascicle lengthening excursion existed. Uphill gait increased Gastrocnemius fascicle shortening in CP and controls (by 23% and 41%) and Tibialis anterior activity during swing (by 33% in CP and 48% in controls). Backward downhill gait more than doubled (+112%) fascicle strains in CP patients. Discussion Having innately shorter fascicles compared to healthy controls, spastic gastrocnemii additionally worked at shorter relative length during gait. Healthy gastrocnemius fascicles usually work near the descending limb of the length-tension curve [4]. Since spastic fascicles worked at shorter length, they may be used more on the ascending limb and thus will provide a lower potential for active force generation. Yet, findings of longer sarcomeres in CP [5] suggest that contractile filament overlap would likely worsen at more extended length. Hence, limited fascicle length during spastic gait could be an adjustment to use short fascicles with long sarcomeres where they produce larger active forces. Uphill gait may be useful to concentrically train push-off skills and foot lift. During backward-downhill gait the spastic gastrocnemius functions as a brake and displays more eccentric excursion which may stimulate sarcomere-genesis in series. CLASSIFICATION AND COMPETITION LEVEL EFFECTS ON PUSH NUMBER IN WHEELCHAIR SPORT SPRINTING

VAN DER SLIKKE, R., BERGER, M., BREGMAN, D., LAGERBERG, A., VEEGER, D.

The Hague University of applied science

Introduction Wheelchair sprinting capacity is best measured in a field test, allowing the athlete to freely choose push strategies adapted to their own wheelchair settings, physical ability, classification and speed changes during a sprint. The key test outcome is sprint duration, but there are various push strategies to accomplish the same sprint time. The effect of classification and competition level on the number of pushes needed for a 12m sprint was investigated by field testing 30 male wheelchair basketball athletes in their own wheelchair. International level athletes were expected to be faster with less pushes, and athletes of higher classification (less impaired) were expected to be faster with an unknown possible effect on the number of pushes. Methods A recently developed method for ambulatory measurement was used to calculate wheelchair kinematics (van der Slikke et al. 2015), providing outcomes on displacement, speed, acceleration and pushes. Additionally maximal isometric push force was recorded and rear seat height was noted. Mutual correlations and competition level differences of sprint characteristics were calculated. Generalized Linear Models (GLM) were drawn to determine the effect of competition level and classification on sprint time and number of pushes. Results Sprint characteristics did not correlate significantly with classification, only if split by competition level there were significant correlations with sprint time ($r=-0.715$, $p=0.006$) and number of pushes ($r=-0.647$, $p=0.017$) in the national level group. Sprint time, number of pushes and isometric push force differed significantly between national and international level wheelchair basketball athletes, with international athletes being faster with fewer pushes. Together, main effects of competition level and classification as factors in GLMs explained 57% of sprint time and 52% of the number of pushes. Discussion As hypothesized, international level athletes were faster with fewer pushes, even though their higher average seat height was less optimal for propulsion (Mason et al, 2013). The expected relationship between classification and sprint time was clear in the national level athletes, but not present in the internationals. Seat height of lowly classified athletes seemed optimized for sprinting, whereas seat height of highly classified athletes with already adequate sprinting capacity was optimized for upward reach. Although more challenging than well controlled experimental research, the field based setting in this research revealed additional information not only describing the relation between wheelchair setting and performance, but also describing its practical applications if other game demands were taken into account. The results of this approach are believed to assist athletes, coaches and wheelchair experts in decision making concerning wheelchair configuration and athlete training References Van Der Slikke et al. (2015). Journal of Biomechanics, 48(12), 3398-3405. Mason, B. S. et al. (2013). Sports Medicine, 43(1), 23-38.

RELATIONSHIP BETWEEN GROUND REACTION FORCE IMPULSES AND SPRINT VELOCITY IN TRANSFEMORAL AMPUTEES

MAKIMOTO, A.1,2, HOBARA, H.1, SANO, Y.1,2, HASHIZUME, S.1, KOBAYASHI, Y.1, MURAI, A.1, TAKEMURA, H.2

1: National Institute of AIST (Tokyo, Japan), 2: Tokyo University of Science (Chiba, Japan)

Introduction Since sprint kinematics in transfemoral amputees (TFAs) are quite different from those of able-bodied sprinters and transtibial amputees, improving sprint performance in this population is very challenging task (Buckley, 1999). According to a previous study (Hunter, 2005), sprint velocity in able-bodied sprinters can be mainly predicted from impulse of propulsive components of ground reaction force (GRF). The purpose of this study was to investigate the relationships between sprint velocity and GRF impulses generated by both intact and prosthetic limb in TFAs. Methods Eight unilateral TFA sprinters (male:female = 5:3, age = 34.7 ± 11.0 years, body height = 1.61 ± 0.09 m, body mass = 55.5 ± 9.75 kg; mean \pm SD) were recruited. All TFA sprinters used same type of prosthetic knees (3S80, Ottobock) and feet (IE90 Sprinter, Ottobock). Subjects were asked to perform maximal sprinting on over 40 m runway embedded with 7 AMTI force plates (sampled at 2000 Hz) which were located halfway of the runway. Sprint velocity was determined using horizontal velocity of sacral reflective marker. Three-dimensional coordinate data (sacral reflective marker) were captured by a motion capture system (VICON MX+, 200 Hz). Impulses of each component of GRF were calculated. We performed a stepwise multiple linear regression with sprint velocity as the dependent variable and impulses of vertical, braking and propulsive components of the GRF on intact and prosthetic limb as the independent variables ($p < 0.05$). Results On average, sprint velocity was 5.69 ± 0.74 m/s. The stepwise multiple linear regression revealed that propulsive impulse on prosthetic limb being the variable to enter the model, and explained 77% ($R^2 = 0.77$, $p < 0.01$) of the variance in sprint velocity. Braking and vertical impulses on both limbs and propulsive impulse on intact limbs did not explain any further variance in sprint velocity and were not included in the model. Discussion We found that propulsive impulses on prosthetic limb accounted for 77% of the variance in sprint velocity in TFAs. The results of the present study suggest that propulsive impulses generated by prosthetic limb rather than intact limb may be the key parameter to achieve faster sprint velocity in TFAs. A GENERIC MOBILITY MODEL FOR STANDARDISATION OF MOBILITY-RELATED ASSISTED LIVING SOLUTIONS: A CONTRIBUTION FROM HUMAN MOVEMENT SCIENCE

BRACH, M.

University of Muenster

Problem Assisted living solutions (AAL) claim to support maintaining independence, one of the most important wishes for ageing or impaired individuals. This includes mobility, i.e. the capability, opportunity and performance of changing body positions and of locomotion. This talk deals with needs and challenges in order to support the development and interoperability of related AAL technology. Methods The DKE, German Commission for Electrical, Electronic & Information Technologies of DIN and VDE, established an AAL standardisation roadmap, and a working group targeting on an application guide to be submitted to DIN and IEC committees. At first, working group members from transportation science and technology, human movement science, telecommunication, building industry, computer science and electrical engineering identified issues the document should deal with: (a) the individual need for support changes on different time scales, due to daily fitness, health or ageing processes, (b) the usage of assisted living (or conventional) utilities itself can modify the user's mobility in a good or harmful way, (c) a barrier (process interruption) between indoor and outdoor mobility can arise when devices and utilities have to be changed. The following steps were conducted: 1. to identify mobility-related aspects in national and in European projects in the field of AAL and in DIN ISO 9999 (a standard including mobility assistant devices) 2. to collect mobility-related user stories 3. to define a common theoretical platform 4. to develop complex user stories, covering different target groups and mobility devices 5. to develop example use cases, using the official UCMR format (Use Case Management Repository) from standardisation procedures 6. to develop a generic mobility model, using UML (unified modelling language) 7. to describe example use cases in UML

Results and perspectives A model combining action theory and a resource-based view is considered useful for identifying and discussing mobility aspects. Its main terms are (a) a situation, which comprises (b) a person with certain internal resources (abilities and skills), facing (c) a task with requirements and affordances, embedded in (d) an environment with external resources. Using this specific language scheme, the terms distinguish mobility as (e) room for action. Consequently, the next step of standardisation in mobility-related AAL should be, that the provider has to state clearly, which options for which target group a product will offer, and which requirements its usage will demand. Example use cases show, that the generic model can easily be adapted to target groups of different age and living conditions in different situations.

OP-BN14 Running Footwear

Efficacy of elastic shoe insoles in kinematics, kinetics, and muscle activity during walking and running

SHIOTANI, H.1, FUKUDA, W.2, KAWAKAMI, Y.2

1, 2: Waseda University (Saitama, Japan)

Introduction There has been some, but not conclusive, evidence for the effect of shoe sole elasticity on exercise performance (1, 2). However, mechanisms of the boosting, if any, effect of adding elasticity onto the foot remain uncovered. The purpose of this study was to investigate the effect of shoe insoles on the mechanical characteristics in the support phase of walking and running. Methods Nine male participants (age: 23.3 ± 3.3 years, height: 171.2 ± 3.0 cm, weight: 55.1 ± 6.2 kg) walked at 1.5m/s and as fast as possible, and ran at 2.5m/s , 3.5m/s , 4.5m/s with the elastic (El) and control (CON) insoles. The angles of 4 lower limb joints (hip, knee, ankle, and metatarsopharangeal), ground reaction force (GRF), and 11 muscles' electromyographic (EMG) data were collected. Two way ANOVA for repeated measures and Shaffer's post hoc test were used to compare the differences between El and CON conditions. The level of significance was set at $\alpha=0.05$. Results Both in walking and running, the maximal plantar flexion angle of the ankle in the stance phase and the maximal dorsiflexion angle of the metatarsophalangeal (MTP) joint in the push-off phase were significantly lower in El compared to CON. The propulsive impulse in the active phase exhibited no significant difference between the insole conditions, while the maximal antero-posterior propulsive force in the active phase was significantly lower and the propulsive impulse in the push-off phase was significantly higher in El. In addition, EMG root mean square (RMS) values of medial gastrocnemius (MG) over one step cycle during running and the tibialis anterior (TA) in the stance phase at 3.5m/s were significantly lower in El compared to CON. Discussion It was demonstrated both in walking and running that El enhanced propulsive impulse while decreasing the maximal propulsive force and the ankle and MTP joints' range of motion in the push-off phase. This was associated with lower activity of muscles around the ankle joint during running. It is suggested that the elastic insoles contribute to body propulsion and energy saving in walking and running. References 1: Roy J-P. R., and Stefanysyn D.J. (2006). Influence of running shoes on the negative works of the lower extremity joints: A preliminary study

HASHIZUME, S.1, MURAI, A.1, HOBARA, H.1, KOBAYASHI, Y.1

1: National Institute of Advanced Science and Technology (Tokyo, Japan)

Introduction One of major functions of running shoes is decrease in risks of running-related injuries. The effects of running shoes on risks are sometimes assessed using the ground reaction force (GRF) (Nigg et al., 1987). However, the GRF may not be enough necessarily to interpret risks of running-related injuries. Muscles of lower extremity are common injured parts of running-related injuries. Nosaka and Newton (2002) reported that eccentric muscle contraction induced larger muscle damage than concentric muscle contraction. Negative joint work is thought to be generated by force due to eccentric muscle contraction (Cavagna et al., 1964), suggesting that decrease in the negative works of the lower extremity joints reduce risks of running-related injuries occurring on muscles of lower extremity. The present study, therefore, preliminary confirmed the influence of different running shoes on the negative works of the lower extremity joints. Methods Three young adult males voluntary participated. Two types of running shoes with different sole design were used in this study: SOR-TIEMAGIC and GT-2000 (ASICS) having thin and thick soles, respectively. Retroreflective markers were attached on to pelvis and lower extremity. Subjects were asked to run on runway at 3.0 ± 0.3 m/s. The three-dimensional coordinates of each marker and the GRF were recorded using motion capture system and force platforms. The joint angles of lower extremity were computed as Cardan angles for each local coordinate system embedded to distal segment relative to that embedded to proximal segment. Inverse dynamics approach was used to calculate the negative works for the hip flex-extension, the knee flex-extension and the ankle plantar-dorsiflexion during stance phase of running. Results The negative works of the hip flex-extension were 17.7 ± 5.6 J and 13.0 ± 7.9 J for trials with shoes having thin sole and with shoes having thick sole, respectively. The negative works of the knee flex-extension were 32.6 ± 9.0 J and 38.7 ± 4.1 J for trials with shoes having thin sole and with shoes having thick sole, respectively. The negative works of the ankle plantar-dorsiflexion were 15.1 ± 6.1 J and 15.3 ± 6.1 J for trials with shoes having thin sole and with shoes having thick sole, respectively. Discussion The negative works of the hip flex-extension and the ankle plantar-dorsiflexion were similar between trials with two types of shoes, whereas the corresponding values of the knee flex-extension was larger for trials with shoes having thick sole than those with shoes having thin sole. Furthermore, the negative joint work was markedly larger for the knee flex-extension than the other two joint movements. These results suggest that shoes having thin sole may reduce risks of running-related injuries occurring knee flexor and extensor muscles. References Nigg B, Bahlsen H, Luethi S, Stokes S (1987). DEVELOPMENT OF A TEST METHOD TO COMPARE DYNAMIC PARAMETERS OF SPORTS SHOES

DE RAEVE, E., VERTOMMEN, H., PEERAER, L., MURARU, L.

University College Thomas More Kempen

INTRODUCTION Shoe properties like anti-pronation [1] damping and flexibility [2] can play an important role in reducing the risk of running injuries. However it is difficult to evaluate different sport shoe types considering above mentioned parameters. This work belongs to a larger project aiming to develop a test protocol for measuring a number of relevant shoe parameters, independent of shoe size, shoe type and runner, but measured in real running conditions. **METHODS** 55 healthy persons ran 10 times with 5 different running shoes. Ground reaction force and 3D movement of shoe sole and shank were recorded simultaneously with a force plate (Amsil) and a motion tracking system (Codamotion) with a 28 markers protocol. According to the manufacturer shoe 1 is an antipronation shoe, shoe 2 is a neutral but very flexible shoe, shoe 3 has good shock absorption properties, shoe 4 is an antipronation shoe and shoe 5 is a reference shoe. Five shoe parameters were calculated: the angle between calcaneus and Achilles tendon and the angle between heel and ground (antipronation), the steepness of the active peak of the ground reaction force (damping) and the sagittal and torsional bending magnitude in the forefoot (flexibility). A paired t-test was done for all parameters between every couple of shoe types. **RESULTS** Both antipronation parameters of shoe 1 are significantly different ($p<0.001$) than all other shoes. 84% of the test persons has a more controlled unroll of the heel when running with shoe 1 than with shoe 5. Shoe 2 is significantly more flexible ($p<0.001$) than all other shoes. 72% of the test subjects bent the forefoot at least 10% more when running with shoe 2 compared to shoe 5. Shoe 3 has a significant higher damping than all the other shoes ($p<0.001$). There is no statistically significant difference of antipronation properties between shoe 4 and the reference shoe. **DISCUSSION** A method to quantify shoe parameters and to compare different shoes was developed. Shoe manufacturers can obtain truthful feedback about shoe properties. Although according to the manufacturer shoe 4 should be antipronating, there is no difference in the chosen anti-pronation parameters. All other distinct shoe features given by the manufacturers were proven by measurements. To make statistical relevant results in a smaller time frame, we are transferring the measurement protocol to our robotic gait simulator. **REFERENCES** [1] Cheung R.T.H., Wong M.Y.M. & NG G.Y.F. LONG-TERM EFFECT OF THE SHOE DROP ON RUNNING BIOMECHANICS: A RANDOMIZED CONTROLLED TRIAL

GETTE, P., MALISOUX, L., CHAMBON, N., URHAUSEN, A., THEISEN, D.

Luxembourg Institute of Health

Introduction Among numerous technological features of modern running footwear, heel to toe drop is deemed crucial to modify the running style. So far, only few biomechanical studies have addressed the acute effect of the drop in standard cushioned running shoes, but longitudinal studies are lacking. Therefore, we conducted a randomized controlled trial to investigate if the drop of standard cushioned shoes induces specific long-term adaptations in running technique. **Methods** Leisure-time runners ($n=59$) unexperienced with minimalist shoes were randomly allocated to the three study groups and followed-up for 6 months. Each group was assigned an anonymised version of a conventional running shoe model with strictly identical features except for the drop: either 0 mm (D0, $n=20$), 6 mm (D6, $n=17$) or 10 mm (D10, $n=22$). Running mechanics were tested on a treadmill at the participant's preferred running speed before and after the 6-month period. Systems for three-dimensional motion analysis and optical timing were synchronized to record spatio-temporal and kinematic variables of running trials at 200 Hz. Joint angles were investigated at initial contact (IC) and mid-stance phase (MSP) of 151 ± 22 analysed steps per record. Two-way analysis of variance for repeated measures with the post hoc Bonferroni correction was used and accepted significance was set at $p<0.05$. Results Between pre- and post-tests, participants performed on average a total of 332 ± 178 km over 163 ± 16 days. Overall, increased contact time (286 ± 28 vs. 292 ± 30 ms, $p<0.001$) and stride frequency (82.3 ± 4.2 vs. 82.8 ± 4.0 cycles.min $^{-1}$, $p=0.030$), but decreased stride length (2.07 ± 0.27 vs. 2.06 ± 0.27 m, $p=0.021$) were observed. No interaction between shoe drop and time was found for any of the spatio-temporal variables. Kinematic evaluations at IC showed an increased ankle dorsiflexion (-0.4 ± 4.3 vs. $0.6\pm4.5^\circ$, $p=0.001$) and decreased knee flexion (12.9 ± 4.8 vs. $11.3\pm4.6^\circ$, $p<0.001$) after the follow-up, while foot/ground angle remained unchanged (10.5 ± 4.9 vs. 11.0 ± 5.4 , $p=0.072$). No interaction between shoe drop and time was found for any angles at IC. At MSP, a significant shoe drop by time interaction was found for knee abduction angle ($p=0.032$). For D0, knee abduction decreased (-0.3 ± 3.1 vs. $-1.3\pm2.6^\circ$) in contrast to D6 and D10 groups (0.3 ± 2.7 vs. $1.3\pm3.1^\circ$ and -0.2 ± 3.2 vs. $0.5\pm3.1^\circ$, respectively). **Discussion** This is the first randomised controlled trial to investigate the long-term effect of shoe drop in cushioned shoe on running biomechanics. After the follow-up of six months, there was no difference between the three shoe versions except for decreased knee abduction at mid stance phase. However, given the effect size, this may not be clinically relevant.

Oral presentations**OP-BN19 Motor Learning & Development****EVALUATION OF THE BRAKING STRENGTH PRODUCTION AND CONTROL ON A BICYCLE WITH A NEWLY DESIGNED BRAKE LEVER IN 5- TO 7-YEAR OLD CHILDREN**

MORIO, C., MARTIN, V., RATEL, S.

Decathlon SportsLab

Introduction A new bicycle brake lever (StopEasy, B'Twin™) has been recently designed to facilitate the braking in young children. This new brake lever was based on (i) a shorter course of displacement adapted for the children's hand size (Norris & Wilson 1999), and (ii) a reduced moment arm. It was hypothesized that children would produce more force during maximal voluntary contraction with the StopEasy compared to a classical brake lever. Furthermore, the force steadiness could be improved during sustained submaximal braking tasks with the StopEasy. **Methods** Twenty-nine children (17 girls, 12 boys) aged 5- to 7-year old participated in the present study. All of them performed on a stationary bicycle three maximal voluntary contractions (MVC) and three submaximal contractions at 30%, 50% and 70% of MVC using either the StopEasy or a classical brake lever. Electromyographic activity (EMG) of the extensor carpi radialis (ECR) and flexor digitorum superficialis (FDS) muscles and the force signals were simultaneously recorded during MVC and submaximal conditions.

The sample entropy (SampEn) of the force signal was calculated during submaximal contractions and considered as a task complexity index (Richman & Moorman 2000). Paired Student t-tests were used to compare the variables obtained during MVC. Two-way (2 brake levers x 3 force levels) ANOVA with repeated measures were performed to test the variables during submaximal conditions. Results During MVC, no significant difference of force and EMG activity of the ECR and FDS muscles was observed between the StopEasy and the classical brake lever. During submaximal conditions, the EMG activity of the FDS was similar between the two brake levers. However, the ECR showed a lower EMG activity with the StopEasy for the same force level ($p<0.01$). Finally, the SampEn increased with the force level when the classical brake lever was used ($p<0.01$), whereas it remained unchanged with the StopEasy whatever the force output. Discussion Interestingly, the EMG activity of the ECR was lower with the StopEasy during submaximal contractions, hence suggesting that less wrist stabilization was required with the StopEasy compared to the classical brake lever. The SampEn results also suggest that the motor control during submaximal braking was more effective with the StopEasy, even at high force levels. From a practical point of view, the StopEasy could facilitate the control of the braking, even in emergency situations where high braking forces need to be finely tuned. To conclude, the newly designed StopEasy lever is likely to improve the effectiveness of braking on bicycle in 5- to 7-year old children compared to a traditional brake lever. VARIABILITY AND SPACING – DO THEY INTERFERE WITH EACH OTHER?

BECKMANN, H., SCHNEIDER, F.J.M., SCHÖLLHORN, W.I.

Johannes Gutenberg-University Mainz

Introduction: Research evidence shows better learning results if people practice skills in larger numbers of shorter practice session compared to a massed practice schedule (Magill & Anderson, 2014). But the relationship between spacing and learning effort is still unclear. Beckmann et al. (2014) showed an optimal spacing of 48 hours between sessions when novices learn a field hockey task by the differential learning approach (DL; Schöllhorn, 2000). While Shea et al. (2000) identified spacing as a confounding factor in motor learning studies the following study examines if the optimal spacing depends on the practice protocol. Methods: Therefore the hockey dribbling performance of 32 novices (physical education students, M age = 21.6 years, SD = 2.1) was calculated from the dribbling and sprint performance in a 15 m slalom parcour (Lemmkink et al., 2004). After the pretest participants were separated into three groups. Each group performed five practice sessions for the hockey dribbling according to a high contextual interference (CI) schedule. Only the spacing between the practice sessions was different for each group (24, 48 and 72 hours). After the third practice session all participants completed an intermediate test and at the end of the last session the posttest. One week after the posttest all participants returned for a retention test. Results: The results of the repeated measurement ANOVA show a significant effect for the factor time ($F(1.6; 46.4) = 94.525$; $p < .001$; partial eta-square = .765) but no group or interaction effects. Discussion: In two aspects these results (CI) differ from the results Beckmann et al. (2014) showed for the DL. Firstly, the trend of the learning curves in the CI condition do not show a continuous increase in dribbling performance and secondly, there are no differences between the three groups. This confirms the annotation from Shea et al. (2000) that the spacing of the practice sessions might be a confounding factor when results of CI-studies under laboratory circumstances are transferred to the field. Also the results refer to the possibility that the amount and structure of variation during practice interfere with the spacing of the practice sessions. This might be an unnoticed aspect in the development of practice schedules. References: Beckmann H, Schöllhorn WI (2014). 19th annual congress of the ECSS. Book of abstracts, 515. ASSOCIATION BETWEEN THE DEVELOPMENT OF MOTOR PERFORMANCE AND SELF-RATED HEALTH IN CHILDHOOD AND ADOLESCENCE

ALBRECHT, C.1, HANSSEN-DOOSE, A.1, MEWES, N., HÖLLING, H.3, WORTH, A.1

1 University of education Karlsruhe; 2 KIT, 3 RKI

Introduction In adulthood motor performance (MP) is considered one of the most important health markers, as well as a predictor of morbidity and mortality for cardiovascular disease (Ortega, 2008). However, there are only few studies that examine the association between MP with health outcomes (a) in children and (b) longitudinally. The purpose of this longitudinal analysis is to investigate, whether there is an association between changes in MP in childhood and adolescence over a period of 6 years (t0-t1) and self-rated health (SRH) after this period (t1). Methods To examine the association between development of MP and health, MP and SRH were assessed within the framework of the longitudinal German Health Interview and Examination Survey for Children and Adolescents (KiGGS) and the Motorik-Modul (MoMo). In this nationwide sample of children/ adolescents in Germany (age: 4-23 y; n=2,167) MP was assessed by means of the MoMo test profile covering four dimensions of MP (strength, endurance, coordination, flexibility) (Wagner et al., 2013). SRH was measured with a single item which is a valid measure for general health (Lunberg & Manderbacka, 1996). For statistical analyses bivariate correlations (Spearman) were conducted. Results There were significant positive correlations between MP development (t0- t1) and SRH at t1 for the MP tasks bicycle ergometer (PWC 170) ($r=.11$; $p=.00$; $n=1,148$) and standing long jump ($r=.11$; $p=.00$; $n=1,851$), but not for jumping sideways. ($r=.05$; $p=.05$; $n=1,838$), static stand ($r=.04$; $p=.11$; $n=1,859$), and stand & reach ($r=.04$; $p=.10$; $n=1,863$). To conclude: the analyses revealed significant positive correlations in MP development (t0- t1) and SRH at t1 for MP tasks which are predominantly determined by physical condition but not for tasks testing coordination and flexibility. Children/ adolescents with a higher increase in MP from t0 to t1 show a higher SRH value at t1. Discussion Our results emphasize that elevating the MP is a marker for health already in childhood. The enhancement of MP, for example by increasing time spent in vigorous physical activity, should be emphasized in public health promotion policies. On account of the fact that different MP tasks relate in different ways to other different (objective) health outcomes more in-depth analyses will be conducted. TRAINABILITY OF POSTURAL CONTROL IN CHILDREN

WÄLCHLI, M., RUFFIEUX, J., MOUTHON, A., KELLER, M., TAUBE, W.

University of Fribourg

Introduction In contrast to the benefits of balance training on postural control in healthy young adults (Lesinski et al., 2015), no clear evidence have been found in children. Previous studies in children have revealed divergent results concerning the trainability of balance skills. Children aged from 11-14 y displayed improvements whereas younger children did not - at least in transfer tasks. The question therefore is, whether the young age of the children prevents postural adaptations or the implemented training regimes have not been suited to improve these skills. Hence, the present study applied for the first time an identical, children specific training regimen in three different age groups (old: 14-15 y; middle: 11-12 y; young: 6-7 y) to shed light on the abilities to improve postural control in response to balance training in childhood. Method 77 children (10.7 ± 3.4 years, 1.46 ± 0.20 m, 42.5 ± 17.4 kg; 38 f and 39 m) were distributed to three age specific intervention (INT) and control groups, respectively. The training was arranged holistically and playfully and took place during physical education lessons (5 weeks with 2 sessions per week of 45 minutes). Postural control was assessed by different static and dynamic (among others: single leg stance on spinning top (STIL) and single leg stance on Posturomed (POSIL)) postural control tests. In addition, jump height of countermovement jumps and rate of force development (RFD) in a plantar flexion motion task were measured. Results No statistical differences in static balance tasks could be found. A three-way mixed design ANOVA with repeated measures revealed a significant GROUP*TIME interaction for one dynamic test (STIL; $F_{1,66} = 6.652$; $p = .012$; $n2p = 0.092$) and for RFD ($F_{1,68} = 4.375$; $p = .040$; $n2p = 0.060$). Age specific adaptations were observed by GROUP*TIME*AGE interaction in STIL ($F_{2,66} = 3.217$; $p = .046$; $n2p = 0.089$) and POSIL ($F_{2,69} = 4.069$; $p = .021$; $n2p = 0.106$). Discussion The present study shows evidence that dynamic postural control and explosive strength in children can be improved by holistic balance training. Age specific adaptations revealed greatest gains in the youngest group. This is the first study demonstrating that postural control can be trained already at the age of 6 years onwards in healthy children. Furthermore, the kind of balance training seems to be essential to improve balance in children. Literature Lesinski, M., Hortobagyi, T., Muehlbauer, T., Gollhofer, A., & Granacher, U. (2015). Dose-response relationships of balance training in healthy young adults: a systematic review and meta-analysis. Sports Medicine, 45(4), 557-576.

OBJECTIVE PROFILING OF CHILDREN'S ACTIVITY USING MOTION MAPPING AND MACHINE LEARNING

BARNES, C., CLARKE, C.T., REES, P., STRATTON, G., SUMMERS, H.D.

Swansea university

Introduction In children's activity programmes the challenge is to obtain information on their physical motion using techniques that do not hinder natural motion and that can be implemented in ecological settings. Accelerometers are widely used to study exercise and activity [1] and have been shown to be informative of motion mechanics [2]. We present a novel analysis framework for activity assessment that uses accelerometry to create sophisticated motion maps and demonstrate their utility in profiling and categorising movement mechanics in a diverse range of activities. Methods Acceleration data were collected from ankle and wrist mounted sensors. Children aged 9 - 11 years were assessed in a multi-stage fitness test (increasing run speed) and a fundamental motor skill (FMS) challenge (9 exercises testing agility, balance and coordination). Radial acceleration data from the ankle was used to construct spectrograms and phase maps of running motion. Ankle and wrist acceleration traces were used to create motion maps of the activities. Whole-activity profiling of the cohorts (ranking and sub-group identification) was completed using multi-dimensional scaling of correlation matrices obtained from pairwise cross-correlation of spectrograms and activity maps. Specific activity components were analysed through pattern recognition using machine learning. Results Analysis of the first stage of the fitness test yielded cross-correlation indices in the range $0.5 < p < 0.7$. Dimensional scaling of this data provided an accurate description of child-to-child variation in a 2D space. Motion maps of ankle and wrist acceleration within the FMS challenge, displayed patterns clearly linked to specific activities such as throwing, jumping and body roll. These were sufficient to classify performance into activity categories using pattern recognition and a training set from expert observer scores. Discussion We have shown that detailed mapping of children's mechanical motion patterns can be achieved, in a range of activity settings using light weight, low cost wearable sensors. These motion maps can be predictive of performance based on limited sampling allowing population profiling with sub-maximal fitness testing and FMS profiling. The recording of position and acceleration of wrist and ankle provides detailed information on dynamic system behaviour which when allied to computerised pattern recognition and classification gives an objective scoring of complex motion, normally requiring subjective assessment by expert human observers. Oral presentations**OP-PM62 Risks & Injury: Screening, Prevention & Treatment****CONTEMPORARY MODELS OF PRE-EXERCISE SCREENING AND RISK STRATIFICATION**

NORTON, L., NORTON, K.

Flinders University, University of South Australia

Introduction Each year in Australia approximately 40% of the adult population report beginning or upgrading an exercise program [PA]. A national adult pre-exercise screening system [APSS] was developed jointly by three professional groups to refine the way risk stratification is undertaken [FA 2010]. The superseded system was based on a strict cut-off of common risk factors [RF] whereby 2 or more RF resulted in a medical [GP] referral. In recent years this conservative thinking about RF, risk stratification and physical activity promotion has changed. The APSS identifies people at moderate risk [>2 RF] but does not automatically involve GP referral. The APSS has not been applied to a normative population. Methods Individual record data from the Australian Health Survey 2011-12 was processed through the APSS. The adult proportion [$>=18$ yr] with $>=2$ RF was determined using both self-report [SR; n=20,762; age $>=45$ or 55yr (f), smoking, PA <150 min/wk, BMI $>=30$, high BP, cholesterol or glucose] and measured variables [ME; n=6,923; BMI $>=30$, SBP $>=140$ or DBP $>=90$ mmHg, waist girth >94 or 80cm (f), cholesterol $>=5.2$ mM, glucose $>=5.5$ mmol]. Results Using SR, there were 41.3% with 2 or more RF. This approximately doubled when variables were ME. The three most common SR RF were insufficient PA [46.3%], age [40.8%] and BMI [27.5%], while ME RF were waist girth [58.9%], high lipids [53.4%] and BMI [25.1%]. Discussion The APSS was developed to reduce the

burden of excessive referrals to the medical system, minimise unnecessary barriers to exercise adoption, and encourage more people to become habitually physically active. It was also based on the notion that fitness professionals working with people new to PA should assume more responsibility to prescribe appropriate intensity tailored for individuals and progress cautiously, especially for those at moderate risk. There is substantial evidence that light-moderate PA is safe for most people. The results of this study show there is a very large proportion of adults who have multiple risk factors. Previous conservative approaches would have recommended this population seek medical guidance before beginning a PA program. The APSS, and the more recent ACSM recommendations (Riebe et al., 2015), reflect a new approach to RF management and PA promotion. When more than half the population is not sufficiently active, and are obese with large waist girths, the most important advice we can give as health professionals is to be more active. INJURY TRENDS AT A SELECTIVE-ENTRY YOUTH SPORTS ACADEMY: IMPLICATIONS FOR LOAD MONITORING AND PROGRAM DESIGN FOR STUDENT-ATHLETES

PANE, C.

Mariaburnong Sports Academy

AIM To investigate the incidence, timing and type of injuries to student-athletes, with the applied aim to identify strategies to mitigate the risk of injury within a talent-identified youth student-athlete cohort. Mariaburnong Sports Academy (MSA) is a the specialist sport school of the Victorian Government now supporting over 500 student-athletes. In 2015, over 200 MSA student-athletes achieved selection to state and/or national representative squads. METHODS Injury data was collated on all student-athletes this information includes and is not limited to diagnosis, injury mechanism, injury type and training location where the injury occurred. RESULTS Data for the period of January to November 2015 show that out of the six highest monthly injury tallies, four of these months coincided with the start of a new school term. Higher incidences of sudden onset acute injuries as opposed to chronic injuries occurred at the start of each school term. MSA student-athletes obtained 56% of all injuries outside of structured MSA training (i.e., local club & talent pathway sport). Further 19% of all injuries were attributed to activities at MSA including technical sport training, school sport/competition, Athlete Development Program (ADP) and Physical Education. The other 25% of injuries to the student-athletes were attributed and classified as overuse aetiologies which highlights a potential disconnect of what training is taking place outside of MSA. Most common type of injuries were strains (15.6%) of all injuries, ligaments (14.4%), bone injuries (13.6%), teninopathies (9.2%) and contusion (8.1%). It was found that the more common overuse injuries in adolescent athletes (Anderson, 2005; Soprano et al., 2007) accounted for 22.9% of all injuries. These included AFL sprain (6%), Hamstring strain (4.1%), Facet Joint (3.7%), Patello femoral joint pain (PFJ) (3.5%), Osgood Schlatters disease (3.5%) and severs disease (2.1%). CONCLUSIONS Implementation of more systematic load monitoring procedures for both MSA sport programs and for external sport activities will provide an evidence-based approach to drive new strategies to reduce the risk of injury. Program design changes that have been influenced by the data presented herein and plans for increased load monitoring will be discussed. This includes the reduction of load at peak times of identified risk (i.e., start of each term) and the on-going identification of external load points such as the commencement of club and pathway sport competitions. SAARLAND INJURY MOVEMENT SCREEN : CONCEPTION AND INTRA-/INTER-RATER RELIABILITY

MCCUNN, R.1, AUS DER FÜNTEN, K.1, GOVUS, A.D.2, JULIAN, R.A.1, SCHIMPCHEN, J.1, MEYER, T.1

1: Saarland University (Germany), 2: University of Bedfordshire (UK)

Introduction Assessment of movement quality is widely used within applied practice. One goal is to highlight athletes with an increased likelihood of injury (McCunn et al., 2015). A number of movement screens exist within the scientific literature; however, few have been specifically designed to serve one particular sport. The newly developed Saarland Injury Movement Screen (SIMS) was designed for use within soccer. It comprises five movements: the anterior reach portion of the Y-balance test (ARI), single-leg deadlift (SLDL), in-line lunge (ILL), single-leg hop for distance (SLHD) and the tuck jump assessment (TJ). Scoring criteria relate to both objective (e.g. distance achieved) and subjective (rating of movement quality) criteria. The aim of the present study was to establish the intra- and inter-rater reliability of the test. Methods Twenty-five (male=11, female=14) recreationally active university students (age 25.5 ± 4.0 years, height 170.9 ± 8.9 cm, weight 64.7 ± 12.6 kg) were assessed using the SIMS on three separate occasions separated by an average of 3.5 days. Two raters (Raters 1 and 2) assessed all participants on each occasion. An additional third rater (Rater 3) scored 15 of the 25. Raters scored two of the five movements (AR and SLHD) in real-time. The remaining three movements (SLDL, ILL and the TJ) were filmed from both the frontal and sagittal planes using Apple iPhone 4S devices and retrospectively scored. Two-way mixed model intraclass correlation coefficients (ICC; 3,k) were calculated as a measure of intra- and inter-rater reliability. Results The average intra-rater ICC values for the composite score (across all three testing occasions) for Raters 1, 2 and 3 were 0.72 (95% CI: 0.56-0.84), 0.70 (95% CI: 0.52-0.83) and 0.65 (95% CI: 0.39-0.83) respectively. In addition, average inter-rater ICC values for occasions 1, 2 and 3 (n=15) were 0.92 (95% CI: 0.81-0.97), 0.95 (95% CI: 0.87-0.98) and 0.92 (95% CI: 0.80-0.97) respectively. Conclusion Various qualitative interpretations of ICC values exist and these are largely subjective (Atkinson and Nevill, 1998). A reasonable consensus of what constitutes 'good' reliability based on other studies investigating movement screens is an ICC value ≥ 0.70 . This initial study reveals the SIMS appears to possess moderate to good intra-rater and good inter-rater reliability. Future research using the SIMS will seek to assess its usefulness in applied practice within soccer. References McCunn R, aus der Fünten K, Fullagar HHK, McKeown I, Meyer T. (2015). THE EFFECT OF A CONTROLLED MANDIBLE POSITION MOUTHGUARD ON STRENGTH AND POWER IN TRAINED ATHLETES

DIAS, A., REDILNHA, L., MALAQUIAS, F., TAVARES, F., PEZARAT-CORREIA, P.

Faculty of human Kinetics

INTRODUCTION The use of mouthguards is widely accepted on sports for injury protection. Research has suggested that they might also enhance athlete's muscle strength, but this is still a controversial issue. Thus, the aim of this study was to objectively determine if the use

of a controlled mandible position mouthguard may influence athlete's strength and power. METHODS Ten rugby players (25.3 ± 3.29 yrs; 1.85 ± 0.1 m; 97 ± 11.1 kg) volunteered for the research. Each subject performed a 1RM bench press test to ascertain their maximal load. Test protocol applied was a bench throw at 40% of the 1RM results, in the following randomized conditions: a) no mouthguard; b) controlled mouthguard (jaw in centric relation); c) over-the-counter mouthguard (placebo) d) Occlusal splint. All tests were applied on a smith machine, with 48h between them. RESULTS The results revealed that from the several parameters scrutinized, acceleration, peak acceleration, peak force, time to peak velocity and time to peak acceleration were improved when using the controlled mouthguard ($p < 0.05$). No placebo effects were found. DISCUSSION The findings in this study suggest that the use of a controlled mouthguard may improve athlete's strength in power exercises. To the best of our knowledge, this was the first study that assessed strength while using a mouthguard that placed the mandible in centric relation, which is the most orthopaedic musculoskeletal stable position of the mandible (Okeson, 2008). Involuntary teeth clenching occur during physical exercise (Yokohama, 1998) and may optimize performance (Ebben et al., 2008), as it was previously demonstrated during countermovement jump. Therefore, it might be speculated that this controlled mouthguard optimizes the relation between mandibles, providing better stability for the mandible while clenching, which in turn allowed for an improvement in strength related skills. Since the position of the mandible is anatomically determined and therefore reproducible, this mouthguards provide a different and novel approach. They enable the comparison between participants using similar mouthguards, with controlled anatomical positions. This controlled mandible mouthguard is in contrast with similar studies on this subject, that perform random teeth fitting for manufacturing the mouthguard and did not control (clinically) the position of the mandibles. PREDICTION OF KNEE VALGUS MOMENT DURING A HOP-AND-SIDESTEP TEST SIMULATED SIDESTEP CUTTING IN RUGBY PLAYERS

ITO, W.

National Institute of Fitness and Sports in Kanoya

Introduction Many non-contact anterior cruciate ligament (ACL) injuries have been reported to occur during sidestep cutting in rugby players. There is no screening tool of ACL injuries caused by sidestep cutting. Knee valgus moment is recognized as an important predictor of non-contact ACL injury risk. Since actual sidestep cutting are complicated to be tested, we have suggested to use hop-and-sidestep as simple and easy clinical screening test. Hop-and-sidestep is associated with sidestep cutting in knee valgus moment. The purpose of this study is to investigate lower extremity and trunk motion which predicts knee valgus moment during hop-and-sidestep in male rugby players. Methods Twenty one male rugby players (20.9 ± 2.8 years, 171.6 ± 4.0 cm, 75.4 ± 7.1 kg) participated in this study. We performed hop-and-sidestep test as follows; single leg hop forward, landing with the same leg, and cutting to the opposite direction of the standing leg. The testing procedures were repeated three times and the average data was recorded. A three dimensional motion analysis system featuring ground reaction force was used to determine kinematics and kinetics of both legs. We calculated Peak knee valgus moment, lower extremity and trunk angle (lower leg medial tilt, knee flexion, hip abduction, trunk flexion and trunk lateral flexion) during the test. Peak knee valgus moment was normalized to weight. Kinematic data was recorded at peak knee valgus moment. Multiple regression analysis was used to correlate knee valgus moment with lower extremity and trunk angle. Results Lower leg medial tilt, hip abduction and trunk lateral tilt angle explained knee valgus moment ($p < 0.01$), while knee flex and trunk forward tilt angle were not significant predictors of knee valgus moment. Multiple regression revealed that 74% ($r = 0.86$) of knee valgus moment was explained by the combination of the three predictors. Conclusion We reveal that lower leg, hip and trunk angle predict knee valgus moment during hop-and-sidestep. Hop-and-sidestep might be an effective clinical screening test predicting knee valgus moment. The three predictors should be frontal plane motions. To prevent ACL injuries during sidestep cutting, athletes are required the ability to coordinate their body in side-to-side motion. Contact E-mail: wtr0804@hotmail.co.jp

ASSOCIATION BETWEEN THE USE OF ANALGESICS AND DOPING - A SURVEY IN 2,997 TRIATHLETES

DIETZ, P.1, DALAKER, R.2, LETZEL, S.3, ULRICH, R.4, SIMON, S.5

University of Graz

1: University of Graz, (Austria), 2: University Medical Center Schleswig-Holstein (Luebeck, Germany), 3: University Medical Center (Mainz, Germany), 4: University of Tuebingen (Germany), 5: University of Mainz (Germany) Introduction According to several epidemiological studies, the use of doping substances has been reported to be common practice among competitive athletes (Dietz et al., 2013; Striegel et al., 2010). Further studies showed that non-prohibited physical performance-enhancing substances, such as nutritional supplements (NS), provide a gateway for using doping substances (Backhouse et al., 2013). Additionally, the use of non-steroidal anti-inflammatory drugs (NSAIDs), including over-the-counter (OTC) analgesics, directly before a competition, has also been reported to be common use among endurance athletes such as marathon runners (Kuster et al., 2013) and triathletes (Gorski et al., 2011). The objective of this study was to test whether the use of analgesics is associated with the use of doping and therefore provides a gateway to doping as discussed for NS. Methods A questionnaire primarily addressing the use of analgesics and doping was distributed among 2,997 triathletes. The randomized response technique (RRT) was used to estimate the 12-month prevalence of doping in order to assess whether users of analgesics have a higher potential risk for doping than non-users. Statistical power analyses were performed to determine sample size. The bootstrap method was used to assess the statistical significance of the prevalence difference for doping between users and non-users of analgesics. Results The 12-month prevalence estimate for the use of doping substances (overall estimate 13.0%) was significantly higher in athletes that used analgesics (20.4%) than in those athletes who did not use analgesics (12.4%). Discussion The results of this study revealed that athletes who use analgesics prior to competition may be especially prone to using doping substances. As a practical implication of the present findings, we recommend athletes and coaches to handle the consumption of analgesics with care, and only use them for therapeutic reasons instead of pain prevention. OP-SH12 Sociology: Gender

CREATING ORGANISATIONAL CULTURES TO SUPPORT THE PROGRESSION OF WOMEN COACHES AND COACH EDUCATORS

NORMAN, L., RANKIN-WRIGHT, A.J.

Leeds Beckett University

Introduction The aim of this study was to understand the experiences of women coaches and coach educators in progressing through the licensed coaching and tutoring system within an English National Sporting Governing Body, The English Football Association. Statistics show that there is an average 75% drop-off in the number of women at each stage of the coaching pathway and an average 97% drop-off in the number of women progressing through the coach education (tutor) pathway from level 1 to 4. The focus of this paper centres specifically on examining the organisational structures and practices that influenced women's careers at critical points of their coaching development. Personal experiences were considered as an interplay of not only individual choices and circumstances, but also related to organisational contexts and relations with others within the system. Method 26 semi-structured interviews were conducted with a sample of licensed women coaches and tutors, at different points of the respective pathways, within the English Football Association. Interviews focused on the participants' entry and progression into coaching and coach education, experiences of initial training and professional development, motivations for leadership / to progress, their experiences as a woman within their sport, and their experiences of the organisational context in which they work. Results For women to thrive and progress as coaches and coach educators, particular organisational values are key in supporting their career. Creating a culture that values and nurtures the contribution that women can make to the coaching and tutoring professions, creating a culture that accepts women in and associates women with, leadership, retaining frequent and meaningful relationships between organisations and staff, and rewarding and recognising women's experiences and achievements all serve to create organisational cultures that are welcoming and inclusive of diversity. Discussion Gender needs to be understood as a complex set of social relations enacted across a range of social practices, rather than merely as a biological status. An interrogation of the social order of sport is required, that is how structures, practices, relations and values maintain and enforce particular ways of relating and being, and result in unequal social relations. Addressing the types of gendered social practices that exist within sporting organisations and ideologically reframing gender equality are avenues for change to the current status quo within sport. The challenge then, is to redefine this coaching culture rather than simply to operate within the constraints of the existing system. Contact L.J.Norman@leedsbeckett.ac.uk

GENDER POSITIONS IN SCHOOL SPORT: FLOORBALL AND SOCCER

LARNEBY, M.

Malmö University

In Sweden, organized team sports performed during leisure time are mainly separated for boys and girls. As Messner (2002) argues, this often reproduces traditional gender hierarchies within sport, in which boys are favored and girls undervalued. In sport schools, however, mixed-sex training groups are as common as separated groups. Anderson (2009) discusses that mixed-sex team sports may effectively reduce gender stereotypes, because men and women need to cooperate. Therefore, it is of interest to study mixed-sex and separated team sport groups at a sport school. The aim of this study was to explore and discuss young people's construction and display of gender in floorball and soccer groups at a sport school, and in what way gendered power relations were exercised. Methodology and theory An ethnographic approach was used to access voices, attitudes and actions on and off the floorball and soccer lessons (cf. Ennis & Chen 2012). Young teenagers attending floorball and soccer lessons at a sport school (7th to 9th grade) were observed and 21 one of them interviewed. Lorber's (1994) theory of gender as a social institution was used to analyze and interpret their expressions and actions, attitudes and notions of sport. Results "Boys are better than girls" was the hegemonic discourse in the training groups. The mixed-sex floorball setting seemed to actualize an unquestioned need to dichotomize and construct distinct groups of boys and girls. However, the floorball girls emphasized that they empowered themselves by improving their athletic skills together with boys. Though being recognized by the boys, they were also patronized in various ways. The floorball boys reproduced an orthodox masculinity and similarly challenged this masculinity by most often appreciating the girls as skilled training peers. The soccer girls experienced a verbal patronizing as the soccer boys frequently told them that "girls are rotten soccer players", though never having trained together. The soccer boys weren't as reflective as the floorball boys, instead maintaining that "boys are better than girls" and that a mixed-sex setting was evidently unacceptable. Conclusion Although the boys and girls constantly emphasized differences due to gender, they strove towards a uniform level of skills and ideal way of play—to be fast, tough, strong and technical. Gender seemed to lose significance in this common strive for similarity, still they continued to compare each other with boys as the norm. Therefore, gendered power relations set an agenda based in a notion underlining that "boys' way to play" is the ideal. References Anderson, E. 2009. GENDER MARKING IN MEDIA COVERAGE OF SPORT - LONGITUDINAL ANALYSES ON THE VISUAL REPRESENTATION OF FEMALE AND MALE ATHLETES IN GERMAN PRINT MEDIA

HARTMANN-TIEWS, I.

German Sport University Cologne

Introduction The visual representation of athletes via sports photographs is one of the most powerful medium for the social construction of gender relations in sport. Research in the anglo-american countries has revealed a continuous gender marking, denoting female athletes' otherness and their sport as something less valuable than that of men. The respective gender markings in media communication include 'compulsory heterosexuality', 'appropriate femininity', 'infantilization', 'emphasis on non-sport related aspects', 'sexualisation' and 'ambivalence' in reports. To sum it up, it is the discourses through which media construct knowledge that leads to shared under-

standings and practices that reinforce rather than challenge the existing gender order and relations of power (Bruce 2013). During the last three decades social change has affected the gender order, management of sport events and marketing of athletes. However, there is only little research on the relevance and impact of social change to gendered print media coverage and discourses and no respective research in Germany. Research questions and methods The question to put forward is, whether media discourses on sport have changed towards a more gender-neutral presentation of athletes. In order to get answers to these questions, we designed two follow-up studies. The first one refers to daily newspaper coverage and the original study of Klein (1986) on print media coverage in Germany in 1979. The longitudinal study is based on a systematic content analysis of four national newspapers in Germany in 2000 and 2010 in order to compare data over a period of 30 years. The sample consists of a total number of 852 texts and 352 photographs 2000/2010. The second longitudinal study is based on a systematic content analysis of the visual representation of athletes during the Olympic Games 2004, 2008 and 2012 and a total sample of 2424 photographs in two national newspapers [777 photographs in 2004, 876 photographs in 2008 and 771 photographs in 2012]. Results are presented and discussed against the background of theoretical assumptions about social construction of gender and gender order in sport. 'TWO GIRLS; THAT MUST BE OKAY, RIGHT': SEXUAL CONSENT AND ABUSE IN KARIN'S COACH-ATHLETE LESBIAN RELATIONSHIP

JOHANSSON, S.

The Swedish School of Sport and Health Sciences

Introduction Female elite-athlete Karin* was 17 years old when the considerably older, team coach Selma* became her girlfriend. Five years later Karin contacted me, offering to share her story. To date there are no studies on coach-athlete lesbian or gay relationships and literature on legal coach-athlete sexual relationships is sparse. Although sexual consent is often the defining characteristic of sexual abuse, the meanings of consent are rarely explicitly defined, problematized or comprehensively investigated (Beres, 2007). The current study investigates how Karin makes sense of her coach-athlete lesbian relationship and what can be learnt about sexual consent from this story. Methodology Drawing on qualitative methodology, the study uses a narrative case study design. First, a loosely-structured interview was performed, inductively analysed within-case, and presented in form of a literary short story. Second, the story was analysed and discussed in reference to literature on sexual consent, abuse, gender, and sexuality. Findings and discussion Karin's story gives a rare insight to a lesbian coach-athlete sexual relationship that unfolded in a consent and abuse grey-area. Social and sexual conventions, normative notions, and corresponding regulations to protect athletes can (unintentionally) result in stigmatisation and isolation that facilitate abusive, harmful coach-athlete relationships. For example, heteronormativity and predominant male perpetrator – female victim stereotypes (Johansson & Larsson, 2016). Karin's story moreover illustrates that socially and relationally, consent is not necessarily amenable to a mutually exclusive yes or no answer to sexual relations (Beres, 2007). Sometimes consent is alternately absent and present during events and phases; before, during and after a coach-athlete sexual relationship. This negotiation and renegotiation depends on contextual factors both within and outside of the relationship. Karin's negotiation of consent circled primarily around her need for friendship. Sharing stories like Karin's breaks the prevailing silence and marginalisation. Further research into the contextual, complex, and sometimes contradictory negotiations of sexual consent, that intersect both structure and agency, and needs to regard gender, sexuality, athlete empowerment, and preventing sexual abuse among sexual majorities and minorities is proposed. * Pseudonyms References Beres M (2007). ACTION FOR MEN – PERCEIVED REASONS FOR AND BARRIERS TO PARTICIPATING IN PHYSICAL ACTIVITY IN MEN AGED 50 PLUS

STROBL, H.1, TITTLBACH, S.1, LOSS, J.2, WARRELMANN, B.2

1: University of Bayreuth, Germany, 2: University of Regensburg, Germany

Introduction Men at and over the age of 50 represent a special target group for physical activity promotion trials: In general, men experience higher mortality rates due to chronic diseases than women, but health promotion offers are more frequently utilized by women than men. Even so, there is little published evidence in how to promote men's engagement in physical activity (Robertson et al., 2008). Literature suggests that programs effective in increasing physical activity respond specifically to local needs and barriers by being regionally grounded and multi-sectoral (Cordier and Wilson, 2014). This is the key strategy of the project Action for men, granted by Germany's Federal Ministry of Education and Research. In two rural communities (5.000 to 10.000 inhabitants each), key stakeholders from a variety of sectors (e. g. local health authority, adult education centers and sports associations) are participating in a task force that will develop and implement programs to promote physical activity among men aged 50 plus. To inform the development of interventions, a needs assessment and barrier analysis was carried out. Methods A standardized quantitative questionnaire was sent to 2.500 men at and over the age of 50, including questions about perceived reasons for and barriers to partaking in physical activity and about stages of behavioral change of the participants. Results In total, 431 men between the ages of 50 and 92 answered the questionnaire. Exemplary, two significant results concerning barriers to physical activity are illustrated: Perceived lack of time as well as perceived uncertainty with physical ability decrease continuously across stages of change. There are significant differences between the stages for both types of barriers, but more variance can be explained by uncertainty (lack of time: F=8,39; p<0,01; $\eta^2=0,13$; uncertainty: F=35,30; p<0,01; $\eta^2=0,38$). Discussion Contrary to middle-aged persons (e. g. Duan et. al, 2013), men aged 50 plus perceive uncertainty with their own physical ability as a greater barrier to physical activity when compared to lack of time. This has to be considered in developing activity promotion trials for older men. References Duan Y, Brehm W, Strobl H, Tittlbach S, Huang Z, Si G. (2013). *J Exerc Sci Fit*, 11(2), 63-77. OP-PM40 Kayak & Rowing

OXFORD AND CAMBRIDGE BOAT RACE: PACING AND TACTICS BETWEEN 1890 AND 2014.

HETTINGA, F.I., GUY, J.H.2, EDWARDS, A.M.2

University of Essex

1: University of Essex, Colchester, UK 2: University of St Mark & St John, Plymouth, UK Introduction: The Oxford and Cambridge Boat Race is one of the oldest, continuing sporting events in the world. Historically as well as scientifically, the race is of unique value, as performance data have been collected in the same event over 125 years. The purpose of this study was to investigate the pacing and tactics employed by crews of the Oxford and Cambridge head-to-head race between 1890 and 2014. Methods: To examine pacing profiles, 4 intra-race checkpoints were used (1: Mile Post, 2: Hammersmith Bridge, 3: Chiswick Steps, 4: Barnes Bridge and the Finish). In addition, the pacing strategy in terms of section times of the crews was considered in accordance with 1) the overall profile across checkpoints and 2) the degree to which all crews sought to gain tactical advantage during the race. This was investigated by assessing each crew's average boat speed (m/s) across the full course (6.8km) and comparing the crew's average speed between checkpoints. To evaluate categorical data and the impact of factors such as starting station and the extent of fast start strategy, Chi Squared analyses were performed. Results: There was no tactical advantage from commencing on either Surrey (55% of victories) or Middlesex (45% of victories); however, all crews (n=228) adopted a fast start strategy, with 81% of victories achieved by the crew leading the race at the first intra-race checkpoint at 24% of the total race distance. Crews leading the race at the final checkpoint (83% of total distance; 1143m) achieved victory on 94% of occasions. Discussion: Tactically gaining the early lead position with a fast start strategy seems particularly meaningful to success in the Boat Race, and is of greater importance to race outcome than factors such as starting station. An early lead is associated with taking the preferential racing line from the opposition, while also giving the trailing crew disturbed (wake) water which disrupts balance, aerodynamics and consequent pace of the boat (Garland, 2005). This is opposite to the finding that the final stages of the race are crucial to performance in other head-to-head competitive sports such as short-track speed skating, where the trailing rider has a clear aerodynamic advantage of drafting in the slipstream of the preceding competitors (Konings et al 2016). As previously found when comparing cycling with skating (Stoter et al in press), pacing strategies might differ related to the specific nature and characteristics of the different sports. PHYSIOLOGICAL AND BIOMECHANICAL CHARACTERISTICS OF SIMULATED OLYMPIC KAYAK DISTANCES WITH A KAYAK ERGOMETER.

PAIZIS, C.1,2,3, LEPERS, R.1,2, HILT, P.1,2, GARNIER, Y.1,2

1: UFR STAPS, Université de Bourgogne (Dijon, France), 2: CAPS UMR1093, INSERM, (Dijon, France), 3: CEP G. Cometti, (Dijon, France)

Introduction The physiological characteristics in Olympic flat water kayaking races are well known today (1) and the latest studies are turning more to the kinematic (2) and neuromuscular parameters (3) of the activity. However, no studies have assessed the specificity of these characteristics in relation to the duration of the effort. The purpose of this study was to investigate modifications that occur in the paddling technique using a paddling ergometer during different maximal effort trials (40 seconds and 4 minutes). Methods Nine experienced kayak paddlers who have competed at the French national level (female = 2, 18.6 ± 3.5 years) participated in this study. Athletes performed two maximum-effort trials of 40 seconds and 4 minutes, simulating an Olympic distance sprint (respectively 200m and 1000m). Physiological (Grip strength, blood lactate and muscle activity), biomechanical (power output, stroke rate) and kinematics data were recorded throughout the experiment. Results The average maximum power output values were higher for 40 seconds over 4 minutes ($p < 0.01$). Moreover maximum power output values were higher during the first 25% of the exercise compared to the 50%, 75%, 100% of the total exercise duration for both exercises ($p < 0.05$). Muscular EMG activities were more important during the 40 sec exercises compared to the 4 min. Moreover the left triceps showed more activity changes over the two exercises. In addition the latissimus dorsi (during the 40s) and the right biceps (over 4 min) also show EMG activity changes. A grip strength loss (8.5% ± 4.67) was observed only after the 40 sec exercise for the right forearm. Post exercise blood lactate levels were significantly higher ($p < 0.01$) for both types of maximal effort trials Discussion Our results show that anaerobic qualities are a very important factor for middle distance races such as a 1000 m in kayak. Muscle fatigue associated with the reduction of the maximum grip strength of the right hand after an exercise of 40 seconds could result from the different roles of the hands on the paddle. The orientation of the blades in water is ensured only with the right hand which requires continuous muscle contraction throughout the paddling while the left hand is contracted only during the left traction phases. Further work would be needed to confirm this hypothesis by comparing other kayakers using their left hand in the orientation of the blades in water. References 1. Bishop D. (2000). FOUR WEEKS OF INTENSIFIED TRAINING DECREASES RESTING METABOLIC RATE IN ELITE ROWERS.

WOODS, A.1,2, GARVICKAN-LEWIS, L.1,2,3, LUNDY, B.2, RICE, A.2, THOMPSON, K.1

Introduction: Elite rowers must complete a high volume of training across a number of exercise modalities to build aerobic endurance, anaerobic power, strength and technical ability. Periods of heavy training may influence energy expenditure and subsequently, resting metabolic rate (RMR). Appropriate periodization of training is important to ensure consistent preparation and adaptation to the work prescribed, and to minimize illness and injury risk. Methods: Seventeen national-level rowers undertook a four-week period of intensified training. A block periodization approach was employed, emphasizing endurance capacity. RMR, body composition (DXA) and rowing performance were assessed PRE and POST the four-week period. Wellness was evaluated weekly using the Multicomponent Training Distress Scale (MTDS). Key on-water and ergometer sessions were monitored for physiological parameters. Results: Significant decreases were observed in: (mean ± SD of difference, p-value): absolute RMR (-466 ± 488 kJ.day-1, $p = 0.01$) and relative RMR (-1.91 ± 1.95

cal.kg.FFM-1, $p = 0.01$) in the ten athletes who completed the training block. Significant reductions in body mass (-1.64 ± 1.28 kg, $p = 0.003$) and fat mass (-2.20 ± 1.22 kg, $p = 0.0001$) were also observed, while energy intake was unchanged. Rowing performance did not improve. Fatigue and total mood disturbance were significantly increased across the training period (Tests of Within-Subjects Effects: F(5, 45) = 5.413, $p = 0.001$; F(5, 45) = 3.180, $p = 0.02$), but post-hoc analysis did not determine the time point of change. Discussion: Four weeks of heavy training decreased RMR and body composition in elite rowers, likely due to an imbalance between training load and energy intake. Future training cycles of this nature should ensure energy needs are met to enhance physiological adaptation and performance.

PREDICTION OF SIMULATED 1000 M KAYAK ERGOMETER PERFORMANCE IN YOUNG ATHLETES.

RAMA, L., COELHO, A., CARRIÓN-BALBUENA, M.E., ALVES, F.

Faculty of Sport Sciences and Physical Education of Coimbra

Introduction The competitive distance of 1000m-kayak effort is characterized by a large requirement of aerobic cardio-circulatory and respiratory system, and at the same time, a great ability to produce work through anaerobic lactic metabolic pathway. The performance of young athletes is also modulated by morphological and maturation status. This study aimed to evaluate the predictive value of cardiorespiratory fitness, anthropometric, maturation and biomechanical indicators to the performance in of 1000 meters in kayak ergometer in young athletes. Methods 12 young kayak athletes of Portuguese national level (16.0 ± 1.1 years old; 63.8 ± 7.2 kg body mass; 174.9 ± 7.2 cm; with $100.1 \pm 5.7\%$ of mature height predicted; mean weekly training is 10.5 ± 2.4 hours, were submitted to two protocols in kayak ergometer (Dansprint,UK) with 48 hours apart. In the first visit to the laboratory, they accomplished a specific warm-up to familiarize with the ergometer (15'). After resting (10') they underwent an incremental protocol starting 8 km.h⁻¹ with increments of 1 km/h each 2 minutes, until exhaustion. In the second visit to the laboratory at the same time of the day, they accomplished the same warm-up and rest interval and then they underwent a simulated maximal 1000m assuming the same approach as they use in competition. Results In the incremental protocol a VO₂ max of 3.4 ± 0.6 (L.min⁻¹), a mechanical power of 138.5 ± 24.5 watts (MAP) at a speed of 13 ± 0.5 km/h (MAS) were reached. The first ventilatory threshold was held at $57.4 \pm 8.8\%$ and the respiratory compensation point at $79.2 \pm 7.1\%$ of VO₂max. At the 1000m simulating the race 292.25 ± 15 seconds was spent, maintaining a mean speed of $97 \pm 2.8\%$ of MAS and $90 \pm 6.5\%$ and 95.7 ± 16.6 of the VO₂max and PAM respectively. Discussion Important correlations were found between the performance in the 1000m and chronologically age, VO₂max MAP, MAS, stroke frequency at VO₂max, velocity at first ventilatory threshold and compensation respiratory point, and HR at Lv1. The final lactate accumulation confirmed the important contribution of lactic anaerobic (12.4 ± 2.4 mmol.L⁻¹). The variation of results in 1000 meters in kayak ergometer was strongly associated to maximal aerobic power (MAP) and with stroke frequency at VO₂max. An estimated explanation regression model for performance (s) of 1000 meters in kayak ergometer was found to the performance on 1000m with the PAM and stroke frequency at VO₂max speed. Time 1000m (s) = $413.378 - 0.433$ (PAM) – 0.554 (SF at VO₂max); R² = 84.5%. The maximal aerobic power and the stroke frequency at this intensity seems to be an important strategy to monitor training adaptation, namely to predict performance in young kayakers. ACUTE EFFECTS OF CONCURRENT STRENGTH AND ENDURANCE TRAINING ON PHYSIOLOGICAL AND SPECIFIC PERFORMANCE PARAMETERS IN WELL-TRAINED KAYAKERS.

MATZKA, M.I., PATTERSON, S.I., WALDRON, M., KRAKOWSKI-ROOSEN, H.2

1: Saint Mary's University Twickenham (England) 2: Hamm-Lippstadt University of Applied Sciences (Germany)

Introduction The sport of Olympic sprint kayaking depends on both high aerobic and strength capabilities. Concurrent development of these components is a common training aim. However, concurrent training (CT) appears to have a negative impact on strength development, with no detrimental effects on endurance performance. García-Pallarés et al. (2010) proposed strategies to minimize these detrimental effects, one of which includes sequencing strength training before endurance workouts. Based on this recommendation, the aim of this study was to analyse whether hypertrophy strength training (HST) has negative effects on physiological performance parameters on a subsequent aerobic endurance bout in elite kayakers. Methods Eleven well-trained youth kayakers had to perform two different training sequences in a randomized crossover design. One consisted of a HST performed before an aerobic endurance training (AET) that lasted 40 minutes at a velocity equal to 55% of VO₂peak on an air-braked kayak ergometer with 20 minutes rest in-between. The second session included the AET without a preceding HST. Relative and absolute oxygen consumption, respiratory exchange ratio (RER), blood-lactate and stroke-rate data were collected every 10-minute interval during AET. Results Wilcoxon test demonstrated no significant differences between training sequences for relative and absolute oxygen consumption, blood-lactate and stroke-rate during each interval and the entire endurance bout ($P < 0.05$). RER differed between sequences in each of the four intervals with significantly ($P < 0.05$) lower RER values in the AET bout that was subsequent to the HST session (HST+AET: 10' = 0.85; 20' = 0.87; 30' = 0.86; 40' = 0.85 / AET only: 10' = 0.88; 20' = 0.9; 30' = 0.89; 40' = 0.88). Discussion Sequencing HST prior to AET may be a possible strategy to optimize concurrent training of strength and endurance. Especially, in the general preparation phase of sprint kayakers, where muscle growth and aerobic endurance capacity are major training aims, this sequencing may enable the athlete to produce favourable strength gains compared to an opposite sequencing. Lower RER after HST may even show a positive side effect of this order. Because of depleted glycogen storages consumption of fatty acids seems to be augmented. Future research should focus on long-term adaptations to this approach to examine this order effect on performance. ROWERS' ON-WATER POWER OUTPUT IS COMMONLY UNDERESTIMATED

LINTMEIJER, L.L., HOFMIJSTER, M.J., BEEK, P.J., SCHULTE FISCHEDICK, G.A., ZIJLSTRA, P.J., SOEST, A.J.

Vrije Universiteit Amsterdam

Introduction In rowing, mechanical power output is a key parameter for biophysical analyses and monitoring of performance and should therefore be measured accurately [1,2]. It is common practice to estimate a rower's on-water power output as the time average of the dot product of the moment of the handle force relative to the oar pin ($M_{FH,r}$) and the oar angular velocity (ω_{ol}) [3,4]. In a theoretical analysis we have shown that this measure differs from the true power output (Prower) by an amount that equals the mean of the rower's mass (M_r) multiplied by the rower's center of mass acceleration ($Arcom$) and the velocity of the boat (V_b) (Presidual). The purpose of this study was to quantify Presidual for different rowers under different rowing conditions. Methods Nine rowers participated in an on-water exper-

iment consisting of 7 trials in a single scull. Stroke rate, technique and forces applied to the oar were varied between trials. Inertial sensors (Xsens MVN motion capture suit; 60Hz), a GPS (LOCOSYS, Taiwan; 10Hz) and a pre-calibrated conventional digital scale obtain Arcom, Vb and Mr. Forces applied to the oar and oar angle were determined using instrumented oarlocks (Peach Innovations, UK; 100Hz). The average ratio of Presidual to Prower per trial was calculated as a measure of the difference between true power output and power output estimated while using the common proxy. Results On average, the ratio of Presidual to true power output was 0.123 with only small variations between rowers and rowing conditions ($SD = 0.011$). A multilevel analysis revealed an effect of stroke rate: an increase in stroke rate from 18 to 32 strokes per minute resulted in an increase of the ratio of Presidual to true power output from 0.120 to 0.133 ($p < .001$). Discussion The results of this study indicate that a rower's mechanical power output is underestimated by 12.3% on average when calculated according to the common proxy. In order to accurately analyze and monitor rowing performance, a correction of the determination of rowers' on-water power output is, therefore, required. References [1] Hofmijster, M. J. (2010). OP-PM48 Fatigue

ARE REACTION TIME AND ACCURACY INFLUENCED BY MENTAL OR PHYSICAL EFFORT?

ROELANDS, B.1,2, VAN CUTSEM, J.1,3, MARCORA, S.3, MEEUSEN, R.1,4

1 Vrije Universiteit Brussel, BELGIUM 2 Fund for Scientific Research Flanders, BELGIUM 3 University of Kent at Medway, UK 4 James Cook University, AUSTRALIA

Purpose: The present study was designed to examine the individual and combined effects of a mentally fatiguing task and subsequent exercise, both performed in 30°C, on accuracy and reaction time during a short cognitive task (Flanker test). Methods: Ten endurance-trained male athletes (Age: 22±3y; Wmax: 332±41W) completed two experimental trials in a single blind, randomized, cross-over design in 30°C (30% RH). The trial started with subjects completing a 5min Flanker task (FL1). Next, either 45min of Stroop (mentally fatiguing task) were performed or a documentary (control) was watched. Upon completion the second Flanker task (FL2) was performed. Then subjects cycled for 45min at a fixed pace equal to 60% Wmax, immediately followed by a self-paced time-trial in which they had to produce a fixed amount of energy (equal to cycling 15min at 80% Wmax) as fast as possible. To conclude subjects performed the third Flanker test (FL3). Reaction time and accuracy were measured during each 5min Flanker task and during the Stroop task. Thermal sensation, ratings of perceived exertion, the NASA-Task Load Index (NASA-TLX) and a mental fatigue-VAS-scale (M-VAS) were assessed throughout the entire trial. Results: The NASA-TLX scale showed that the Stroop task was more mentally demanding than the documentary ($p < 0.05$). This was supported by the M-VAS that indicated that subjective mental fatigue was significantly higher during and after the Stroop compared to the control condition ($p < 0.05$). During the Stroop task mean reaction time and accuracy did not significantly change. Accuracy during the Flanker task decreased over time in both conditions, but no effect of the intervention was observed. In the mental fatigue condition reaction time only improved significantly for FL2 vs FL3 (% performance change compared to FL1: FL2 97% and FL3 86.5%; $p = 0.001$), while in the placebo condition reaction time was improved at all time points (FL1 vs FL2; FL2 vs FL3; $p < 0.015$). Conclusion: Subjective measures (M-VAS & NASA-TLX) indicated that the mental task was more mentally demanding and that MF was successfully induced in the heat. MF induced a decrease in accuracy while reaction time did not significantly change. Subsequent exercise further decreased accuracy and improved reaction time. In contrast, after the documentary accuracy also decreased, but there was a significant improvement in reaction time. Exercise resulted in a further aggravation of accuracy and improvement of reaction time. We conclude that heat stress potentially overruled the effects of MF on cognitive parameters.

THE EFFECTS OF MENTAL FATIGUE ON LONG-TERM ENDURANCE PERFORMANCE

GATTONI, C.1, O'NEILL, B.V.2, MARCORA, S.1

1: University of Kent (Medway, UK); 2: Glaxo Smith Kline (London, UK)

INTRODUCTION Mental fatigue is a psychobiological state caused by prolonged and demanding cognitive activity (Boksem et al. 2008). It has been previously demonstrated that mental fatigue has negative effects on perception of effort and endurance performance during laboratory tests lasting between 4 and 25 minutes (Marcora et al. 2009; Pageaux et al. 2013; Brownsberger et al. 2013). However, the effects of mental fatigue on longer term endurance performance and on the field have never been tested. Therefore, the main aim of the current study was to investigate the effects of mental fatigue on perception of effort, heart rate, pacing and performance during a simulated half-marathon race in amateur runners. METHODS Sixteen amateur marathon runners (means ± SD: age 41.9 ± 9.1 yr, body mass 75.1 ± 7.8 kg, height 1.76 ± 0.06 m) were randomly allocated to either a group performing a 50-min mentally-fatiguing task before the half-marathon, or a control group (reading magazines for 50 min before the half-marathon). All subjects completed psychological questionnaires and fatigue visual analogue scales before and after experimental treatment, and after the half-marathon. Performance time, speed, heart rate and rating of perceived exertion (RPE) were measured during the simulated race. RESULTS Runners who performed the mentally-fatiguing task completed the half-marathon approximately five minutes slower ($6,664 \pm 860$ s) than the control group ($6,358 \pm 634$ s) (Cohen's $d = 0.41$; $p = 0.432$). Practically, the true effect size at the population level is possibly harmful (65.6% probability), unlikely trivial (22.1% probability) and unlikely beneficial (12.3% probability). DISCUSSION In conclusion, because of low statistical power, the data collected so far do not provide reliable evidence that mental fatigue reduces long-term endurance performance. However, magnitude-based inference suggests that mental fatigue is possibly harmful to half-marathon performance in amateur runners. Additional data will be collected to draw a firmer conclusion on the null hypothesis and provide more precise estimates of the effects of mental fatigue on long-term endurance performance. MENTAL FATIGUE DOES NOT IMPAIR ALL-OUT SPRINT IN ELITE TRACK CYCLISTS BUT IT ALTERS PERCEPTUAL RESPONSES DURING CONTINUOUS SUBMAXIMAL EXERCISE

STAIANO, W.1, FLYGER, N.2, MENASPA, P.3, MARTIN, D.2, MARCORA, S.5

1: Team Danmark (Copenhagen, Denmark), 2: AIS (Adelaide, Australia), 3: ECU (Perth, Australia), 4: University of Kent (Chatham, UK)

INTRODUCTION Mental fatigue (MF) has a detrimental effect on endurance performance by altering perceptual responses of effort despite no changes in physiological parameters (Marcora et al., 2009). Moreover, recent studies have proven that MF does not alter anaerobic capacity in a 3 min all out cycling exercise (Martin et al., 2014). The present study had two aims. Firstly, to assess the impact of a cognitive demanding task (Stroop) on anaerobic capacity of elite cyclists during an all-out cycling sprint test (AOS). The second objective was to elucidate the negative effect of MF during a submaximal cycling step test. **METHODS** 10 internationally competitive track cyclists completed 30 min of an incongruent Stroop colour-word test, or the equivalent time in a control condition in a cross-over study. Participants completed a submaximal 3-step cycling test (5 min for each step) at a constant power increasing at each step and afterwards they completed a 15 sec AOS. Physiological and perceptual measures of heart rate (HR), cadence (RPM), lactate and rating of perceived exertion (RPE) were collected during the submaximal test and the AOS. Psychological questionnaires were used to assess fatigue and mental demand of the Stroop. **RESULTS** The Stroop test was rated as more fatiguing ($p<0.001$) and mentally demanding ($p<0.001$) than the control task. There was no significant difference between conditions during the AOS for peak power ($p=0.67$), mean power ($p=0.69$) and fatigue index ($p=0.96$). During the submaximal step test, there were no significant differences between condition for HR ($p=0.23$), RPM ($p=0.88$) and lactate ($p=0.13$). However, a significant interaction time (step) x condition has been reported for RPE ($p<0.05$). **DISCUSSION** No difference in performance between Stroop and control condition suggests that cognitive processes do not regulate maximal anaerobic exercise in AOS for elite cyclists. Anaerobic capacity during AOS seems to be mainly regulated by peripheral parameters. Whereas, 30 min of mentally demanding test negatively impact submaximal endurance exercise during the step test. In line with previous studies, it appears that RPE, is the main variable affected by MF. This is the first study assessing the influence of MF in AOS performance and submaximal exercise in an elite group of track cyclists. **REFERENCES** Marcora SM, Staiano W, Manning V. EFFECTS OF VOLUNTARY AND EVOKED LOCOMOTOR MUSCLE FATIGUE ON RESPIRATORY RESPONSES TO A HIGH INTENSITY INTERVAL TRAINING SESSION

PAGEAUX, B., ASSADI, H., THEUREL, J., LEPERS, R.

Université de Bourgogne

Introduction High intensity interval training (HIIT) is a time-efficient training method to improve aerobic capacities. In the present study, we tested the impact of pre-fatiguing the locomotor muscles on respiratory responses to a HIIT session. As muscle fatigue can be induced by evoked (electromyostimulation, EMS) or voluntary (VOL) contractions, we also tested whether EMS fatigue and VOL fatigue could differently impact respiratory responses to a HIIT session. As EMS contractions involve a different muscle fibres recruitment pattern and higher respiratory responses than VOL contraction (Maffuletti 2010), we hypothesised than EMS fatigue would have the greater impact on respiratory responses to a HIIT session. **Methods** Fifteen subjects completed a control session, an EMS fatigue session and a VOL fatigue session. Each session consisted in the completion of a running intermittent time to exhaustion test (30-30, 30s run interspaced by 30s rest) performed at the speed eliciting $\text{VO}_{2\text{max}}$. Subjects were pre-fatigued with EMS or VOL contractions. The EMS fatigue protocol consisted in 30 bilateral intermittent isometric evoked contractions of the knee extensors. In the VOL session, subjects performed as many bilateral intermittent maximal isometric voluntary contractions (MVC) of the knee extensors as necessary to induce the same decrease in force experienced following the EMS fatigue protocol. Respiratory parameters were collected during the 30-30. **Results** Time to exhaustion decreased in both fatigue conditions with a greater decrease following the EMS fatigue compared to the VOL fatigue. This decrease in time to exhaustion was associated with a decrease in absolute time spent above 90% $\text{VO}_{2\text{max}}$ (t90). When normalised by the performance of each respective session, the relative t90 decreased only during the VOL fatigue session. Both fatigue protocols induced an increase in respiratory responses to the exercise. Interestingly, higher VO_2 , respiratory frequency and ventilation was observed during the EMS fatigue session compared to the control and VOL fatigue session. **Discussion** Both pre fatigue protocols induced an increase in respiratory responses to the exercise, leading to a decrease in time to exhaustion. Interestingly, due to the greater respiratory responses, only the absolute t90 and not the relative t90 was altered by the EMS fatigue. Future research should aim to investigate whether integrating pre-fatigue of the locomotor muscles induced by EMS before completion of a HIIT session could have beneficial long term effects for athletes and patients. **References** Maffuletti NA (2010) Physiological and methodological considerations for the use of neuromuscular electrical stimulation. *Eur J Appl Physiol* 110 (2):223-234.

FATIGUE DOES NOT ALTER FLUCTUATIONS OF STRIDE INTERVAL IN GAIT

MICKEL, C.1, KOLLECKER, G.2, HERMANN, U.1, HARTMANN, H.1, SANDER, A.3, KEINER, M.4, WIRTH, K.5

1: Goethe-University (Frankfurt, Germany), 2: TU Darmstadt (Germany), 3: Bobsleigh and Luge Fed. Germany, 4: Swimming Fed. of Lower Saxony, 5: University of Applied Sciences Wiener Neustadt

Introduction Plenty of studies have reported long-range correlations in stride interval fluctuations under different conditions for healthy subjects, while it has been shown that this structure breaks down with aging and several pathologies [1-8]. A decrease in strength has been proposed to explain the reduction in stability [6]. Therefore, we induced fatigue to check if this alters the structure in the fluctuations of healthy subjects. **Methods** 30 healthy individuals (20 f, 10 m) (h: $165\text{cm} \pm 9.3$, w: $65.5\text{kg} \pm 1.4$, age: $25.3\text{ years} \pm 1.4$) that had no acute or chronic lesions or diseases of the lower extremities wore pressure-sensitive insoles (T&T, Schönefeld, Germany) when walking on a treadmill (Woodway, Weil a. R., Germany) in their preferred walking speed (=PWS) [determined as in 9]. Measurements (pre and post fatigue) were performed with a sampling frequency of 300 Hz for consecutive 237 s. To induce fatigue, participants were asked to run on the treadmill starting with 8 km/h. Treadmill speed was increased by 1 km/h every two minutes until subjects reported a value of 13 on Borg-Scale. Subsequently, they had to continue in that particular speed until a value of 17 was reached. Immediately after, the post-fatigue measurement was performed at the earlier determined PWS [10-11]. Results Detrended fluctuation analysis (=DFA) was performed.

DFA pre resulted in $\alpha=0.67$ and post in $\alpha=0.64$, while both varied significantly from their surrogates. Discussion The results show each condition to resemble persistent long-range correlations [12]. Fatigue did not alter the structure of the fluctuations in this study. References [1]. GRADED DEEP WATER RUNNING IN WARM WATER ACCELERATES FATIGUE AND PEAK HEART RATE RESPONSES

KITTA, I., SOULTANAKIS, H.

UNIVERSITY OF ATHENS

Introduction Deep water running (DWR), is an alternative mode of enhancing cardiorespiratory fitness in healthy athletes, and is used extensively in rehabilitation. Heart rate and perceived exertion in the water change significantly in DWR, compared to land running (Svendenhag and Seger, 1992), but the effect of temperature still needs to be determined. This study was undertaken, to observe the effect of warm water temperature on heart rate (HR) responses, perceived exertion (RPE), and time to exhaustion during graded DWR. Methods Nine active men (22.2±3.1 years), wearing a flotation belt, performed two incremental deep water tests to exhaustion (at 24oC and 31oC), by increasing the stride frequency and/or the load in 3-min stages, in a cross-over design. Heart rate (HR), and ratings of perceived exertion (RPE), were continuously monitored throughout the stages. Blood pressure and lactate, were also measured before and after the tests. Data were analysed via a two-way repeated measures ANOVA test and paired t-tests, with post-hoc Bonferroni test when needed, at a p<0.05 level of significance. Results The length of time to exhaustion was significantly lower in warm versus cool water reaching stage 5.99±0.58 in warm, versus 7.13±0.72 in cool water (p= 0.007). Peak HR occurred earlier in warm versus cool water, and was manifested at stage 5.56±0.53 in warm water versus 6.78±0.68, in cool water (p= 0.005). Peak HRs were not different between the two conditions (175±4.5 vs. 174±3.4 bpm) in warm and cool water respectively (p = 0.88). The RPE data showed no significant differences, and there was no indication that warm water was perceived to be more difficult than cold at any stage. Discussion Studies performed on DWR demonstrate suppressed maximal and sub-maximal cardiorespiratory responses when compared to land running (Dowzer et al., 1999). The effect of cool and warm temperature hasn't yet been seriously addressed in DWR target heart rate estimation (Barbosa et al., 2009; Frangolias and Rhodes, 1996). The accelerated manifestation of peak HRs in response to graded DWR, with no changes in RPE, coupled with the natural drop in heart rate (of up to 17 beats/min), when immersed in water, appear to underestimate exercise intensity during DWR, in warm water of 31oC. GOLF SWING ANALYSIS - THE CENTER OF MASS AS A VALUABLE DIAGNOSTIC PARAMETER

KREUZPOINTNER, F., EIBL, F., TUSKER, F.

Technische Universität München

Introduction There are several swinging techniques in golf which result in different movement sequences. Weight transfer can therefore be a very useful diagnostic parameter to measure differences between skill levels. Top coaches on the PGA Tour stated that the weight transfer is the most important factor within the golf swing [1]. This indicate a relevance for figuring out parameters which can be used by practitioners. So the objective of this study was to distinguish between experts and intermediate players by the variability of their golf swing. Methods The sequence of interest (SOI) of the golf swing was from take away to impact. Eight experts (n=4 professionals and n=4 with a HCP of -1.25 ± 1.9) and five intermediate players (HCP = -28.3 ± 15.0) were included. Outcome parameters were the traveled distance of the COP, the period of the SOI and the area of variation of the COP (AOV) around the address position during the SOI. The AOV is calculated as an ellipse. The axes of the ellipse are built by the standard deviation of the COP around the medio lateral axis and the anterior posterior axis during the movement. The analysis took place on a pressure distribution platform (4096 sensors with 300Hz; RSscan International®). All subjects performed a neutral swing on the platform with a pitching wedge. For group comparison the Mann-Whiney U test was used. For correlation analysis the Spearman-Rho correlation coefficient was calculated. The level for statistical significance was set to $p < 0.05$. Results The period of the SOI was statistical significant shorter in the expert group (848.6 ± 208.6 ms) than in the intermediate group (1166.0 ± 176.4 ms) ($p < .05$). The traveled path of the COP (expert group: 211.2 ± 49.6 mm; intermediate group: 227.4 ± 44.0 mm ($p = .56$)) and the AOV (expert group: 11.9 ± 9.5 cm 2 ; intermediate group: 14.5 ± 6.4 cm 2 ($p = .60$)) did not show any statistical significant differences. Correlation analysis showed a statistical significant relationship between the HCP and the period of SOI ($r = 0.64$, $p < .05$). There is no correlation between the AOV and the HCP nor for the traveled distance of the COP and the HCP. Discussion Wrobel et al. 2012 [2] found out in the contrary that stated that good players have a decreased COP displacement in comparison to novice players. The reason why we found no difference was because our subjects were more skillful. The higher the quality of the players is the more complex it is to find differences between the skill level. The data show a shorter period of SOI which claims that this might be a relevant performance parameter for better players. References 1. VALIDATION OF TWO BASED ACCELEROMETRY DEVICES FOR ESTIMATING ENERGY EXPENDITURE OF WALKING IN DIABETIC PATIENTS

CARON, N., PEYROT, P., CADERBY, T., VERKINDT, C., DALLEAU, G.

Université de la Réunion

Introduction Nowadays, physical activity (PA) is recognised as non-therapeutic treatment for the prevention of diabetes mellitus (DM) and its complications. Basic recommendations are to practice a daily PA such as walking to improve or maintain health (Sigal et al, 2004). To optimise the effect of exercise, patients need to have an accurate estimation of PA dose by using daily energy expenditure or activity energy expenditure (AEE). Currently, it exists several commercially actimeters to estimate daily energy expenditure or AEE, such as the RT6. To the best of our knowledge, the validity and reliability of these sensors have never been evaluated in diabetic people. The aim of this study was to compare two methods for assessing the AEE in diabetic people with indirect calorimetry measurement. Methods Thirteen diabetic patients (3 males, 10 females; age = 56.9 ± 9.6 years, BMI = 27.9 ± 2.4) participated at the study. The subjects were asked to walk on a treadmill at various speeds (0.5, 0.75, 1, 1.25, and 1.5 m.s⁻¹) in a randomized order with a 5 min rest period between two consecutive trials. One inertial sensor (MTW, Xsens, Culver City, USA) was placed at the hip and recorded the accelerations along three-axis at a sampling frequency of 75Hz. AEE was determined with a formulae proposed by Bouten et al. (1994) but with a customised gravitational component processing (method 1). The RT6 was placed at the contralateral hip (method 2). Results Method 1 presented no significant difference with the reference method for each speed of walking. Method 2 underestimated net EE at the lower speed of walking (0.5 m/s) ($p<0.05$). Inversely, it overestimated net EE during walking at fast speed (1.5 m/s) ($p>0.001$). When all trials were pooled, the two sensors gave accurate estimation of AEE with standard error of measurement of 0.85 and 0.63 kcal/min for the method 1 and method 2, respectively. Discussion Although, method 2 showed a good overall standard error of measurement, method 1 presented a better agreement for each walking speed. Thus, further studies could be conducted to test validity and usefulness of this methods to estimate AEE in diabetic everyday life under free-living conditions. ACCURACY OF ANKLE AND KNEE ANGLE MEASUREMENTS WITH THIN FLEX SENSORS

SCHINDELWIG, K.N., MARTERER, D., MORAWETZ, S., KAPFERER, R., CSAPO, W.

University Innsbruck

Introduction The accurate determination of joint angles is an important tool for biomechanical research. Electronical goniometers are cheap and easy to use but, in some situations, their application is complicated. For instance, in alpine skiing, the thickness of goniometers precludes mounting within ski boots, impeding the reliable acquisition of ankle joint angles. Externally fixed goniometers are also prone to damage, e.g. through impacts with external objects such as flex poles. Flex sensors feature a thickness of 0.4 mm only and may, therefore, represent an alternative when the use of conventional goniometers is not feasible. The aim of this study was to determine the accuracy of knee and ankle joint angles as measured by flex sensors during deep squats. Methods Three subjects (age 21.3 ± 1.6 yrs, height $1.72 \pm .09$ m, mass 68.1 ± 3.1 kg) performed 6x15 repetitions of deep squats. After completion of 2 series, movement speed was gradually increased from 15-45 repetitions per minute. Movement speed was controlled through the use of an electronic metronome. The 11.4 cm long flex sensors (Spectra Symbol, SEN-08606, Salt Lake City, UT) were attached on both legs, across (i) the tibiotalar joint (from the navicular bone to the distal end of the tibia) and (ii) the knee joint (along the popliteal fossa). The attachment sites were chosen to allow longitudinal motion of the sensors. Data were sampled at 1500 Hz and transmitted wirelessly to a recording system (Telemo 2400T G2, Noraxon, USA). Reference measures were acquired with an active three camera motion capturing system sampling at 100 Hz (AS 200, LUKOtronic, Austria). Optical data of the right and left leg were separately recorded and manually synchronized with the flex sensor recordings. The maximum and standard deviation (SD) of differences between the data obtained with both systems were calculated as measure of accuracy of the flex sensors. Results Across the six deep squat series, the mean ranges of movement in ankle and knee joint were 39° and 94°, respectively. For the ankle and knee joint, the mean of the maximum differences between the measures obtained by flex sensors and motion analysis were 9.1° (23.6%) and 13.1° (14.0%), respectively. The mean of the SDs of differences were 2.9° (7.5%) and 4.0° (4.3%). Measurement accuracy was independent of movement speed. Discussion The flex sensors yielded a satisfactory accuracy for measurements of ankle and knee angles. Therefore, they may be used as low-cost system for angle measurements that may be applied where usage of electronic goniometers is not feasible due to space constraints or risk of damage. However, it should be noted that conventional goniometers feature superior accuracy and should be used when high measurement precision is required. Contact kurt.schindelwig@uibka.ac.at

IMU-BASED FIELD DIAGNOSIS FOR JUMPING AND SPRINTING IN TRACK AND FIELD EVENTS

SCHMIDT, M.1, RHEINLÄNDER, C.2, WILLE, S.2, JAITNER, T.1

1: TU Dortmund University, 2: TU Kaiserslautern University

Introduction In highly dynamical sports, such as track and field, athletes must be able to generate high forces within a very short time. Temporal parameters like stance and flight durations during jumping and sprinting represent main indicators of performance (Slawinski et al., 2010). Objective feedback of these parameters is crucial to ensure a high quality of training as sprinting and jumping performance cannot be assessed precisely enough by pure observation or over longer distances. In this study, we present an IMU-based wearable measurement system for field-based performance analysis and online monitoring for a group of athletes, that allows an accurate in-field detection of temporal parameters in track and field events. Methods For the group monitoring of stance durations (TS) in field-based conditions a wearable measurement system including inertial sensors (IMU), a microcontroller unit, a detection algorithm and an Android™ application was developed. Evaluation studies included 18 participants for Dropjumps (DJ) as well as 12 participants for sprints (SP). Reference measures were a force plate, a contact mat and the Optojump™ system (OJ), respectively. For statistical analyses, absolute differences and Bland-Altman-Plots (BAP) of TS between IMU and reference measurements were calculated. Results Throughout the DJ protocol participants executed an overall of 204 jumps including 194 correct detections (95%). Mean absolute difference for TS was 4.7 ± 3.5 ms and BAP 95% limits of agreement (LoA) ranges from 13 to -7.3ms. Out of 380 contacts during sprinting, 364 were detected correctly (96%). TS showed a mean absolute difference of 4.3 ± 3.2 ms between OJ and IMU. BAP derive LoA in the range from 6.8 to -11.8 ms. Discussion The IMU device provides reliable and accurate measurements of stance and flight durations and can be considered as a suitable tool for jump and sprint diagnostics. The accuracy of the system is higher compared to previous studies (e.g. Bergamini et. al,

2012). Overall, the system enables providing objective real-time feedback for a group of athletes during a training session or competition and can overcome restrictions in measurement range as it offers precise results over an entire competition distance (e.g. 400m). Therefore it supports expanding opportunities to analyze human performance in field-based settings that may offer a considerable contribution to enhance the quality of training and lead to a deeper understanding of performance in track and field events. THE VALIDITY AND INTER-DEVICE VARIABILITY OF THE APPLE WATCH FOR MEASURING MAXIMAL HEART RATE

ABT, G.1, BRAY, J.1, BENSON, A.C.2

1: The University of Hull (Hull, UK) 2: RMIT University (Melbourne, Australia)

Introduction Maximal heart rate (HRmax) is a fundamental measure used in exercise prescription (Achten and Jeukendrup, 2003), yet its measurement during free-living conditions using a chest strap telemonitoring device is not always feasible. The Apple Watch can measure heart rate using an optical sensor. However, the validity and inter-device variability of the Apple Watch heart rate sensor are unknown. Methods Fifteen participants aged 32(10) y completed an incremental maximal oxygen uptake test (0.5 km.h⁻¹ every 30 s) on a motorised treadmill while wearing a first generation Apple Watch (OS 2.0.1) on each wrist. Heart rate data were recorded every 5 s on each watch using the 'Workout' app. Heart rates and sampling times were retrieved via a bespoke iPhone app written in Xcode 7.2.1 using the Apple HealthKit framework (Apple, Inc). Criterion HRmax was measured using a Polar chest strap interfaced to a Cortex Metalyzer 3B metabolic cart. The highest 30 s mean heart rate was used as the criterion value. All data were log-transformed. Apple Watch validity ($N = 13$) is reported as a Pearson correlation (r), standardised mean bias, and standardised typical error. Inter-device variability is reported as the typical error (%CV) and intra-class correlation (ICC). Uncertainty is reported as 90% confidence intervals. All data were analysed using custom-designed Microsoft Excel spreadsheets (Hopkins, 2015). Results Mean (SD) HRmax were 183(12) and 182(12) beats.min⁻¹ for the left and right watches, respectively (mean difference -1 [90%CI: -4 to 2]). Mean (SD) HRmax as measured by the Polar chest strap was 180(12) beats.min⁻¹. There were very large to nearly perfect correlations between the watches and criterion (left: $r = 0.87$ [90%CI: 0.67 to 0.95]; right: $r = 0.98$ [90%CI: 0.94 to 0.99]). Standardised mean bias for the left and right watches compared to the criterion were 0.14 (90%CI: -0.12 to 0.39; trivial) and 0.04 (90%CI: -0.07 to 0.15; trivial). Standardised typical error for the left and right watches compared to the criterion were 0.51 (90%CI: 0.38 to 0.80; small) and 0.22 (90%CI: 0.16 to 0.34; small). Inter-device typical error was 2.9% (90%CI: 2.2 to 4.2), ICC = 0.84 (90%CI: 0.65 to 0.93). Discussion The Apple Watch displays high criterion validity for measuring HRmax compared to the widely accepted Polar chest heart rate monitor. The mean bias and typical errors are trivial and small, respectively. Inter-device variability in HRmax measured by the Apple watch is low, when worn simultaneously on different arms. COMBINED DIFFUSION TENSOR AND MAGNETIC RESONANCE IMAGING FOR IN VIVO ASSESSMENT OF HUMAN MUSCLE FUNCTION

KARAKUZU, A.1, PAMUK, U.1, ACAR, B.2, OZTURK, C.1, YUCESOY, C.A.1

Bogazici University

Introduction Muscle fiber direction strain provides invaluable information for characterizing muscle function. Methods that allow its assessment in human muscles *in vivo* are scarce. Combining magnetic resonance (MR) imaging based deformation analyses (Yaman et al., 2013) with diffusion tensor (DT) imaging based tractography, we aimed at assessing muscle fiber direction local tissue deformations within the human medial gastrocnemius (GM) muscle caused by (A) passive knee extension and (B) submaximal isometric contraction. Methods Healthy female subjects ($n=5$) were positioned prone within the MR scanner using a custom-made test apparatus with the ankle angle fixed at 90°. Sets of 3D high resolution MR, and DT images were acquired in three subsequent conditions: (1) in relaxed state, when the knee was brought to flexion (140.8±3.0°) and (2) after it was extended (177.0±1.0°). (3) During sustained isometric plantarflexion at 15% of maximum voluntary contraction. Tractography and Demons nonrigid registration algorithm were utilized to calculate local deformations along GM muscle fascicles comparing (2) to (1), and (3) to (2). Therefore, effects of imposed passive knee extension and submaximal isometric contraction were assessed, respectively. For each experimental condition separately, the reference image sets were also transformed by a synthetic rigid body motion to quantify algorithm artifacts. Results Mean artifacts were significantly smaller than mean fiber direction strains (for passive knee extension, lengthening: 0.2±0.1% vs. 8.7±8.5%, shortening: 3.3±0.9% vs. 7.5±4.6%; for submaximal isometric contraction, lengthening: 1.9±1.0% vs. 16.0±9.3%, shortening: 1.8±0.9% vs. 4.0±3.7%). Passive knee extension caused shortening and lengthening (up to 23.3% and 116.7%, respectively) to occur simultaneously along individual fascicles despite imposed GM lengthening. Similarly, submaximal isometric contraction, caused shortening and lengthening (up to 108.9% and 23.6% respectively) to occur simultaneously along individual GM fascicles. Mean fiber direction strains of different tracts also show heterogeneity. Discussion MR and DT imaging analyses combined presents a powerful tool for quantifying deformation along human muscle fibers *in vivo*. Non-uniformity of fiber strain indicates sarcomere length heterogeneity and can be explained by epimuscular myofascial force transmission (Yucesoy, 2010). Sarcomere is the key functional element. Therefore, the methodology developed is relevant for assessment of normal and pathological muscle function, mechanisms of treatment techniques and ergonomics. TUBITAK grant (111E084) is acknowledged. OP-PM20 Soccer Training

RESISTANCE TRAINING STATUS AND EFFECTIVENESS OF LOW FREQUENCY RESISTANCE TRAINING ON UPPER-BODY STRENGTH AND POWER IN SOCCER PLAYERS.

HERTZOG, M.1, RUMPF, M.C.1,2, HADER, K.1

ASPETAR

1: ASPETAR (Doha, Qatar), 2: AUT University (Auckland, New Zealand) Introduction Soccer is classified as a contact/collision sport with many player-to-player duels. Winning these duels, shielding the ball or fending off an opponent requires upper-body strength and power. Therefore, the purpose of the study was, a) to examine upper-body strength and power changes in elite soccer players with different resistance-training (RT) status, b) to investigate if the RT status influences performances throughout an entire competitive season. Methods Twenty-eight elite young male soccer players (age 18 ± 1 years, height 178 ± 5 cm, body mass 71 ± 7 kg) participated in this study and were divided into a trained (TG; n=14) and a novice (NG; n=14) group, according to their RT status (Rhea et al., 2003). Both groups performed the same upper-body RT once a week besides the soccer-specific team training over 30 weeks. Maximal strength was assessed via one repetition maximum (1RM) for bench press (BP) and bench row (BR) before (T1), after 10 weeks (T2) and the competitive season (T3). Maximal power (MP) was assessed in the BP exercise only. Results At T1, TG presented significant and moderately greater 1RM in BP (+9.9 ± 10.2%; effect size, ES=1.0) and MP (+14.0 ± 13.1%; ES=1.1) than NG. There was no between-groups difference in 1RM for BR. At T2 and T3, both groups showed significant improvements in the 1RM. The magnitude of changes was small (TG; +5.9 ± 2.6%; ES=0.3-0.4) and large (NG; +11.7 ± 3.2%; ES=0.9-1.3) at T2 and increased to moderate (TG; +13.4 ± 3.1%; ES=0.7-0.9) and very large (NG, +20.6 ± 3.8%; ES=1.8-2.1) at T3. There is no change in MP at T2 and moderate improvement at T3 (+13.0 ± 5.8%; ES=1.1) for NG. TG presented a significantly small decrement at T2 (-11.6 ± 3.9%; ES=0.4) and small improvement at T3 (+7.7 ± 4.9%; ES=0.3). At T2 and T3, there was no between-groups difference in 1RM while MP remained moderately greater for TG. Discussion The players with less RT experience presented a greater rate of improvement in maximal strength after 10 weeks only (Kraemer et al., 2004), notwithstanding a low RT frequency; while maximal power was not affected positively over the same time. One RT session per week is considered as an effective frequency for muscular strength and power maintenance (ACSM, 2009), however our results show that RT throughout a competitive season may elicit substantial improvement in upper-body maximal strength and power regardless of players' RT status. ISOKINETIC STRENGTH QUALITIES THAT DIFFERENTIATE RAPID DECELERATION PERFORMANCE IN ACADEMY MALE YOUTH SOCCER PLAYERS

HARPER, D.J.1, JORDAN, A.1, WILKIE, B.1, LIEFEITH, A.1, METCALFE, J.1, THOMAS, A.1, KIELY, J.2

1: York St John University (York, England); 2: University of Central Lancashire (Preston, England)

Introduction Decelerating (DEC) is just as frequent as accelerating in contemporary soccer match play (Russell et al., 2014). Recent evidence suggests that lower body eccentric strength directly improves the ability of a player to produce and tolerate braking forces (Spiteri et al., 2014). The aim of the present study was to identify if measures of isokinetic strength can differentiate performance of a rapid DEC maneuver. Methods Nineteen (n=19) academy youth soccer players (age: 16.7±1yrs; height: 175±8.4cm; body mass: 69.1±7.5kg; body fat: 9.5±3.9%) participated in the study. Tests included: isokinetic dynamometer (Cybex International Inc., New York, USA) strength profiling of quadricep (Q) and hamstring (H) peak concentric (con) and eccentric (ecc) torque (both dominant [kicking leg] and non-dominant legs) assessed at slow (60°/s) and fast (180°/s) angular velocities. Functional H:Q ratios representative of knee flexion (Hcon:Qecc) and extension (Hecc:Qcon) was also calculated; 30m linear sprint time (with 5m, 10m and 20m splits) was recorded using a single beam timing system (Witty, Microgate, Italy) and rapid DEC quantified using time to stop (TTS) and distance to stop (DTS) determined following a 20m maximal acceleration (within 5% threshold of best 20m linear sprint time) using video analysis (Dartfish, Fribourg, Switzerland) captured from a 50Hz video camera (Panasonic HDC-HS900, Japan). Results 10, 20 and 30m sprint times had moderate to large correlations with fast con peak Q and H torque. Slow velocity con peak H torque in dom leg had moderate to large correlations with 10, 20 and 30m sprint times. No significant correlations were found for peak con strength in either Q or H for DEC performance (TTS and DTS). Slow velocity ecc peak Q torque and time to peak torque was significantly correlated to DEC TTS. No significant correlations were found for fast ecc strength parameters in Q or H for either sprint or DEC performance. Sprint and DEC performance had no significant correlations. Discussion Players with superior sprint speed can produce high peak con forces in both Q and H at fast velocities. DEC seems to be a unique movement skill requiring specific ecc strength qualities. Interestingly, in this study slow velocity ecc strength of the Q seems to be critical for production of braking forces and reducing the time spent DEC. In conclusion this study highlights the need for careful consideration to developing specific strength qualities needed for DEC alongside those more commonly known for sprinting and accelerating. THE RELATIONSHIP BETWEEN PRE-SEASON WORKLOAD INDICATORS AND CHANGES IN THE YO-YO INTERMITTENT RECOVERY TEST IN PROFESSIONAL SOCCER

JASPERS, A., BRINK, M.S., FRENCKEN, W., HELSEN, W.F.

University of Leuven (KU Leuven)

Aim In pre-season, a main objective is to develop aerobic fitness to prepare for the competitive season. Workload monitoring can aid in maximizing training adaptations. However, it remains unclear which workload indicators best relate to changes in fitness in professional soccer [1]. Therefore, the aim was to examine the association between workload indicators and changes in the Yo-Yo intermittent recovery test. Methods During the first 2 weeks of pre-season, both external (total distance, distance covered in velocity zones (15-20 km/h, 20-25km/h and >25km/h) and PlayerLoadTM) and internal (sRPE multiplied by duration) training and match load were collected in 15 professional soccer players (mean age ± SD: 22.2 ± 3.6 years). A submaximal Yo-Yo intermittent recovery test level 1 (YYIRT1; a duration of 8

minutes and 58 seconds, up to 8 repetitions at 15 km/h) was performed at baseline and 2 weeks thereafter. Cumulative workloads over 2 weeks as well as in the week preceding the second sYYIRT1 were related to relative changes in average heart rate over the last 60 second (HRex) of sYYIRT1. Pearson correlations were used to assess relations. Results A significant lower average heart rate ($p < 0.01$) was observed during the second sYYIRT1 (167.9 ± 7.7 beats/min) compared to the first test (179.8 ± 8.2 beats/min). More distance covered in velocity zone 15–20 km/h in the week preceding the second sYYIRT1 was related to a negative percentage change in HRex ($r = -0.64$, $p < 0.05$). Other indicators were not significantly related to changes in HRex. Conclusion Distance covered in velocity zone 15–20 km/h in the week preceding the second sYYIRT1 is related to improvements in fitness during pre-season. The Yo-Yo test performance is positively related to distance covered above 15 km/h in professional matches [2]. A similar type of workload (15–20 km/h) in turn appears to result in a beneficial stimulus for the physical capacity in intermittent exercise. Careful planning of distance covered in the 15–20 km/h velocity zone should be considered to optimize training regimes during pre-season. References 1. CHANGES IN TRAINING LOAD, FITNESS, POWER AND BIOCHEMICAL CHARACTERISTICS THROUGHOUT PROFESSIONAL RUGBY UNION SEASON IN BACK PLAYERS.

DUBOIS, R., PAILLARD, T., CHAMARI, K., MAURELLI, O., PRIOUX, J.

Laboratoire Mouvement, Equilibre, Performance, Santé (MEPS) and Mouvement, sport et santé (M2S)

Introduction Elite rugby game induces acute fatigue (inflammatory, catabolic states and muscle damages) which requires between 2 and 5 days to return to baseline level (McLellan, 2010). Furthermore, the game frequency and the duration of the competitive period may result in chronic fatigue illustrated by biochemical disturbances as well as a predominance of catabolic process (Banfi et al., 2006). Consequently, it appears essential to monitor and manage training load (TL) throughout a professional rugby season in order to optimize physical performance and reduce injury risk. Therefore, the aims of this study were quantifying TL throughout a professional rugby season and observed, in parallel, changes in physical performance and biochemical characteristics. Methods Eight professional rugby union back players participated in this study. Weekly TL was assessed through 2 methods: S-RPE (Foster et al., 2001) and GPS technology (minimax S4, Catapult). Physical performances were evaluated by 5 YoYo recovery test level 2 (YYRT2) and 27 drop jump tests (DJ). Biochemical characteristics were assessed through three blood samplings were carried out in the first, the middle and the last part of the season. Results - Weekly TL (S-RPE) progressively decreased ($p < 0.001$), especially due to a decrease ($p < 0.001$) in training volume throughout the season. - External TL parameters (GPS) revealed a progressive reduction in total distance travelled ($p < 0.001$). However, no significant change was observed for the high-speed running (HSR) distances, but the average speed of HSR significantly increased ($p < 0.001$) over the season. - YYRT2 performances were not significantly changed during the season. - Negative significant correlations were found between training volume parameters and Δ DJ ($r = -0.49$, $p < 0.001$), whereas intensity parameters showed positive correlation ($r = 0.38$; $p < 0.01$). - The blood cell and reticulocyte concentrations significantly increased during the last part of the season ($p < 0.05$). The cortisol concentration was also significantly increased ($p < 0.05$). However, the testosterone/cortisol ratio was not significantly changed. Discussion The TL decrease does not seem to affect fitness level, conversely, it may permit to optimize power production. Furthermore, this decrease may permit to avoid overreaching states (related to the biochemical state) likely to be induced by the accumulation of matches and training stress. It may also contribute to the final victory of the team studied. Références Banfi G, Fabbri MD, Mauri C, Corsi MM, Melegati G. (2006). Clin Lab Haem 28(3):183–8. Foster C, Florhaug, Franklin. A COMPARISON OF SLEEP CHARACTERISTICS DURING WEEKLY IN-SEASON COMPETITION VS PRE-SEASON TRAINING IN AUSTRALIAN RULES FOOTBALLERS

BARTLETT, J.D., PITCHFORD, P., THORNTON, H., FULLAGAR, H.H.K.

Victoria University

Introduction: Team-sport athletes experience impaired sleep on the night of matches (Fullagar et al., 2016) and during periods of high training stress (Killer et al., 2015). However, the period observed is either isolated to training or competition and is short in duration. Thus, the aim of this study was to compare sleep habits of Australian Rules Footballers (ARF) across the season incorporating pre-season training and weekly competition. Methods: Eight professional ARF had sleep assessed during in-season (IS) competition (11 ± 4 4-day periods) and pre-season (PS) training (8-days). Time in bed (TIB), total sleep time (TST), sleep efficiency (SE; TIB/TST), sleep onset latency (SOL) and wake after sleep onset (WASO) was measured by wristwatch actigraphy. Paired t-tests were conducted to compare PS to IS sleep and one-way repeated measures ANOVA ($P < 0.05$) to compare IS nights' sleep between the night before a match (MN-1), match night (MN) and two recovery nights (RN1 and RN2). Tukey post-hoc analysis was run to identify true differences. In addition, Cohen's effects sizes (d) were used to interpret the magnitude of difference. Results: Although TIB was similar (IS; 507 ± 83 min, PS; 494 ± 63 min, $P=0.277$, ES 0.12), TST was greater during IS (458 ± 77 min vs. 432 ± 57 min, $P=0.017$, ES 0.26), resulting in higher SE ($90.2 \pm 3.2\%$, vs. $87.7 \pm 6.3\%$; $P<0.001$, ES 0.39). During IS, MN-1 TIB was longer than MN (30%), RN1 (6%) and RN2 (8%). Further, TIB was longer during RN1 (18%) and RN2 (17%) vs. MN. Similarly, MN-1 TST was longer vs. MN (32%), RN1 (8%) and RN2 (10%). Additionally, TST was longer during RN1 (18%) and RN2 (17%) vs. MN. SE was higher for MN-1 vs. RN1 (1.5%) and RN2 (1.6%), while, WASO was shorter during MN vs. RN1 (-19%) and RN2 (-19%), and SOL only shorter for MN-1 vs. RN2 (-36%). Conclusion: While ARF sleep longer IS compared to PS it appears they also increase TST by ~2h the night before games, incur reduced sleep on match nights and subsequently repay this sleep loss in the following recovery nights. The presence of reduced sleep during PS and following MN may allow practitioners to target specific seasonal periods so as to maximise sleep opportunities. References: Fullagar, H. OP-SH09 Psychology: Behavior & Social Support

DOES THE PHYSICAL ENVIRONMENT MODERATE THE EFFECTS OF HIGH INTENSITY EXERCISE ON AFFECTIVE STATES?

KINNAFICK, F., THØGERSEN-NTOUMANI, C.

University of Northampton

Introduction The physical environment and moderate intensity physical activity can independently (Thompson Coon et al., 2011) and collectively (Kinnafick & Thøgersen-Ntoumani, 2014) improve affective states. High intensity or supra-threshold exercise has been shown to provide physiological benefits in previously inactive adults (Shepherd et al., 2015). However, it has been argued, using the Dual Mode Theory, that negative changes to affect occur at supra-threshold intensities (Ekkekakis, Parfitt, & Petruzzello, 2011). However, it is unknown if the physical environment moderate the effects of high intensity exercise on affective states. The current study investigated the effects of two opposing environments (urban versus natural) and 2 types of high intensity activity (continuous and High Intensity Interval Training) on affective states within a laboratory setting compared to a control condition (sitting). Methods Using an experimental within subject design, 24 (9 females, 15 males; BMI: 21.34 kg/m², SD = 2.91; age: 22.25 years, SD = 4.28) physically inactive participants, completed all 6 counter balanced conditions in a laboratory setting over a 4 week period. Participants were asked to cycle at >90% HRmax, on a Wattbike, for either 4 minutes of continuous exercise or for 8 repeated 30 second sprints, interspersed with 30 seconds of active recovery whilst watching video clips of either a natural or urban environment. Participants also watched each clip whilst sitting for 4 minutes as a control condition. Measures of affect (Feeling Scale, Felt Arousal Scale, Rate of Perceived Exertion (RPE) and perceived pain) were administered pre, mid, post and following 10 minutes of recovery after each condition. Positive and negative affect (PANAS) were also assessed pre, post and following a 10 minute recovery period. A 3 way (Environment x 2, Time x 3, intensity x 3) repeated MANOVA was used to analyse the data. Results Preliminary findings indicate that exercising at high intensity, regardless of whether it is continuous or HIT increases negative affect ($p<0.01$), reduces positive affect ($p<0.01$) and reduces positive feelings (FS; $p<0.05$) compared to sitting. However, results show that being exposed to a natural, as opposed to an urban, environment lessens the negative impact of HIT on negative affect and RPE ($p<0.05$). Discussion High intensity exercise can lead to increases in negative affect, thus supporting propositions of the Dual Mode Theory. However, when physically inactive adults choose to engage in HIT, it is important to consider the role of the physical environment, specifically natural open space, in an attempt to reduce the magnitude of negative affect.

ESSENTIAL COMPETENCIES IN CONTEMPORARY APPLIED SPORT PSYCHOLOGY: SOUTH AFRICAN AND UNITED KINGDOM PERSPECTIVES

JOOSTE, J.

Tshwane University of Technology

Investigation of essential competencies in present-day sport psychology practice is critical to keeping the training, education and regulation standards of applied sport psychology (ASP) practitioners at the forefront of research (Fletcher & Maher, 2013) as well as to offering a new rationale for promoting academic inquiry in developed and developing contexts (Edwards & Barker, 2015). This study focused on identifying essential competencies in contemporary sport psychology practice and exploring the comparative views of a purposefully selected sample ($n=9$) of expert ASP practitioners/psychologists. Data were gathered by means of semi-structured interviews with stakeholders in South Africa (SA) and the United Kingdom (UK). Interview data were analyzed using thematic content analyses. Main findings suggested that a relational and dependable character, a client-centered focus, an all-encompassing counselling skills-set (facilitative and restorative), and explicit expertise in the domains of psychology, sport and sport science are indispensable to current sport psychology practice. Views generated by both stakeholders were remarkably similar and overlapped extensively, which indicated the advanced levels of sport psychology praxis in both contexts. The recommendation arising from the results is that behavioural indicators (personal character) and certain skills prerequisites merit special consideration for candidates entering ASP training and practice. An interdisciplinary training model in ASP with acquired competency in both kinesiology/sport science and psychology-based training should become the accepted standard in the training and development of practitioners for the purpose of garnering an inclusive capacity to render client-centred services. Toward a competency-based understanding of the training and development of applied sport psychologists. Sport, Exercise, and Performance Psychology, 2(4), 265-280. doi:10.1037/a0031976

DEVELOPMENT AND VALIDATION OF THE EXERCISE SOCIAL SUPPORT QUESTIONNAIRE

ZHONG, T.1, CHUNG, P.K.1, LIU, J.D.1, HU, L.2

1: Hong Kong Baptist University, (Hong Kong), 2: Zhejiang University (China)

Development and Validation of the Exercise Social Support Questionnaire Introduction Social support plays an important role in understanding exercise behavior. The measurement of social support should be specific in different research domain. However, exercise specific social support measurement is not available in Chinese, which creates a critical barrier to an accurate understanding of this topic in Chinese population. The purpose of the current study was to develop and validate an exercise social support questionnaire (ESSQ) for Chinese adults. Methods Qualitative research (semi-structured interviews, experts' consultation, etc.) was firstly conducted to establish the item pool of the initial scale. Questionnaire administration consisted of 2 phases. During phase 1, 378 valid responses were obtained (participants age=25.13±7.63, 56% male and 44% female). The factorial structure of the measure was explored using exploratory factor analysis (EFA). Moreover, internal consistency as well as test-retest reliability was examined. In phase 2, 419 valid responses were acquired (participants age=33.50±10.78, 44.3% male and 55.7% female). Confirmatory factor analysis (CFA) was employed to validate the structure of the ESSQ. Additionally, criteria validity tests (with general social support, physical exercise, etc.) were also adopted for assessment of the sensitivity of the ESSQ. Results Following the procedure of qualitative research as abovementioned, 36 items were generated for subsequent quantitative study. The quantitative research results indicated: (1) According to the outcome of EFA, the ESSQ consisted of 4 dimensions, namely emotion, information, instrument and companion support, with 6 items for each dimension. Moreover, the

test-retest reliability ($r=0.74\text{-}0.89$) and internal consistency ($\alpha=0.75\text{-}0.94$) were all fairly good. (2) Based on the model fit indices of CFA, its construct was further validated (e.g., NNFI=0.943, CFI=0.949, NFI=0.938, RMSEA=0.078, SRMR=0.086). In terms of its criteria validity, exercise social support was significantly correlated with general social support ($r=0.29$, $p<0.01$); moreover, it was more specific in the exercise domain which correlated higher with exercise behavior ($r=0.28$, $p<0.01$). Discussion In present study, the ESSQ was preliminarily developed and validated. Moreover, compared with general social support scale, the newly developed questionnaire had its unique merit for application under the context of exercise in the Chinese population. Future studies should examine the validity of this ESSQ across different Chinese populations and establish normalized standard, as well as explore the role (e.g. serving as moderating or mediating variable) of social support in understanding exercise behavior among Chinese people. THE PREDICTION OF PROACTIVE PERSONALITY AND SOCIAL SUPPORT ON TAIWAN FEMALE PROFESSIONAL GOLFERS' CAREER SATISFACTION

CHUANG, H.Y., CHI, L.K.

National Taiwan Normal University

Introduction Proactive personality is considered a "stable disposition to take personal initiative in a broad range of activities and situations" (Bateman & Grant, 1993). Previous studies have highlighted the importance of proactive personality in fostering individual's career satisfaction in the workplace (Seibert, Crant, & Kraimer, 1999). However, only a few studies explored athletes' career satisfaction in professional sports. In addition to personality, environmental factors also play an important role on career satisfaction. Therefore the purpose of this study was to examine the predictive utility of proactive personality and social support on Taiwan ladies professional golfers' career satisfaction. Methods Forty-five female professional golfers ($M_{age} = 32.36$, $SD = 12.96$) were requested to complete inventories that assess proactive personality (Seibert et al., 1999), social support, and career satisfaction (Greenhaus, Parasuraman, & Wormley, 1990). Research data were analyzed by Pearson's correlation and multiple stepwise regression. Results Proactive personality ($r = .35$, $p < .05$) and social support ($r = .31$, $p < .05$) was positively associated with career satisfaction. Multiple regression analyses indicated that proactive personality ($R^2=12.2\%$) and social support ($R^2=9.4\%$) positively predicted career satisfaction. Discussion The finding of the study shown that proactive personality positively predicted female golfers' career satisfaction, which is consistent with the results of Li, Wang, Gao, & You (2015) that used school teachers as participants. In other words, female professional golfers who had higher proactive tend to reported greater career satisfaction. In addition, social support positively predicted career satisfaction. Therefore based on the results of the study, cultivate proactive attitude could help professional golfers having greater career satisfaction. Moreover, giving professional golfers more encourage and support to enhance career satisfaction is recommended in the future. References Bateman, T. S., & Crant, J. M. (1993). FACTORS THAT INFLUENCED THE EFFECTIVENESS OF RECEIVED SUPPORT IN SPORT

FU, D., HASE, A., FREEMAN, P.

Centre for Sports and Exercise Science

Introduction The presence of supportive relationships is crucial in health and sporting contexts. Paradoxically, the actual receipt of supportive behaviours from these relationships is sometimes ineffective or even detrimental. One explanation for this is that the amount of support individuals receive should meet what they want. Therefore, the aim of this study was to examine whether the interaction of wanted and received support influenced psychological and performance outcomes. Methods A convenience sample of 226 university students who were novice golfers completed a questionnaire assessing how much support they would want prior to a golf-putting task. Participants who wanted high levels of support ($n = 44$) and those who wanted low levels of support ($n = 44$) were randomly assigned to receive either a support manipulation or control group, before completing measures of self-confidence and affect, and executing 10 golf putts. Results A 2 (wanted support: high, low) by 2 (manipulation: support, control) between-subjects ANCOVA (controlling for gender) was conducted. Significant interactions of wanted support and received support were only found on psychological outcomes (self-confidence: $F_1, 83 = 39.15$, $p < .001$, $\eta^2 = .32$; positive affect: $F_1, 83 = 1542.02$, $p < .001$, $\eta^2 = .35$; negative affect: $F_1, 83 = 10.60$, $p < .005$, $\eta^2 = .11$), but not performance (mean distance: $F_1, 83 = .80$, $p = .38$, $\eta^2 = .01$). Following the significant interactions on psychological outcomes, simple contrasts were conducted using the low wanted, control group as the reference condition. Participants in the low wanted, support condition reported similar confidence and affect to those in the reference condition. In contrast, participants in the high wanted, control condition reported less favourable confidence and affect than those in the reference condition. Finally, participants in the high wanted, support group reported higher confidence and positive affect (not negative affect) than those in the reference condition. Discussion The findings highlight that the effects on psychological outcomes of received support are contingent on the support athletes' actually want. Individuals who wanted but did not receive support experienced poorer psychological outcomes. In contrast, individuals who wanted and received support experienced more favourable psychological outcomes. Overall the findings emphasise that the effectiveness of received support was particularly salient for those who wanted high levels of support, and athletes' support networks should be mindful to meet athletes' support needs. OP-PM25 Balance

THE RELATION OF ASYMMETRY IN POWER AND BALANCE IN THE LOWER EXTREMITIES

BLIEKENDAAL, S., PLOMP, S., RICHARDSON, A., STUBBE, J.

Amsterdam University of Applied Sciences

Introduction Asymmetry in the lower extremities can affect performance (Portegijs et al., 2005) and increase injury risk (Smith et al., 2015). Common ways to identification asymmetry are single legged measures of power or balance. However, there is little understanding about the relation between asymmetries in these capacities (Overmoyer et al., 2013). This study aims to explore the relation between asymmetry in power and balance in the lower extremity in a young athletic population. Methods A total of 196 subjects participated in this study. All participants were first year physical education students with a mean age of 19.5 (± 2.4) years for men (N=132) and 18.3 (± 2.6) years for woman (N=60). Balance was determined by anterior reach of the Starr Excursion Balance Test (Hertel et al., 2006). Jump height of single legged counter movement jumps were used to calculate power for each leg with the Sayers formula and normalized for body weight. Results Anterior reach was on average 66.5% (± 5.6) of leg length for men and 68.9% (± 4.0) of leg length for woman. Anterior reach asymmetry was on average 2.4% (median: 1.7; range: 0.0-20.2) for men and 2.5% (median: 1.8; range: 0.0-17.0) for woman. Average power was 29.9 W/Kg (± 2.8) for men and 24.4 W/Kg (± 2.4) for woman. Power asymmetry was 1.6 W/Kg (median: 1.4; range 0.1-6.2) for men and 1.6 W/Kg (median: 1.1; range: 0.1-7.1) for women. Values for power and anterior reach did not correlate ($p=0.078-0.636$). Asymmetry in power and anterior reach significantly correlated for women ($r=0.393$, $p=0.004$). This relation was not significant for men ($r=0.162$, $p=0.083$). Discussion Small asymmetries in balance and power are common in a healthy and active population. In few cases asymmetry was found to be large. Values for power and balance did not correlate. Asymmetries in power and balance have a weak relation for woman. This implies that asymmetry in balance or power are to a large extent independent of each other. Asymmetry in power and balance should therefore be identified complementary. DIFFERENT DIFFICULTY LEVELS OF BALANCE TASK INDUCED SPINAL EXCITABILITY ALTERATION

SMAJLA, D., STROJNIK, V., TOMAŽIN, K.

University of Ljubljana

Introduction In balance training, there are no scientific guidelines concerning the optimal duration and intensity of these exercises (Taube, Gruber and Golhofer, 2008). Therefore, the aim of this study was to determine mechanical differences between different difficulty levels of balance task and their acute influence on H-reflex amplitude. Methods The research included 13 participants. Each of them performed balance task of three difficulties in random order (20 s, 7 repetition, 150 s rest). The rest time between each intensity was one week. Balance task was performed on balance board with motion in sagittal plane. We measured soleus H-reflex in standing position, active time of establishing balance control, number of hand supports because of losing balance, distance and speed of balance board. Normal distributed variables were analyzed with Shapiro-Wilk test. Differences between dependent variables were analyzed with repeated measures ANOVA procedure. In case of statistical significance, we used Tukey-Post-hoc test. For abnormal distributed variables, we used Friedman test (in case of sig., Wilcoxon rank sum test). Spearman correlation coefficients were calculated to analyze dependence of chosen variables. Results Active time of establishing balance, number of hand supports because of losing balance and speed of balance board are statistically different between difficulties (all: $p<0.001$). Mean values of wave H amplitude measured standing after whole balance task were significantly lower than before ($p<0.01$). Although we did not find significant differences between difficulties, H-reflex amplitude was significantly reduced already after the second repetition ($p<0.05$) in the most difficult and after the fifth repetition ($p<0.05$) after the easiest balance task. Discussion We assume that the most difficult balance task induces greater alteration in excitability of alpha motoneurones and/or presynaptic inhibition of Ia afferents due to the need for more precise control of movement. The advantage of reduced spinal reflexes in balancing tasks was assumed to rely on the prevention of reflex-mediated joint oscillations and on a shift in movement control to higher centres (Llewellyn et al., 1990; Koceja and Mynark, 2000; Solopova et al., 2003; Taube et al., 2008). It would be useful to research chronological adaptations induced by different difficulties of balance task on spinal and higher centres. References Koceja DM, Mynark RG. (2000). MAXIMUM MUSCLE STRENGTH AND BALANCE PERFORMANCE AFTER THE HIGH INTENSITY STRENGTH AND AGILITY EXERCISE OF THE FOOT AND LEG MUSCLES

KOYAMA, K.1, NAGAHUJI, Y.1, YAMAUCHI, J.2,3

1: Toin University of Yokohama, 2: TMU, 3: FISS

[Introduction] Physical exercises cause to muscle fatigue, which is a decrease in the ability of muscles to produce force (Bigland and Woods, 1984) and a decrease in the ability of nerves to transmit signals (Hagg, 1992). Muscle strength of the foot and leg is important essentials for physical performance in standing. We showed that the foot strength was significantly correlated with dynamic lower-limb physical performances such as sprinting and jumping in children (Morita et al. 2015) and adolescent (Otsuka et al. 2015). Also, we showed that limitation of ankle joint movement decreased vertical jump performance (Koyama et al. 2014) and the foot strength (Yamauchi and Koyama, 2015). The foot muscles are a unit that produces force for postural control during the locomotion. However, there are no studies how physical exercises affect to the force generating capacity of the foot and leg muscles as well as the postural balance ability.

[Purpose] The purpose of this study was to investigate the effects of high intensity strength and agility exercise on maximum muscle strength of the foot and leg and static balance. [Methods] Eighteen healthy men performed the high intensity strength and agility exercise with barefoot for an hour, and their toe flexor strength (TFS), ankle plantar flexor strength (PFS) and postural ability were measured before and after the exercise. The exercise program consisted of muscle strength of the foot and the leg and balance exercises such as calf-raise, balance ball, ladder training and mini hurdle exercises. Static balance was evaluated from the path of the center of pressure (COP) during three balance tasks (bipedal standing with open eyes, bipedal standing with closed eyes, and one-legged standing with open eyes) for 40s. Total length (TL), mean velocity (MV), total area (TA), rectangular area (RA), effective area (EA) and TL per unit area (TL/A) were calculated from COP data. [Results] After the exercise, TFS at both feet with standing and sitting were significantly decreased. PFS at both feet were significantly decreased. TL, MV, TA, RA, EA and TL/A of COP variables in the bipedal standing with open and closed eyes conditions were not significantly different. TA, RA, EA and TL/A of COP variables in the one-legged standing with open eyes were not significantly different; however TL and MV of COP were significantly decreased. [Conclusion] This study suggested that muscle fatigue of the foot and leg after the high intensity strength and agility exercise with barefoot might improve some variables of the standing balance ability in one-legged standing with open eyes. POSTURAL CONTROL PROFILE OF AMATEUR RUGBY PLAYERS

CHOW, G.C.C., CHUNG, J.W.Y., FONG, S.S.M., MA, A.W.W., MACFARLANE, D.J.

The Hong Kong Institute of Education

Introduction Injuries during rugby training or competitions might disrupt the sensory and motor systems that affect postural control. However, no study has explored the sensory organisation and reactive balance control of rugby players. This study compared (1) the sensory organisation of balance control and (2) reactive balance control, of amateur rugby players and active individuals. Methods Forty-one amateur rugby players (22 males and 19 females; mean age \pm SD: 21.4 ± 2.1 years) and thirty-one young active individuals (22 males and 9 females; mean age \pm SD: 20.6 ± 0.9 years) completed the measurements in the study. Their sensory organisation and bipedal standing balance performance were evaluated using a sensory organisation test (SOT), and their reactive balance performance was assessed using a motor control test (MCT). The major outcome measures were the SOT equilibrium scores (ES) and sensory ratios and the MCT motor response latencies. Results Rugby players had lower SOT ESs under different sensory environments (all $P < 0.001$) and prolonged reactive motor response times in the MCT ($P < 0.001$) compared to the active controls. The SOT vestibular and visual ratios were also lower in the rugby group ($P = 0.005$). However, no significant between-group difference was found in the somatosensory ratio ($P = 0.853$). Discussion Rugby players demonstrated inferior standing balance performance compared to their non-trained counterparts. They relied less heavily on vestibular and visual information to maintain standing balance under sensorial challenging environments. Additionally, they reacted more slowly to postural threat, reflecting their suboptimal reactive balance ability in upright standing.

HOW DOES THE GYMNASTIC APPARATUS INFLUENCE THE MUSCLE ACTIVITY OF A GYMNAST IN A HANDSTAND?

NIESPODZIŃSKI, B.1, KOCHANOWICZ, A.2, MIESZKOWSKI, J.1, ZASADA, M.2, SAWCZYN, S.2

1: UKW (Bydgoszcz, Poland); 2: AWFIS (Gdansk, Poland)

Introduction Gymnasts perform handstands on various apparatus, both in stable and unstable conditions. Such a balance task requires specific muscle activation which should differ depending on the wrist joint position and the specificity of the apparatus. Therefore, the aim of the study was to show differences in surface electromyography activity (sEMG) of gymnasts' muscles during a handstand on various apparatus. Methods 10 elite male gymnasts participated in the study. Their mean age was 25 ± 3.94 years. In the study, gymnasts performed a 5-second handstand in three conditions: on the floor, on parallel bars and on still rings. During performance, sEMG of 13 muscles was recorded. Mean values of three proper handstands on each apparatus were taken into analysis. Each value was normalized to maximal voluntary isometric contraction (MVIC) performed on Biodes System 4. Results In comparison to a handstand on the floor ($60 \pm 28\%$), gymnasts' wrist flexors muscles on parallel bars ($42 \pm 25\%$) and still rings ($43 \pm 32\%$) exhibited decreased mean percentage activity of the MVIC. On parallel bars it was associated with an increase in rectus femoris activity by about 76% in comparison to that on the floor. Most of the muscles (biceps brachii, deltoids, pectoralis major, latissimus dorsi, trapezius descendens) showed increased activity in unstable conditions of still rings. The activity of triceps brachii (15% MVIC) did not differ between each condition. Discussion The reason for such results may lie in different positions of wrist joints, where on the floor the wrist flexors are the most active muscle group, which determines balance in an inverted position (Hedbáry et al., 2008). Parallel bars enforce a specific hand grip, which shows more balanced sEMG activity of wrist flexors and extensors. As this provides less mobility in the wrist joint due to a lesser range of abduction/adduction motions in it as well as its lower torque production capabilities in such motions (Delp et al., 1996), it may facilitate the use of the two other (shoulder and hip) strategies (Yeadon and Trewartha, 2003), manifested by an increase in the lateral deltoid and the rectus femoris activity. Conclusions The obtained results showed that unstable conditions of still rings increase the sEMG activity of all gymnasts. A different handgrip position between a handstand on the floor and on parallel bars can change the activity of not only forearm muscles but also distal muscles. FACTORS INFLUENCING QATARI WOMEN TO ADOPT PHYSICALLY ACTIVE LIFESTYLE

ZIMMO, L., JANZEN, B., ABONYI, S., FARAG, M., HUMBERT, L., HANSON, L.

Aspetar Orthopaedic and Sports Medicine Hospital; University of Saskatchewan

BACKGROUND: There is no doubt that physical activity (PA) has numerous health benefits (1). Despite this fact, data show that 60% of Qatari females do not engage in regular PA (2). The high prevalence of physical inactivity in Qatar has contributed to a rise in obesity and chronic diseases (3). To modify PA behavior successfully among Qatari women, it is necessary to understand the factors that influence this behavior. **PURPOSE:** This study aimed to understand the factors that influence Qatari adult women to adopt a physically active lifestyle. **METHODS:** This is an ethnographic study involving three data collection methods: observation, interview and photovoice. The observation sessions were conducted in public areas; such as gyms, malls, parks, and workplaces, in order to report the Qatari women interaction with their environment. A total of eight Qatari women aged 18-44 years, from different backgrounds (education, occupation, and tribal affiliations) were involved in interviews and/or photovoice activities. Participants were recruited through an opportunistic sampling technique. This study is framed by Islamic feminism and guided by a socioecological model. Thematic analysis was used to identify key themes and subthemes across all transcripts. **RESULTS:** Eight themes emerged within this study: limited PA domains in Qatar; Qatari culture does not support women PA; the desert environment as a barrier; practicing PA requires visiting specific locations; adopted luxurious lifestyle fosters sedentary behavior; perceived low motivation for PA; positive perception about PA with some misconceptions; and other individual factors such as health status and eating habits were found to affect PA. **CONCLUSION:** Results suggest that various cultural, environmental, and economic factors play a key role in Qatari women's physical activity. The facilitators and barriers identified from this study provide important insights on how Qatari women might change their physical activity behavior. **REFERENCES:** 1. BENEFITS OF ADAPTED PHYSICAL ACTIVITY IN WOMEN AFTER TREATMENT FOR BREAST CANCER.

FRACCA, I., MOROSATO, V., LANZA, M.

University of Verona

The main aim of the research is evaluate the physical benefits of a program of Adapted Physical Activity (APA) for cancer survivor (CS) after adjuvant therapy made with lower costs for users, out of the health care system. Methods A "natural experiment" was adopted. Sixteen patients with breast cancer, BMI > 25 or who have increased their weight by 5% during the adjuvant therapy, have agreed to undergo a APA program for 6 months, 2 lessons/week of 60 minutes following this protocol: 10' dynamic stretching, 20-30' aerobic exercise, 10-15' strength exercises, 10' static and passive stretching. The assessment of training effectiveness was carried out three time: initial (M1), at three months (M3), final (M6). Measures adopted was: back scratch test (right and left), sit and reach test, arm curl test for limb of the mastectomy, 30° chair stand test, neck pain with NRS scale (0-10) in best and worst condition within the last 24 hours, RPE Borg Scale for fatigue on two flights of stairs, MMRC Dyspnea Scale, arm abduction test right and left. Results All parameters improved at three or at six month (*=p<0.001 M6 vs M1; °=p<0.001 M3 vs M1; ^=p<0.001 M6 vs M3). Flexibility is improved in all tests: Back Scratch test right (M1=-7.25±9.10; M3=-4.00±7.24; M6=-3.38±7.42*; p<0.001), Back Scratch test left (M1=-10.81±10.88; M3=-7.34±8.65°; M6=-5.84±7.81*; p<0.001) with greater improvements limb of the mastectomy 62,50% cancer survivor after 3 month, 75% after six month; Sit and Reach test (M1=-3.63±5.35; M3=-1.25±4.37°; M6=-0.44±3.89*; p<0.001); the two subjects that at M1 does not get the maximum values of arm abduction test (right and left) have reached them at M3. Strength is improved in both test: Arm Curl test (M1=1.81±7.01; M3=30.34±4.85°; M6=32.97±4.73*^; p<0.001); 30"Chair Stand test (M1=12.75±2.89; M3=16.88±2.99°; M6=19.69±2.89*^). RPE Borg Scale for fatigue on two flights of stairs decreased (M1=9.44±3.08; M3=7.38±1.86; M6=6.25±0.45*; p<0.001). MMRC Dyspnea Scale overall decreased (M1=0.75±0.86; M3=0.31±0.48; M6=0.19±0.40; p=0.002). Neck pain NRS improved both in worst condition (M1=6.00±3.08; M3=3.75±2.77°; M6=1.75±2.02*; p<0.001) and in best condition (M1=1.00±1.21; M3=0.63±1.31; M6=0.25±1.00; p<0.001). Discussion The cancer survivors, after 6 months of APA, have significantly improved their physical fitness and this will allow them to undertake the physical activity of their choice and consolidate an active lifestyle. It seems reasonable to assume, therefore, that an low cost APA program is able to contribute to winning the sedentary lifestyle that these people adopt since the first diagnosis. This can be an important step toward an active lifestyle that can reduce or delay recurrence or a second primary cancer and to reduce, attenuate and prevent long-term and late effects of cancer treatment.

ACCUMULATION OF RECOMMENDED PHYSICAL ACTIVITY IN OLDER ICELANDIC ADULTS

SVEINSSON, T.1, ARNARDOTTIR, N.Y.1, BRYCHTA, R.J.2, KOSTER, A.3, EIRIKSDOTTIR, G.4, SVERRISDOTTIR, J.E.4, JOHANNSSON, E.1, LAUNER, L.J.5, GUDNASON, V.4, HARRIS, T.B.5, CHEN, K.Y.2

1: UI (Reykjavík, Iceland), 2: NIDDK (Bethesda, USA), 3: MU (Maastricht, The Netherlands), 4: IHA (Kopavogur, Iceland), 5: NIA (Bethesda, USA)

Introduction In many European countries, published guidelines recommend older adults to conduct at least 150 min/week of physical activity (PA) of moderate or vigorous intensity (MVPA). Generally, the guidelines state that aerobic PA should be performed in episodes of at least 10 min bouts. However, studies have shown that health benefits might also be gained with bouts of lower intensity and activity that last less than 10 min. The aim of this study was to objectively assess the proportion of older Icelanders accumulation recommended PA using two different definition of a minimum bout of PA, in a sample of older community-dwelling Icelanders from the Age, Gene/Environment Susceptibility Reykjavik study (AGESII study). Methods Free living PA was measured by a waist-worn accelerometer in 138 older adults (61.1% women, 80.3±4.9 yrs) during both summer and winter months. One-week assessment period was used each season for each participant. A bout of MVPA was defined as at least ten consecutive minutes of activity counts above the moderate

threshold (2020 counts/min), allowing for one minute outside of the threshold. A bout of life style PA (LSPA) was defined as at least five consecutive minutes of activity counts above the LSPA threshold (760 counts/min), allowing for one minute outside of the threshold. Results Sedentary behaviour (SB) was high, or about 75% of registered wear time. More PA were accumulated in LSPA bouts during summer than winter. The number of bouts, counts and minutes accumulated in LSPA bouts were higher during the summer compared with winter. For accumulated PA in MVPA bouts there was no significant difference between the seasons. Only 1.5% reached the recommendation of accumulating 150 min per week of PA in MVPA bouts during the summer, and 4.4% during the winter. When LSPA bouts were used as a minimum of continuous PA, 26.8% accumulated at least 150 min per week of PA during the summer and 17.4% during the winter. Discussion The results support the notion, that the minimum of 10 min bouts of MVPA when accumulating PA, may be too ambitious for many older adults. By reducing the intensity and time of the minimum bout to 5 min of LSPA, it seems to be more achievable and realistic for larger part of older adults to reach the recommendations. Thus, it may be more realistic to use LSPA in 5 min bouts as a minimum when accumulating the recommended 150 min per week of PA for older adults. Contact thorasve@hi.is

PATTERNS OF ACTIVITY BEHAVIOR IN OLDER AFRICAN AMERICAN: PRELIMINARY FINDINGS

SEBASTIAO, E., CHODZKO-ZAJKO, W., SCHWINGEL, A.

University of Illinois

Introduction The way in which daily activity is accrued in older African American women (OAAW) is not well understood. This study explored amounts and patterns of physical activity (PA) and sedentary behavior (SB) (i.e., activity behavior) in both sufficiently active (SA) and insufficiently active (IA) OAAW. Methods Twenty OAAW were recruited to take part in this study. Activity behavior was objectively measured through accelerometry over the course of 7 consecutive days. Individual accelerometer data was processed using the ActiLife 6 software. Information regarding accelerometer use (i.e., wear time and valid days), PA volume (i.e., sedentary, light intensity and MVPA, steps/day) (Freedson et al., 1998), and PA patterns (i.e., breaks in sedentary time, maximum length of sedentary bouts, average length of sedentary bout, number of sedentary bouts large than 30 minutes) was assessed. Participants were categorized into SA ($n = 9$) or IA groups ($n = 11$) based on national PA recommendations (DHHS, 2008). Results The average age of participants was 68.3 (6.1) years. As expected, IA women spent significantly less time in light activity and MVPA per day compared with the SA group; (82.9 (16.5) vs. 121.5 (38.7), $p < 0.01$; and 17.4 (2.8) vs. 42.9 (5.3), $p < 0.01$, respectively. The average length of sedentary bouts and the average number of sedentary bouts longer than 30 min were both significantly greater in the IA group compared with the SA group; (24.3 (1.4) vs. 17.1 (2.4), $p < 0.01$; and 7.95 (1.4) vs. 3.5 (1.5), $p < 0.01$, respectively. No significant differences were found between groups regarding total amount of sedentary time, number of breaks in sedentary time, and maximum length of sedentary bouts. Discussion Overall, the findings on activity behavior observed in the present study are similar to those reported previously in a similar population (Evenson et al., 2012). The findings of this study suggest that women in the IA group are at increased risk of developing health problems because of cumulative adverse effects of low levels of PA and prolonged sedentary bouts. These findings underscore the need for interventions aimed at reducing SB and increasing PA among older African-American women. References Freedson, P. S., Melanson, E., & Sirard, J. (1998). EFFECTS OF FOOT PAIN ON DYNAMIC PLANTAR FOOT PRESSURE IN ATHLETES

SIMSEK, D.1, ONARICI GUNGOR, E.1, YILDIZER, G.1, KIRKAYA, I.2

Anadolu University

Introduction The purpose of this study is to investigate the effect of foot pain on plantar peak pressure, maximum force of right and left foot. Methods Nine male athletes who have foot pain (FP) (20.50 ± 1.16 year; 1.78 ± 0.06 m; 76.64 ± 8.93 kg; 23.85 ± 1.74 kg/m 2) and 11 athletes (22 ± 3.52 year; 1.78 ± 0.06 m; 75.30 ± 7.74 kg; 23.40 ± 2.41 kg/m 2) (as the control group) having no history of pain were included in the study. Subjects of FP group were included according to the results of Foot Function Index (FFI) (Budiman-Mak et al. 2013). Dynamic plantar pressure (PP) assessment during walking without shoes was undertaken using the EMED-XL (Novel GmbH, Munich, Germany) PP analysis system sampling at a rate of 100 Hz. The two-step gait initiation protocol with 5 trials was used to obtain foot pressure data. For data analysis the Novel scientific analysis software was used. The following parameters were calculated for the entire foot: Peak pressure (PP in kPa), maximum force (F) contact area (CA in cm 2), and contact time (CT in ms). The F was normalized with respect to the body weight of each participant. Foot was masked as 'big toe, second toe, toes 3-4-5, MH1: 1st metatarsal head, MH2: 2nd metatarsal head, MH3: 3rd metatarsal head, MH4: 4th metatarsal head, MH5: 5th metatarsal head, middle foot and hind foot'. Before statistical analyses, all of the measures were found to be distributed normally based on the Shapiro-Wilk test. It was examined whether there were any statistically significant differences between the experiment and control group means using independent T test. In the measurements 95% reliability range and $P < 0.01 - 0.05$ were accepted as significance level. Discussion According to descriptive data there is no significant differences of descriptive data between the FP and FFP groups ($P > 0.05$). It was found that there were significant differences between the FP and FFP group in terms of relative F (%BW) in total foot (FP: 95.57 ± 4.84 ; FFP: 90.37 ± 4.73), big toe (FP: 15.57 ± 3.40 ; FFP: 9.07 ± 4.30) and second toe (FP: 3.07 ± 1.17 ; FFP: 1.92 ± 1.10) ($P < 0.05$). In addition to this data absolute F of hind foot (FP: 450.94 ± 68.15 ; FFP: 366.51 ± 109.59), big toe (FP: 120.16 ± 33.17 ; FFP: 69.21 ± 36.10) and second toe (FP: 23.68 ± 9.22 ; FFP: 14.60 ± 8.73) were found statistically different between FP and FFP groups ($P < 0.05$). Relative PP of big toe (FP: 33.36 ± 7.26 ; FFP: 26.87 ± 7.36) was found statistically different between groups ($P < 0.05$). Contact area (cm 2) of total foot (FP: 165.22 ± 17.70 ; FFP: 150.53 ± 11.66) and MH1 (FP: 15.37 ± 1.46 ; FFP: 13.53 ± 1.36) was found statistically different between groups ($P < 0.05$). In our findings, increased foot pain would be associated with higher PP, F and CA. Underlying mechanism of these findings may be related with angle deviation of subtalar varus and valgus. FACTORS ASSOCIATED WITH SUCCESSFUL PHYSICAL ACTIVITY INTERVENTION AND ITS EFFICIENCY ON OVERALL PHYSICAL FITNESS IN ADOLESCENTS

KIDOKORO, T., TOYOSHIMA, Y., HASEGAWA, M., YANAOKA, T., KASHIWABARA, K., YAMAGAMI, J., TANAKA, H., MIYASHITA, M.

Tokyo Gakugei University

Introduction The purposes of the present study were 1) to investigate potential factors associated with successful physical activity (PA) intervention and 2) to examine the effects of small amounts of additional PA ($\geq 1,000$ steps per day) on overall physical fitness in adolescents. Methods 324 Japanese adolescents (127 boys and 197 girls; age 12-15 years) participated in a 16-week, single-arm intervention study. At baseline, the participants were asked to wear an accelerometer to evaluate their baseline PA levels. Thereafter, all participants were asked to increase their activities above baseline lifestyle levels by $\geq 1,000$ steps per day for 16 weeks; freely deciding mode, frequency, intensity and content in which the activities occur. During the intervention periods, the participants were asked to record their daily step counts in an activity log. The primary outcome was whether or not the participants achieved the determined goal. The participants who increased their activities by on average $\geq 1,000$ steps per day during the intervention period were defined as "Achieved group" and "Non-achieved group" for the others. Factors potentially associated with successful PA intervention were measured by using questionnaire. The Secondly outcome was changes in physical fitness of the participants. Japanese standardised fitness test including 8 fitness items was conducted at baseline and after 16 weeks. Results Only 33.1% of boys and 24.4% of girls were defined as "Achieved group" in the present study. Higher baseline fitness composite score were positively associated with the successful PA intervention in both boys [odds ratios (ORs) = 1.07, $p = 0.026$] and girls [ORs = 1.05, $p = 0.037$]. In addition, confidence in own fitness levels was positively associated with the success in increasing PA for girls ($5.5 \leq \text{ORs} \leq 11.5$, $p < 0.05$). For the effects of additional PA on physical fitness, there was a significant interaction effect (group \times time) on the fitness composite score in girls ($F = 9.23$, $p = 0.003$), but not in boys ($F = 0.68$, $p = 0.414$). Discussion The present study suggested that encouraging adolescents to increase their activities by only providing a pedometer and the active log might be insufficient to increase PA levels for majority adolescents. In addition, this seems particularly true for those who have lower physical fitness and confidence in own fitness levels before an intervention is implemented. However, if the PA intervention is achieved, additional small amounts of PA (i.e. $\geq 1,000$ steps per day) seem to be effective for improving overall physical fitness, at least in girls.

FIXING THE METABOLIC LEAK IN THE INEFFICIENT MUSCLE CARNOSINE LOADING SCHEME BY ORAL BETA-ALANINE SUPPLEMENTATION

BLANCQUAERT, L.1, BABA, S.P.2, KWIATKOWSKI, S.3, STAUTE/MAS, J.1, CHUNG, W.1, BOAKYE, A.A.2, BHATNAGAR, A.2, VEIGA-DA-CUNHA, M.3, DERAVE, W.1, EVERAERT, I.1

University Ghent

1: GHENT University (Ghent, Belgium), 2: University of Louisville (Kentucky, USA), 3: Université Catholique de Louvain (Brussels, Belgium) Introduction Chronic beta-alanine supplementation is becoming increasingly popular to improve high-intensity exercise performance, as it is the rate-limiting precursor of the dipeptide carnosine (beta-alanyl-L-histidine) in muscle (Harris et al., 2006). Yet, only a small fraction (3-6%) of the ingested beta-alanine is used for carnosine synthesis (Stegen et al., 2013). Thus, the aim of this study was to identify the main alternative metabolic route of ingested beta-alanine and to investigate the putative contribution of two beta-alanine transamination enzymes, namely GABA-T and AGXT2, herein. Methods In a first part, mouse and human GABA-T and AGXT2 were cloned and expressed in HEK293T cells and degradation of beta-alanine by recombinant GABA-T and AGXT2 was explored with and without addition of transaminase inhibitors vigabatrin and aminoxyacetate (AOA). The second part consisted of a nutritional intervention study, in which 66 male C57BL/6 mice were supplemented with different dosages of beta-alanine for two weeks and simultaneously received subcutaneous injections with vigabatrin (500mg/kg body weight) or AOA (10mg/kg). Results Recombinant mouse and human GABA-T and AGXT2 were all able to efficiently transaminate beta-alanine. The reaction catalyzed by GABA-T was inhibited by vigabatrin, whereas both GABA-T and AGXT2 activity were inhibited by AOA, a finding which was also confirmed in vivo. Injection of AOA in C57BL/6 mice placed on beta-alanine (0.1% w/v in drinking water) for two weeks lead to a 3-fold increase in circulating beta-alanine levels and to significantly higher levels of carnosine and anserine in skeletal muscle (+128% in soleus, +105% in tibialis anterior, +21% in gastrocnemius) and heart (+54%). In contrast, specific inhibition of GABA-T by vigabatrin did not affect carnosine and anserine levels in either tissue. Discussion Collectively, these data demonstrate that homeostasis of carnosine and anserine in mammalian skeletal muscle and heart is controlled by circulating beta-alanine levels, which are suppressed by hepatic beta-alanine transamination upon oral beta-alanine intake. This transamination pathway likely creates a major metabolic leak in the presently used beta-alanine supplementation protocols. B-ALANINE SUPPLEMENTATION IMPROVES THE RELAXATION SPEED OF IN-VIVO FRESH AND FATIGUED SKELETAL MUSCLE

STANNARD, R.L., BARNETT, C.T., DAVIDSON, J., MARITZA, B., FRASER, W.D., HARRIS, R., SALE, C.

Nottingham Trent University

PURPOSE: In fresh muscle, supplementation with the rate-limiting precursor of carnosine, beta-alanine (BA), results in a decline in muscle half-relaxation time (HRT) potentially via alterations to calcium (Ca^{2+}) handling. Accumulation of H^+ has been shown to impact Ca^{2+} signalling during muscular contraction and carnosine has the potential to serve as a cytoplasmic regulator of Ca^{2+} and H^+ coupling, since it competitively binds to both ions. The present study examined the effect of BA supplementation on intrinsic in-vivo knee extensor force production and muscle contractility in both fresh and fatigued human skeletal muscle assessed during voluntary and electrically-evoked (nerve and superficial muscle stimulation) contractions. METHODS: Twenty-three males completed two experimental sessions, pre- and post- 28 days supplementation with 6.4 g.day⁻¹ of BA (n=12; age, 22 ± 2 years, height, 1.80 ± 0.05 m, body mass, 76.0 ± 7.3 kg, MVIC, 565 ± 86N) or placebo (PLA; n=11; age, 22 ± 1 years, height, 1.83 ± 0.06 m, body mass, 81.4 ± 14.2 kg, MVIC, 600 ± 149N). The Institutional Ethical Review Committee approved the study. Force was recorded during a series of voluntary and electrically evoked knee extensor contractions. RESULTS: BA supplementation had no effects on voluntary or evoked force production, or twitch electromechanical delay and time-to-peak tension. Nonetheless there was a decline in muscle HRT in fresh and fatigued muscle during both resting (3 ± 13%; 19 ± 26%) and potentiated (1 ± 15%; 2 ± 20%) twitch contractions. CONCLUSION: The key findings from the present study are a) no effects of BA supplementation on force production capacity in either fresh or fatigued skeletal muscle, b) the confirmation of our previous findings (Hannah et al. 2015) showing enhanced fresh muscle relaxation speed following 28 days of BA supplementation and c) that the skeletal muscle relaxation speed is also reduced by BA supplementation following muscle fatigue (H^+ accumulation) in the absence of any change to peak force production or contraction time. The mechanism for reduced HRT in fresh and fatigued muscle following BA supplementation is unclear. Due to the importance of muscle relaxation on total energy consumption, especially during short, repeated contractions, BA supplementation may prove to be beneficial. These data are the first to comprehensively examine the effect of BA supplementation on voluntary and electrically evoked contractile properties of in-vivo fatigued human skeletal muscle.

BETA-ALANINE SUPPLEMENTATION ENHANCES JUDO-RELATED PERFORMANCE IN HIGHLY-TRAINED ATHLETES.

KRATZ, C.I., PAINELLI, V.I., NEMEZIO, K.I., SILVA, R.I., FRANCHINI, E.I., ZAGATTO, A.I., GUALANO, B.I., ARTIOLI, G.I.

1 University of São Paulo; 2 Paulista State University

Introduction In official judo competitions, athletes have to engage in 5-7 matches in the same day (Detanico et al. 2015), during which they perform numerous high-intensity efforts interspersed by short recovery intervals. Thus, glycolytic demand in judo is high and acidosis may limit performance (Artioli et al. 2010). Carnosine is a relevant intracellular acid buffer whose content is increased with beta-alanine supplementation (Harris et al. 2006). Thus, we hypothesized that beta-alanine supplementation could attenuate acidosis and improve judo performance. **Methods** Twenty-three highly-trained judo athletes were randomly assigned to receive either beta-alanine (6.4 g.day⁻¹; n=12; age=19 ± 3 y) or placebo (dextrose, 6.4 g.day⁻¹; n=11; age=17±2 y). Performance was assessed before (PRE) and after (POST) supplementation through a 5-minute simulated fight (randori) followed by 3 bouts of the Special Judo Fitness Test (SJFT) (Sterkowicz et al. 2010). Blood samples were collected for blood pH, bicarbonate (HCO₃⁻) and lactate determination. **Results** Beta-alanine supplementation significantly improved the number of throws per set, as well as the total number of throws (both P < 0.05), whilst placebo did not change these variables (both P > 0.05). Blood pH and HCO₃⁻ were significantly reduced after exercise (all P < 0.001), with no between-group differences (all P > 0.05). However, the lactate responses to exercise were higher in the beta-alanine group as compared to placebo (P < 0.05). **Discussion** The likely elevated muscle buffering capacity has probably attenuated muscle acidosis during the judo-specific protocol, thereby allowing for enhanced glycolytic activation and better performance. In conclusion, 4 weeks of beta-alanine supplementation is an effective dietary intervention capable of enhancing judo-related performance in well-trained judo athletes, suggesting that this modality can also benefit from the ergogenic effects of an increased muscle carnosine content. **References** Artioli GG, Iglesias RT, Franchini E, Gualano B, Kashiwagura DB, Solis MY, Benatti FB, Fuchs M, Lancha Junior AH. ACUTE INGESTION OF BETA-HYDROXYBUTYRATE INDUCES NUTRITIONAL KETOSIS AND ALTERS THE METABOLIC RESPONSE TO EXERCISE

MARK, E., EGAN, B.

University College Dublin

Introduction Ketone bodies, beta-hydroxybutyrate (BHB) and acetoacetate, are fatty acid metabolites produced in the liver as a result of fasting, starvation or a ketogenic diet. Ketone body production is increased during exercise and can be utilized as an alternative to carbohydrate and fat to fuel muscle, but there is a lack of research on the metabolic effects of ingesting BHB prior to exercise. **Methods** Six male trained cyclists (age, 21.3±3.9 y; body mass 72.5±6.1 kg; height 177.5±8.6 cm; VO₂peak 64.4±4.7 mL/kg/min; Wmax 368±42 W) undertook experimental trials after a 10 h overnight fast comprising of a graded exercise protocol performed on a stationary electronically-braked cycle ergometer (Lode Excalibur Sport, Groningen, Netherlands). The protocol incorporated six stages, with each stage lasting 8 minutes at 30%, 40%, 50%, 60%, 70% and 80% VO₂peak. Each experimental trial was identical with the exception of the drink consumed, which consisted of either (i) a bolus of plain water (3.8 mL/kg body mass) ingested at 60 minutes and 15 minutes prior to exercise (CON), or (ii) a bolus of BHB salts (0.38 g/kg body mass) in plain water (3.8 ml/kg body mass) ingested at 60 minutes and 15 minutes prior to exercise (KET). Expired air and heart rate were monitored continuously, and blood samples were collected from an antecubital vein at rest and in the last 30 seconds of each stage for measurement of glucose, lactate and BHB (Randox Daytona). **Results** Ingestion of BHB produced acute nutritional ketosis with plasma BHB concentrations at 1 mM. This resulted in an increase in RER (0.03 to 0.05; p<0.05) versus water during each stages. Heart rate averaged 6 to 9 bpm higher (p<0.05) with ketone supplementation versus water. No differences in VO₂ (L/min) or gross efficiency were observed at any stage of exercise. Delta efficiency was higher with ketone supplementation at 60% VO₂peak (CON, 22.1±1.4% vs. KET, 24.6±2.1%; p<0.05). **Discussion** Acute ingestion of BHB salts alters the metabolic response to exercise in trained male cyclists. The increase in RER is indicative of ketone oxidation, suggesting that the muscle is utilising BHB during exercise. Plasma glucose and lactate concentrations remain to be determined before inferences about substrate utilization can be made. Ongoing work is increasing the n-size and will compare differences, if any, for the effects of acute ingestion of BHB salts on male and female cyclists.

CHANGES IN MUSCLE GLYCOGEN, BODY COMPOSITION, AND ENDURANCE PERFORMANCE DURING 72-HOUR CARBOHYDRATE LOADING WITH EXCESS ENERGY INTAKE

SHIOSE, K., YAMADA, Y., MOTONAGA, K., SAGAYAMA, H., HIGAKI, Y., TANAKA, H., TAKAHASHI, H.

Japan Insititute of Sports Sciences

Introduction Consuming a high-carbohydrate diet for a few days increases muscle glycogen stores (CHO loading). In practical settings, energy intake (EI) during CHO loading tends to exceed the habitual level in order to ingest the requisite carbohydrate amount (10–12 g/kg body mass [BM/d, Burke et al.]). However, few studies have been conducted on the effect of CHO loading with excess EI on body composition and performance. This study aimed to reveal the effects of 72-h CHO loading with excess EI on muscle glycogen concentration, body composition, and endurance performance. **Methods** Eight subjects completed a glycogen-depletion session consisting of endurance and high-intensity intermittent exercise. For 72 h thereafter, the subjects consumed prescribed diets with 12 g/kg BM/d carbohydrate (energy 3686 ± 288 kcal/d, protein 77 ± 7 g/d, fat 33 ± 7 g/d, carbohydrate 770 ± 66 g/d), of which EI is exceeded the habitual diet (2089 ± 258 kcal/d, 73 ± 17 g/d, 65 ± 10 g/d, and 302 ± 51 g/d, respectively). Muscle glycogen concentration was assessed every 24 h after exercise by using ¹³C-magnetic resonance spectroscopy. A 3-compartment model of body composition (i.e., fat mass [FM], total body water [TBW], and fat-free dry solid [FFDS]) was assessed at baseline and 72 h after exercise by measuring body density and using the deuterium dilution technique. The endurance performance test requiring the accomplishment of individualized amount of work as fast as possible was completed at baseline and 72 h after exercise. **Results** Muscle glycogen concentration linearly increased after exercise and reached 2.4- ± 0.8-fold the baseline value at 72 h after exercise (P < 0.001). BM, TBW, and FFDS significantly increased, but FM significantly decreased 72 h after exercise (P < 0.05). Endurance performance significantly improved 72 h after exercise (P < 0.001). **Discussion** CHO loading for 72 h with excess EI increased BM, TBW, and FFDS. These changes were interpreted as increases in muscle glycogen and glycogen-binding water. FM decreased after CHO loading, despite the excess EI. In this study, the amount of carbohydrate intake was largely increased, but the amount of fat intake was reduced by 50% during CHO loading. Because de novo lipogenesis from

carbohydrate is negligible before glycogen stores are saturated, reduction in FM may be induced by reduction in fat intake and glycogen-depletion exercise-related lipolysis. The results of our body composition and performance analyses suggest that CHO loading with excess EI can help improve endurance performance. Reference Burke et al. NUTRITIVE ADMINISTRATION OF CARBOHYDRATES AND PROTEIN INHIBITS SKELETAL MUSCLE INFLAMMATION AND DAMAGE AFTER ACUTE ENDURANCE EXERCISE

DIEL, P., LE VIET, D., HUSS, J., GEISLER, S.

Deutsche Sporthochschule Köln

Scientific Background: Protein ingestion has been recently described to enhance the effects of carbohydrate drinks on skeletal muscle recovery. The aim of this study was to investigate the beneficial effects of a co-ingestion of carbohydrate and protein by food in amateur sportsmen. Methods: 16 male subjects performed a 10km run at 80% of individual ANS. Immediately after exercise subjects ingest either nothing (control), carbohydrates by eating white bread, or a combination of carbohydrates and protein by eating white bread and a sour milk cheese. Blood samples were taken at different time points. Serum glucose, serum insulin, serum creatine kinase (CK) and the serum levels of IL6, IL 10, MIF and TNF alpha were determined. Results: Blood glucose was increased by endurance exercise. Blood glucose levels decreased rapidly after exercise, here the strongest decrease could be observed in the bread /cheese group. Food uptake results in strong increase of serum insulin not differing between bread and bread/cheese. CK serum levels as a marker for skeletal muscle damage strongly increased 24h after exercise in the control and bread group but not in the bread cheese group. Exercise resulted in an increase of serum IL 6 and MIF which was reduced in the bread/cheese group. Serum IL 10 was increased by bread/cheese ingestion. TNF alpha serum concentration was decreased by exercise. This decrease was antagonized by bread/cheese ingestion. Conclusion: Our data demonstrate that uptake of a combination of protein and carbohydrate by food immediately after endurance exercise effect's physiological responses like blood glucose levels of the individual's and antagonize the induction of serum CK, a marker of skeletal muscle damage. Moreover this nutritive carbohydrate/protein uptake seems to influence the inflammatory response of the skeletal muscle indicated by reduced concentrations of proinflammatory markers and an increase of anti-inflammatory markers.

COMPETING AT ALTITUDE: DOES NATURAL ALTITUDE TRAINING OR SIMULATED LIVE HIGH: TRAIN LOW PROVIDE ATHLETES WITH THE BEST PREPARATION?

CARR, A.J.1, GARVICAN-LEWIS, L.A.2,3, VALLANCE, B.S.4, DRAKE, A.P.5, SAUNDERS, P.U.2, HUMBERSTONE, C.E.2, GORE, C.J.2

1: Deakin University (AUS), 2: Australian Institute of Sport (AUS), 3: Australian Catholic University (AUS), 4: Maribyrnong Sports Academy (AUS), 5: England Athletics (UK)

Introduction Natural altitude training is considered optimal for competition at moderate altitude (2000-3000m) (Mazzeo, 2008), however it remains untested if the same is true at low altitude (600-2000m). Potentially, other altitude training methods such as simulated live high: train low (LHTL) could also facilitate effective acclimation and improved performance at low altitude. This study aimed to compare the effects of natural altitude training and simulated LHTL with a control group, on mean blood lactate concentration [La_-], time to exhaustion (TTE) and endurance performance at low natural altitude (~1400m). Methods Twenty-two elite-level, male ($n = 15$) and female ($n = 7$) race-walkers completed 14 days of either: low natural altitude ($n = 7$; living and training at 1380m in Thredbo, Australia); simulated LHTL ($n = 7$; 14h.d-1 at 3000m simulated altitude); or control ($n = 8$; living and training at 600m). A 5 x 2km race-walking performance test, and incremental treadmill test incorporating time to exhaustion (TTE) were performed at 1380m altitude Before and After the intervention. A one-way ANOVA was performed to determine differences between groups, with statistical significance set at $p < 0.05$. Magnitude-based inferences were used to analyse the likelihood of differences between groups exceeding the smallest worthwhile change (SWC) in each variable, which was set at 0.2 of the between-subject standard deviation at baseline. Results There was a significant, post-intervention decrease in [La_-] in both the natural altitude ($p = 0.048$) and simulated LHTL ($p = 0.01$) groups compared with control. For TTE, there were no significant differences between groups from Before to After, however the improvement in the simulated LHTL group compared with control was likely greater than the SWC. Similarly, race walking performance in the natural altitude group was likely improved from Before to After in comparison to control, a result that approached significance ($p = 0.07$). Discussion Our findings suggest that either natural altitude training or simulated LHTL can provide both physiological and performance benefits to athletes competing at ~1400m altitude. Whilst natural altitude training at or near the race altitude remains the likely most beneficial option for athletes competing at altitude, simulated LHTL may provide an alternative method to achieve some level of acclimation prior to competition at low altitude. PREDICTION OF INTERMITTENT CYCLING PERFORMANCE AT ALTITUDE FROM SEA LEVEL CRITICAL POWER

TOWNSEND, N.1, NICHOLS, D.1, RACINAIS, S.1, SKIBA, P.2, PÉRIARD, J.1

1. Aspetar Orthopaedic and Sports Medicine Hospital, Qatar; 2. Advocate Lutheran General Hospital, USA

Introduction The dose-response effect of altitude has been examined previously for VO_{2max} (Wehrlein & Hallen, 2006); but not critical power (CP) and work performed above CP (W'). The aim of this study was to develop an altitude prediction model of CP and W' requiring sea level values only for use in the work-balance intermittent CP model (W'BAL model) at any altitude. Methods Nine trained, male cyclists (mean \pm SD; age 34 ± 6 yr, VO_{2peak} 4.57 ± 0.47 L·min⁻¹) completed a series of 3 cycling time trials (TT; 12, 7 and 3 min), to determine critical power (CP) and work performed above CP (W') at five simulated altitudes (250, 1250, 2250, 3250 and 4250 m). Least squares regression was used to establish a prediction model of CP and W' for altitudes up to 4250 m. On separate days, an intermittent exercise test incorporating three 'all out' sprints followed by a 3 min TT was performed at 250 m and 2250 m. Predicted and actual CP + W' at

2250 m were used to compute W' remaining in the intermittent test using both the differential (W'BALdiff) and integral (W'BALint) forms of the W'BAL model. Mixed linear modeling was used to assess the effect of altitude on CP and W', and t-tests were used to examine differences between predicted or actual modeled W'BAL, and versus a criterion value of 0 kJ at end test. Results Critical power decreased significantly at all altitudes ($P<0.001$), which was described by a 3rd order polynomial function ($R^2 = 0.99$). A significant decline in W' was also found, but only at 3250 m ($P=0.03$) and 4250 m ($P=0.01$). A double-linear function characterised the effect of altitude on W' ($R^2 = 0.99$). Upon completion of the 3 min TT in the intermittent test at 2250 m, W'BALdiff computed from actual (-1.29 ± 3.48 kJ) was not different to predicted (-1.08 ± 3.27 kJ; $P=0.65$). Also, W'BALint was not different between actual modeled (-2.83 ± 2.75 kJ) and predicted modeled (-2.61 ± 2.56 kJ; $P=0.67$). Compared to W'BAL = 0 kJ at end test, no difference was found for W'BALdiff at either 250 m ($P=0.33$) or 2250 m ($P=0.30$). However W'BALint was underestimated at 250 m approaching significance ($P=0.06$), and significantly at 2250 m ($P=0.02$). Conclusion The altitude prediction model for CP + W' developed in this study is suitable for use in the W'BAL model under acute hypoxic conditions. The differential W'BAL equation was found to model intermittent cycling performance effectively at both 250 m and 2250 m, however the integral W'BAL model appeared to underestimate actual performance. We recommend use of the differential W'BAL model for tasks involving maximal effort, short duration sprint intervals. References Wehrlein & Hallen (2006). Eur J Appl Physiol (2006) 96: 404–412

CARDIORESPIRATORY RESPONSES DURING NORMOBARIC HYPOXIC EXERCISE: COMPARISON BETWEEN ADULTS AND CHILDREN

DEBEVEC, T., KAPUS, J., UŠAJ, A., MCDONNELL, A.C., VODIČAR, J., NAJDENOV, P., JAKOVLJEVIĆ, M., JAKI MEKJAVIĆ, P., MLINAR, T., ŽVAN, M., DOLENC GROŠELJ, L., MEKJAVIĆ, I.B.

Jozef Stefan Institute

Introduction Exposure to altitude and/or normobaric hypoxia reduces aerobic performance in a dose-dependent manner (Wehrlein, et al., 2006). Albeit recent investigations (Kriemler, et al., 2016), it currently remains unclear if hypoxia-induced performance reduction is similar in adults and children. The present study aimed to elucidate whether cardio-respiratory responses during submaximal normoxic and hypoxic exercise are comparable between adults and children. Methods Twenty-six healthy, low-altitude residents (Adults, $N=13$, Age= 40(4) yrs., Body mass: 73(12) kg; Children, $N=13$, Age= 8(2) yrs., Body mass: 29(7) kg) were tested in normoxia (Nor: $\text{FiO}_2=0.209$; $\text{PiO}_2=134(0.4)$ mmHg; 940m) on Day 1 and normobaric hypoxia (Hyp: $\text{FiO}_2=0.162\pm 0.003$; $\text{PiO}_2=105(0.6)$ mmHg; ~3000 m) on Day 2 following an overnight hypoxic acclimation (≥ 12 -hrs). On both days the participants underwent a graded exercise test on a cycle-ergometer (30W·2-min-1) and a simulated skiing protocol on a Pro Ski simulator (3 bouts of 2-min skiing). Minute ventilation (VE), oxygen uptake (VO_2), capillary-oxygen saturation (SpO_2) and heart rate (HR) responses were measured continuously during all tests. The graded exercise data were interpolated for two relative workload levels (1 W·kg⁻¹ & 2 W·kg⁻¹). The data from the third exercise bout on the skiing ergometer was used for the analysis. Results Resting SpO_2 was significantly lower in hypoxia (Nor: 97(1)%; Hyp: 91(2)%; $P<0.01$), with no differences between groups. Higher resting HR in hypoxia, compared to normoxia was only noted in Children (Nor: 78(17); Hyp: 89(17) beats/min; $P<0.05$). Minute ventilation, O_2 uptake and HR responses were higher during the hypoxic graded test in both groups ($P<0.05$). Greater change in minute ventilation between normoxic and hypoxic cycling at 2W/kg was observed in Adults as compared to Children ($P<0.05$). Except for greater HR response during hypoxic vs. normoxic skiing in Children (Nor: 155(19); Hyp: 167(13) beats/min; $P<0.05$), all other skiing protocol responses were comparable between groups. Discussion Our data demonstrate comparable cardiorespiratory responses to submaximal hypoxic exercise in adults and children and corroborate recent findings of Kriemler et al. (2016) obtained during maximal exercise at terrestrial altitude. While the observed greater hypoxia-induced HR response in children was reported previously (Springer, et al., 1991), the underlying mechanisms remain to be elucidated. POSITIVE EXPIRATORY PRESSURE IMPROVES ARTERIAL AND CEREBRAL OXYGENATION IN SUBJECTS EXPOSED TO HYPOBARIC AND NORMOBARIC HYPOXIA

RUPP, T.1, SAUGY, J.J.2, BOURDILLON, N.2, VERGES, S.3, MILLET, G.P.2

Université Savoie Mont Blanc

Introduction Positive expiratory pressure (PEP) is commonly used in critical care medicine to improve gas exchange and has been shown to limit hypoxia-induced reduction in arterial oxygen saturation (Nespoulet et al., 2013). However, no analyses have been conducted so far to compare PEP efficiency depending on the type (normobaric vs. hypobaric; NH vs. HH) and the duration of the hypoxic exposure. The aim of this study was to assess arterial and tissue oxygenation while using a PEP device after prolonged exposure to simulated (NH) vs. real (HH) altitude. Methods Fifteen healthy volunteers completed three randomized sessions consisted in 24 h of exposure to either normobaric normoxia (NN, inspired O₂ fraction: $\text{FiO}_2=20.9\%$), NH (hypoxic room 3450 m, $\text{FiO}_2=13.6\%$, barometric pressure: PB=716 mmHg, inspired O₂ pressure: $\text{PiO}_2=91$ mmHg) or HH (Jungfraujöch 3450 m, $\text{FiO}_2=20.9\%$, PB=481 mmHg, $\text{PiO}_2=91$ mmHg). After the 6th (+6h) and the 22nd (+22h) hours of exposure, subjects wore a face-mask allowing 2 x 5 min of quiet PEP (10 cmH₂O) breathing interspaced with 5 min of free breathing. Arterial (SpO_2 , pulse oximetry), quadriceps (Mox) and cerebral (Cox) oxygenation (near-infrared spectroscopy), mean cerebral artery blood velocity (MCAv, transcranial Doppler), ventilation and cardiac function, were recorded continuously. Responses to PEP were average over the two 5-min periods for each time point. Results SpO_2 before PEP was significantly lower in HH (87% on average for both time points) compared to NH (91%) and NN (97%), and SpO_2 was higher at +22h compared to +6h. PEP did not affect SpO_2 in NN but increased SpO_2 similarly in NH and HH (+4.3±2.5 and +4.7±4.1%, respectively at +6h and +3.5±2.2 and +4.1±2.9%, respectively at +22h), the SpO_2 increase being significantly higher at +6h compared to +22h. When pooling all conditions, an inverse correlation was shown between SpO_2 value before PEP and the amplitude of PEP-induced increase in SpO_2 ($R=-0.7$). Cox was significantly improved with PEP in both NH and HH ($P<0.05$) with no difference between sessions. Mox was not affected by PEP. MCAv was reduced by PEP, whatever the session or the time point considered (-6.0±4.2 cm/s on average). Discussion Data indicate that PEP could be an attractive non-pharmacological tool to improve arterial and cerebral oxygenation under both normobaric and hypobaric mild hypoxic conditions in healthy subjects. Future research should explore the relationship between such optimisation of arterial and tissue oxygenation despite a potentially threatened brain perfusion, and the development of acute mountain illnesses during higher and/or longer (chronic) altitude sojourns. References Nespoulet H. et al. (2013). Plos One, 23;8(12) e85219.

INFLUENCE OF HYPERHERMIA AND HYPOXIA ON PERFORMANCE AND PACING DURING A CYCLING TIME TRIAL

PÉRIARD, J.D., RACINAIS, S.

Aspetar Orthopaedic and Sports Medicine Hospital

Introduction The regulation of prolonged self-paced exercise has received considerable interest over the last decade with various models of regulation having been proposed to modulate performance (Abbiss & Laursen, 2008; Edwards & Polman, 2013; Roelands et al., 2013). The aim of this study was to examine the influence of alterations in maximal oxygen uptake ($\dot{V}O_{2\text{max}}$) in mediating performance and pacing during prolonged time trial exercise in cool, hot and hypoxic conditions. **Methods** Twelve well-trained cyclists completed a 750 kJ time trial in temperate (COOL, 18°C), hot (HOT, 35°C) and hypoxic (HYP, 18°C, $F_iO_2: 0.145$) conditions, creating models with a stable, progressively decreasing, and acutely decreased $\dot{V}O_{2\text{max}}$, respectively. Power output, cardiorespiratory, temperature and perceptual measurements were taken throughout the time trials. Results Trial completion was faster in COOL (48.2 ± 5.7 min) compared with HOT (55.4 ± 5.0 min) and HYP (60.1 ± 6.5 min) ($P < 0.001$), with HOT being faster than HYP ($P = 0.028$). Core temperature reached 39.0 ± 0.6 °C (COOL), 39.8 ± 0.5 °C (HOT) and 38.5 ± 0.4 °C (HYP; $P < 0.01$). Power output during COOL was higher than HOT from 40% of work completed onward ($P < 0.05$) and for the entirety of HYP ($P < 0.001$), in which it was lower than HOT at 20–30% ($P < 0.05$). Normalized power output during COOL and HYP varied by ~13% and ~16% respectively, whereas a ~27% variation occurred in HOT. $\dot{V}O_2$ in COOL was higher than HOT from 70% onward ($P < 0.01$) and higher than HYP throughout exercise ($P < 0.001$). Relative to baseline $\dot{V}O_{2\text{max}} (\% \dot{V}O_{2\text{max}})$ in normoxia (COOL and HOT) and hypoxia (HYP), % $\dot{V}O_{2\text{max}}$ during HOT ($78 \pm 8\%$) was lower than COOL ($84 \pm 7\%$; $P = 0.005$) and HYP ($87 \pm 5\%$; $P = 0.003$). The rating of perceived exertion increased in all condition ($P < 0.001$) with the rise in HOT being greater than HYP ($P = 0.029$). Thermal discomfort increased in all conditions ($P < 0.001$) and significantly more so in HOT ($P < 0.001$). **Conclusions** Despite an acutely reduced $\dot{V}O_{2\text{max}}$ and power output in HYP, pacing and % $\dot{V}O_{2\text{max}}$ were similar to COOL. In contrast, the progressive decrease in $\dot{V}O_{2\text{max}}$ and power output in HOT resulted in a more variable pacing pattern with % $\dot{V}O_{2\text{max}}$ decreasing throughout exercise. These data support the premise that pacing is associated with maintaining an optimal performance intensity (Périard & Racinais, 2015), in conjunction with acute and progressive alterations in $\dot{V}O_{2\text{max}}$. **References** Abbiss CR & Laursen PB. Oral presentations**OP-BN16 Muscle & Tendon Architecture****INSUFFICIENT ACCURACY OF THE ULTRASOUND-BASED DETERMINATION OF THE ACHILLES TENDON CROSS-SECTIONAL AREA**

BOHM, S.1, MERSMANN, F.1, SCHROLL, A.1, ARAMPATZIS, A.1

1: Humboldt-Universität zu Berlin

Introduction The accurate assessment of the Achilles tendon cross-sectional area (CSA) is a crucial prerequisite to investigate morphological tendon plasticity and to calculate the tendon Young's modulus (i.e. material properties) (Arampatzis et al., 2007). Besides the established magnetic resonance imaging (MRI), ultrasonography emerged as an alternative imaging technique for the measurement of the tendon CSA. The purpose of the present study was to assess the objectivity and reliability of the ultrasound-based methodology and its validity with respect to an MRI-based assessment. **Methods** The Achilles tendon CSA of 17 healthy male participants (27.8 ± 3.9 yrs., 180.3 ± 6.7 cm, 76.3 ± 8.5 kg) was assessed by means of ultrasonography at the proximal, medial and distal position of the free tendon five times each on two separate days and three independent observers segmented the CSAs. For the validation, MRI-based CSA measurements were provided accordingly. **Results** The objectivity and reliability analysis of the ultrasound-based method revealed significant observer and measurement day effects ($p < 0.05$), despite high intra-class correlation coefficients for the three observers (>0.93) and for both days (>0.89), respectively. The typical percentage error between both days was in average 7.1%. Comparing both methods, ultrasonography underestimated (19% in average) the CSA values obtained by MRI ($p < 0.05$). Although the correlation coefficients of both methods were high in all three positions (>0.88), the respective range of the limits of agreement (Bland and Altman, 1986) of up to $+28 \text{ mm}^2$ and -2 mm^2 evidence considerable inconsistency. **Discussion** The results of the present study provide evidence of strong limitations of the ultrasound-based Achilles tendon CSA determination methodology regarding the three major test quality criteria. Besides the dependency of the CSA determination from the observer, the ultrasound method is not sensitive enough to detect physiological changes in Achilles tendon morphology, as reported for longitudinal intervention studies (Arampatzis et al., 2007; Bohm et al., 2014). Furthermore, the validity analysis revealed a lack of agreement between both methods, since the ultrasound technique provided CSA values from 36% below to 3% above (i.e. relative limits of agreement) those determined by MRI as the accepted gold standard. Therefore, the ultrasound-based methodology cannot be recommended for the accurate Achilles tendon CSA determination *in vivo*. **References** 1. Arampatzis et al. (2007). EFFECTS OF KNEE COOLING ON IN VIVO PATELLAR TENDON MECHANICAL PROPERTIES

ALEGRE, L.M.1, HASLER, M.2, WENGER, S.2, NACHBAUER, W.3, CSAPO, R.3

1. University of Castilla-La Mancha (Spain), 2 & 3. University of Innsbruck (Austria)

INTRODUCTION Controversy exists regarding the temperature dependency of tendon mechanical properties (Kubo et al., 2005; Muraoka et al., 2008). Specifically, no studies have investigated the effects of knee cooling on the *in vivo* human patellar tendon. Therefore, the aim of this study was to assess the material properties of the patellar tendon before and after local ice application. **METHODS** Twenty young, healthy women volunteered for the study. B-mode ultrasonography was used to record patellar tendon elongation during isometric ramp contraction of the knee extensors (5–7 s, 90° knee angle), and calculate tendon stiffness, Young's modulus as well as maximum strain and stress. Skin temperature was measured by infrared thermometry. Data were acquired before and after 30 min of local icing of the knee joint and compared by paired samples t-tests. **RESULTS** After cold exposure, skin temperature at the patellar tendon dropped from 26.1 ± 1.7 to 9.3 ± 2.1 °C. Tendon stiffness and Young's modulus increased from 2189 ± 551 to $2705 \pm 902 \text{ N} \cdot \text{mm}^{-1}$ (+24%, $p = 0.007$) and

1.32 ± 3.4 to 1.60 ± 4.9 GPa (+21%, p=0.010), respectively. Tendon strain decreased from $8.6 \pm 1.6\%$ to $7.8 \pm 1.4\%$ (-10%, p=0.004). A small, albeit significant reduction in maximum tendon force was observed (from 5148 ± 1176 N to 4957 ± 1048 N, -3.7%, p=0.03). DISCUSSION Our data show a significant impact of local cold exposure on in vivo patellar tendon mechanical properties, especially on tendon stiffness and Young's modulus. The observed tendon stiffening may influence the operating range of sarcomeres, limiting the force generation capacity of knee extensor muscles acting on the descending limb of the length-tension curve. On the other hand, the increased stiffness might benefit rate of force development, thus countering the consequences of reduced enzymatic activity described for muscles under cold exposure (Drinkwater & Behm, 2007). Even more, a stiffer tendon would facilitate more accurate joint control (Rack & Ross, 1984). In conclusion, we found a significant impact of local cold exposure on in vivo patellar tendon mechanical properties, which is assumed to influence quadriceps muscle function, especially in explosive contractions. CONTRIBUTION OF BICEPS BRACHII TENDON MECHANICS TO FORCE STEADINESS IN YOUNG AND OLD ADULTS

SMART, R.R., BAUDRY, S., FEDEROV, A., AREFIN, S., JAKOBI, J.M.

University of British Columbia Okanagan

Introduction: Age-related decline in force steadiness (FS) is attributed to differences in absolute strength (1) as well as neural mechanisms associated with motor unit discharge rate variability, and inter-muscular coherence (2). However, muscle force is transmitted through the tendon and the age-related differences in tendon properties (3) have not been previously considered in upper-limb force control. Thus, the purpose of this study was to determine the contribution of the biceps brachii (BB) tendon to age-related decline in low levels of force steadiness in young and old adult men. It was hypothesized that a more compliant tendon in the old men would reduce force control during low-force matching tasks. Methods: Seven young (23 ± 4 yrs) and five old (81 ± 3 yrs) men participated in the present study. Isometric elbow flexion maximal voluntary contractions (MVC) were performed as well as submaximal targets at 2.5, 5, 10, 20, 40 and 60% MVC in a neutral position. Submaximal target forces were held for 5 seconds to assess force steadiness using the coefficient of variation (CV) in force around the target level. Tendon elongation and cross-sectional area were recorded for submaximal contractions with ultrasound to obtain tendon mechanical properties at 2.5% MVC. Surface electromyography (sEMG) of the BB short and long head, and lateral triceps were recorded. Results: Young men (254.8 ± 52.3 N) were stronger than old men (206.8 ± 30.3 N) (p=0.056). Young had lower CV ($1.1 \pm 1.6\%$) of force compared with old ($2.1 \pm 1.0\%$) for all submaximal contractions (p<0.001). Surface EMG was similar between young and old. Tendon elongation was greater in old (2.7 ± 1.7 mm) compared to young (1.2 ± 0.6 mm) (p=0.06) at 2.5% MVC. Young (35.7 ± 20.5 N/mm) had greater tendon stiffness than old (9.8 ± 5.6 N/mm) at 2.5% MVC (p=0.04), and stiffness was moderately correlated with force steadiness (r=0.51). Young's modulus was higher in young (1583.7 ± 921.1 GPa) compared with old (617.9 ± 547.4 GPa) (p=0.06). Discussion: These results indicate that young men are steadier than old men, and this difference might be due to a stiffer tendon improving force transmission from muscle to bone. Thus, changes in tendon mechanics with aging play a key role in older adults' ability to perform precise motor tasks of the elbow flexors. 1. Brown RE et al. (2010). DIFFERENTIAL STRAIN OF THE GASTROCNEMIUS TENDON DURING ISOMETRIC PLANTARFLEXION IN DIFFERENT FRONTAL PLANE FOOT POSITIONS

WOLFRAM, S., MORSE, C.I., HODSON-TOLE, E.F., WINWOOD, K.L., MCEWAN, I.M.

Manchester Metropolitan University

Introduction The Achilles tendon (AT) is one of the most commonly injured sites in the human body. Tissue degeneration has been identified as the main cause (Kannus & Jozsa 1991), which may be influenced by shear forces and non-uniform strain distribution in the tendon. Non-uniform strain may be the result of rearfoot posture as the triceps surae is not only a plantarflexor, but also exerts inversion/eversion moments at the calcaneus (Arndt et al. 1999). The purpose of this study was to investigate possible strain differences in the gastrocnemius tendon by quantifying the displacement of the muscle-tendon junction (MTJ) of the lateral (GL) and medial (GM) heads of gastrocnemius. Methods 16 participants (9 male, 7 female, 26.3 ± 4.7 years) performed ramped isometric plantarflexions to 80%MVC with their left foot while the foot was in 10° eversion, 0° neutral and 10° inversion. Ultrasound imaging was used to determine MTJ displacement of GL and GM. Resting length of the GL and GM tendon was measured with a tape measure after marking the GL and GM MTJ and AT insertion on the calcaneus on the skin under ultrasound guidance. Strain was calculated from displacement and resting length. A One-Way ANOVA was used to test for statistical differences between the three foot positions. Differences between GL and GM were tested with a paired-samples t-test (both alpha=0.05). Results GL tendon strain at 80%MVC was $6.5 \pm 2\%$ in eversion, $6.4 \pm 2\%$ in neutral and $6.3 \pm 2\%$ in inversion. Strain of the GM tendon was 8.2 ± 2 in eversion, 8.4 ± 2 in neutral and 8.1 ± 2 in inversion at 80%MVC. There was no significant difference in strain for GL or GM between the three foot positions. Strain did not differ between GM and GL at lower contraction levels, but a significantly higher strain was found for GM tendon than GL tendon at 70%MVC (p=0.38) and 80%MVC (p=0.01). Discussion A difference in gastrocnemius tendon strain was not found in different frontal plane foot positions. However, GM tendon strain significantly exceeded that of the GL tendon at higher activation levels. This suggests that GM was more activated than GL contributing more to the overall ankle torque. This may be the result of the higher physiological cross-sectional area of GM (Albracht et al. 2008). Further investigation into the effect of frontal plane foot posture and GL and GM function on AT strain distribution is necessary to better understand the aetiology of injury and to improve lower leg muscle models. ACUTE EFFECTS OF LAB- AND FIELD-BASED CONTRACT-RELAX AND MODIFIED CR STRETCHING ON KNEE FLEXOR MUSCLE-TENDON MECHANICS

KAY, A.D., DIXON, J., BLIGH, L.D., BLAZEVICH, A.J.

The University of Northampton

Introduction Similar mechanical and neurological changes have recently been reported at the ankle following traditional contract-relax (CR) stretching and a modified contract-relax (MCR) technique where the contraction phase was performed 'off stretch' (Kay et al., 2016).

However, as these techniques were performed in a dynamometer, the efficacy of the modified technique in an athletic environment remains unknown. Therefore, the acute effects of both techniques were examined in lab- and field-based environments. Methods Using a randomised, cross-over design, 17 recreationally active subjects performed the CRlab, CRfield, MCRLab and MCRfield hamstring stretches (4 x 10-s stretches + 5-s contractions) on separate days. Before and after the stretches, maximal isometric and passive knee flexor moment and knee extension range of motion (ROM) were recorded on an isokinetic dynamometer. Semitendinosus electromyographic (EMG) activity was recorded simultaneously, whilst ultrasound imaging was used to record biceps femoris tendon elongation. Results Significant increases in knee extension ROM (4.6-5.2°; P < 0.01) and elastic energy potential (12.0-23.6%; P < 0.05), and decreases in the slope of the passive moment curve (8.9-12.2%; P < 0.05) and tendon stiffness (10.8-15.1%; P < 0.05) were observed in all conditions. A significant increase in peak passive moment (i.e. stretch tolerance) was observed after field-based stretches only (14.3-14.8%; P < 0.01). No significant change (P > 0.05) in maximal isometric strength, or volitional or reflexive EMG was observed in any condition. A significantly greater increase in elastic energy potential was observed following field- than lab-based stretches (P < 0.05), however no difference in between-condition changes was found in any other measure (P > 0.05). Conclusion The similar mechanical changes observed after CR and MCR stretching in lab- and field-based environments are indicative of common underlying mechanisms explaining the analogous ROM improvements. These data confirm both the efficacy of the MCR stretch technique to enhance knee flexor ROM and the ecological validity of performing this technique in an athletic environment. The implications for current practice are substantial as subjects completed the MCR technique without partner assistance, yet achieved similar acute increases in ROM as traditional CR stretching (i.e. the most effective stretching model). Thus, the MCR stretching technique represents an equally effective yet more practical stretching paradigm. References Kay AD, Dods S, Blazevich AJ. (2016). ACHILLES TENDON ADAPTATION TO NEUROMUSCULAR ELECTRICAL STIMULATION

LETOCART ADRIEN, J., GROSSET, J.F.

Université de technologie de Compiègne

Achilles tendon adaptation to neuromuscular electrical stimulation Running head: NMES and tendon adaptations Abstract Purpose: Neuromuscular electrical stimulation (NMES), used as strength training mode, is known to improve neuromuscular function in healthy individuals with an increase in maximal voluntary contraction (MVC) as the main result. However, it remains unknown if NMES can induce tendon stress enough to lead to changes in tendon architecture or mechanical properties. Thus, the present study aimed to investigate the effect a long term NMES training program of the triceps surae (TS) muscle on architectural and mechanical properties of the Achilles tendon (AT) changes. Methods: Eight young male subjects (27± 3.5 yr) performed a 12 weeks high frequency NMES training program of TS muscle under isometric condition. Achilles tendon architecture was assessed using ultrasonography at rest to investigate changes following NMES training in free AT length, total AT length between musculotendinous junction (MTJ) between medial gastrocnemius and Achilles tendon insertion to calcaneus, and cross sectional area (CSA) at 25%, 50% and 75% of the free AT length. Mechanical properties of the musculotendinous junction between medial gastrocnemius and Achilles tendon were investigated from force and ultrasonographic measurements during maximal isometric ramp contractions. Results: NMES training did not lead to significant changes in the maximum elongation capability, free and total AT length, and AT CSA. Significant increase has been evidenced following a 12-weeks NMES training period in AT force (+25.2%), and stiffness (+5.2%) (P<0.05). After normalization with regard to Achilles tendon dimensions and moment arm, Young's modulus and maximal stress show significantly increase after NMES intervention (+12.4 and 23.4% respectively) (P<0.05). Conclusions: The present results highlight that a high frequency NMES training of the triceps surae muscle over 12 weeks induce a repeated stress sufficient enough to lead to impaired mechanical properties of the Achilles tendon. Thus, high frequency NMES could be an adjunct method for tendinopathy rehabilitation. Moreover, these results suggest that NMES may also be used to induce muscle and tendon stress enough to lead to adaptations during an imposed hypo-activity forbidding external work and then at least attenuate atrophy phenomenon. OP-BN10 Muscle Function

INTER-MUSCLE DIFFERENCES IN HAMSTRINGS STRAIN DURING A STRAIGHT LEG RAISE TEST: AN ELASTOGRAPHY STUDY

KAWAKAMI, Y., KOMIYA, M., IKEDA, N., INAMI, T.

Waseda University

Introduction Muscle's shear modulus (SeM) measured with ultrasound elastography method, changes as a function of joint angle [1] due to strain increase within a passively stretched muscle. Inter-muscle differences in SeM were also reported for the same joint angle: the medial gastrocnemius showing the highest stiffness [1] has a shorter muscle belly length [2] compared to the soleus showing the lowest stiffness. Thus, presumably relatively larger length change of a shorter muscle causes the higher differences in SeM. This may apply to the hamstrings having different muscle belly lengths: semimembranosus (SM) = semitendinosus (ST) < biceps femoris (BF). The aim of this study was to test the hypothesis that SeM is in reverse order with the lengths of hamstring muscles. Methods Ten healthy males (22 +/- 1 yr) participated. In a supine position, the pelvis of a participant was secured to the bed and the fully extended knee joint was fixed to a lever arm of an isokinetic dynamometer. SeM from SM, ST, and BF (long) and hip joint torque were measured during a Straight-Leg-Raise test. The hip joint was changed from 40° (0=full extension) to 70° (ascending) with 10° increments, then from 70° to 40° (descending). Based on Hawkins and Hull [3], muscle-tendon unit lengths were estimated and relative changes in length (dL) were calculated to determine the dL-SeM relationship. The change of the area under the dL-SeM curves in the ascending and the descending phases was used as an index of hysteresis. One-way analysis of variance and multiple comparisons with Bonferroni correction were performed with a significance level of p < 0.05. Results and Discussion The passive hip extension torque and SeM of all muscles increased during hip flexion and decreased during hip extension with a significant amount of hysteresis. SM exhibited significantly higher SeM than other muscles at all angles studied as well as the ascending/descending slopes of dL-SeM curves. Our results showing inter-muscle strain

differences of hamstrings with SM being the most affected suggest that SM is responsible for the limitations of the hip joint range of motion. This notion is consistent with the larger hysteresis of SM SeM (31%) compared to ST (17%) and BF (14%) which might be the sign of prominent stretching effect on SM. Presently shown differences between SM and ST does not support the initial hypothesis and suggests factors on SeM other than dL, such as fascicle length differences between hamstring muscles (SM < BF < ST) [4]. THE INFLUENCE OF SODIUM BICARBONATE ON MAXIMAL FORCE AND RATES OF FORCE DEVELOPMENT IN THE CALF AND TRICEP DURING FATIGUING EXERCISE IN HUMANS

SIEGLER, J., MARSHALL, P., MUDIE, K.

Western Sydney University

Introduction The effect of sodium bicarbonate (NaHCO_3) on fibre-specific maximal force production and rates of force development has been previously investigated in animal models (Broch-Lips et al., 2007; Higgins et al., 2013), with evidence suggesting an improved capacity to rapidly develop force (RFD) in fast- compared to slow-twitch muscle (Higgins et al., 2013). To date, these findings have not been replicated in the exercising human. In the present study, we have attempted to model *in vivo* the fatigue profile of maximal force and RFD in the calf (C) and triceps surae (TRI) after NaHCO_3 ingestion. Methods In a double-blind, 3-way repeated measures design participants ($n=8$) ingested either 0.3 g·kg $^{-1}$ NaHCO_3 (ALK) or equivalent calcium carbonate (PLA) prior to either 2-min of continuous (1Hz) supramaximal stimulation (300ms at 40Hz) of the C or TRI. Maximal voluntary efforts coupled with direct muscle stimulation of C or TRI were measured at baseline, 1-min and 2-min. Results Maximal voluntary force declined similarly over the 2-min in both muscles ($-50.1\pm5.1\%$; $p<0.001$) irrespective of ALK or PLA ($p=0.28$). Voluntary (v)RFDmax (normalised to maximal force) was higher in TRI compared to C throughout the trial (TRI: 10.0 ± 0.3 ; C: 4.9 ± 0.4 ; $p<0.001$), but displayed a similar decline (-2.0 ± 0.4 ; $p<0.05$). v RFDmax was higher in ALK than PLA (ALK: 7.8 ± 0.2 ; PLA: 7.2 ± 0.4 ; $p<0.05$). Maximal twitch amplitudes declined as a function of time for both C and TRI ($-33.5\pm4.2\%$; $p<0.001$), but were not different between ALK or PLA ($p=0.68$). Twitch (t)RFDmax (normalised to maximal twitch) was higher in TRI compared to C (TRI: 9.1 ± 0.5 ; C: 5.3 ± 0.3 ; $p<0.001$), and did not decline during the 2-min. Discussion Although v RFDmax was better maintained during the 2-min in the ALK condition, no differences were observed between the calf and triceps surae for electrically stimulated fatigue. These findings contrast with recent findings in murine models (Higgins et al., 2013), however may also be representative of the difficulty of measuring the effect of pH on different muscle groups *in vivo*. Although the muscle groups selected have been shown to be predominately fast- ($\sim 70\%$ in TRI (Johnson et al., 1973)) and slow-twitch ($\sim 80\%$ in C (Gollnick et al., 1974)), we cannot discount other processes intimately involved in attenuating fatigue (e.g. Henneman's size principle) in the exercising human. THE INFLUENCE OF TRUNK ORIENTATION ON LOWER LIMB KINEMATICS AND LEG FUNCTION

AMINIAGHDAM, S.I., BLICKHAN, R.I., MULLER, R.I., VIELEMAYER, J.I

Friedrich-Schiller-University Jena

Introduction Being almost half of the total body mass, the trunk and its alignment can have an important impact on human motion (De Leva, 1996). Walking with maintaining bent postures may interfere with the pendulum mechanism. The stance dynamics of walking could be approximated by a bipedal spring-mass model. Compliant leg behavior provides explanation for basic dynamics of walking and running (Geyer, 2006). By modelling compliant leg behavior along the leg axis as a parallel spring-damper system, we aim to investigate the contribution of a spring-damper system to the leg behavior as a function of trunk orientation. Methods Kinematic data (Qualisys, 240Hz) and kinetic data (Kistler, 1000 Hz) of 12 able-bodied adults (6 m, 6 f) were recorded while walking at self-selected normal speed with regular erect trunk alignment (RE) and fully flexed trunk (FT). Axial leg function was modelled as parallel spring and damper elements: $F_a = k (l_0 - l) - c_i (F_a)$, axial leg force; l_0 , spring rest length; l , instantaneous effective leg length; i , rate of change in the effective leg length. k and c are the effective leg stiffness and leg damping, respectively, obtained with a nonlinear fit by minimizing for each trial the sum of squared distances between measured forces and the forces calculated with equation (Andrade et al., 2014). Results Compared with RE gait, FT walking demonstrated significantly increased hip, knee and ankle flexion angles at TD and TO as well as greater peak hip and knee flexion angles along with greater ankle dorsiflexion and plantarflexion angles during the gait cycle. On contrary, hip, knee and ankle ranges of motion decreased. The angle of attack at TD and TO significantly decreased for FT (62; 112) compared to RE (66.1; 116), respectively. Effective leg length at TD remained almost unaffected ($P=0.514$), whereas effective leg length at TO significantly decreased by 5.7%. Compared to RE walking, dimensionless effective leg stiffness significantly decreased almost 2 times and damper increased 3.4 times during FT gait. Discussion Walking with fully flexed trunk was associated with drastic kinematic adaptions in lower limb joints necessary for maintaining dynamic balance (Saha et al., 2008). Effective damping property of the leg, induced by bent posture, was responsible for compensatory kinematic adjustments during FT gait. Gait with bent posture is hypothesized to influence leg function such as leg length, leg stiffness and leg damping; thus, our findings would shade further light on the interaction between trunk orientation and leg operation. REGIONAL ACTIVITY OF THE BICEPS FEMORIS AND SEMITENDINOSUS MUSCLES IN NORDIC HAMSTRING EXERCISE AND STIFF-LEG DEADLIFT

HEGYI, A., FINNI, T., PÉTER, A., CRONIN, N.J.

University of Jyväskylä

Introduction Sprinting-type hamstring strain injuries mainly occur in the biceps femoris (Malliaropoulos et al., 2010), with the highest incidence in the proximal region (Silder et al., 2008). It has been shown previously that during the hip-dominant stiff-leg deadlift exercise, biceps femoris is preferentially activated compared to other hamstring muscles (Ono et al., 2011), while in the knee-dominant Nordic hamstring exercise, the semitendinosus is primarily involved (Bourne et al., 2015), implying task-specific relative involvement of hamstring muscles. In this study, we examined whether proximal, middle and distal regions of the biceps femoris and semitendinosus are activated

heterogeneously during these exercises. Methods To date, 10 male subjects without previous hamstring injury have participated in this study, which is ongoing. 16-channel array electrodes were attached over the biceps femoris and semitendinosus muscles to record electromyographic activity from different muscle regions during the Nordic hamstring and stiff-leg deadlift exercises. Root-mean-square activities for the distal, middle and proximal regions of the muscles were calculated in the lengthening phase of the tasks and normalized to the activity in maximal voluntary isometric contraction. Regional differences were analyzed using one-way repeated-measures ANOVA. Significance level was set at $P<0.05$. Results During Nordic hamstring exercise, biceps femoris muscle activity was 22% lower in the proximal region compared to the distal region on average ($p<0.001$), while semitendinosus muscle did not show regional differences in muscle activity. However, in stiff-leg deadlift, no differences were observed between regions in either of the muscles. Discussion Our results imply that recruitment of biceps femoris muscle regions is heterogeneous and task-specific. Lower activity in the proximal region may be a contributing factor to region-specific muscle strain injuries. Future studies should determine whether these findings can be replicated in real-life movements associated with hamstring strains; and how lower contribution of the proximal region can be modified by training. EXPLOSIVE TORQUE CAPACITY AND FASCICLE BEHAVIOUR DURING ACCELERATED CONCENTRIC CONTRACTIONS

BAKENECKER, P., ZINKE, F., HAHN, D.

Ruhr-Universität Bochum

Introduction Rate of torque development (RTD) is considered to be a functionally more relevant neuromuscular measure than maximal voluntary torque. However, despite the fact that many movements are characterized by acceleration, RTD usually is still evaluated during maximal voluntary isometric contractions (MVC) and it has never been obtained for accelerated instead of isovelocity concentric contractions. Therefore, this study investigated explosive torque capacity and fascicle behaviour during isometric and fast concentric contractions of quadriceps femoris. Methods Ten participants performed an isometric contraction (ISO), an isovelocity and additional concentric knee extensions (CON) at given angular accelerations ranging from 700 to 4000°·s⁻² on a isokinetic dynamometer (IsoMed2000, D&R Ferstl, GmbH, Hemau, GER, 1 kHz) that all resulted in an angular velocity of 300°·s⁻¹ at 40° knee flexion. Participants performed three MVC at the ISO and all CON conditions, which resulted in a total of 30 MVCs. Ultrasound (LogicScan 128 CEXT-1Z Kit, Telemed, Vilnius, Lithuania, 103-124 Hz) of vastus lateralis was measured to determine muscle fascicle length, pennation angle and fascicle velocity (FV) under each contraction conditions. Muscle torque and ultrasound data from CON were always obtained at the target angle of 40°. Additionally torque at 40° knee flexion was corrected for inertia and the corresponding isometric torque was obtained at the specific time from contraction onset to the time when the target knee angle of 40° was reached during CON. Results While isometric explosive torque capacity decreased from 189.7±39.7 Nm (ISO700) to 139.0±46.1 Nm (ISO4000) because of reduced available contraction time and increasing FV, the corresponding time matched explosive torque capacity (ETC) during concentric contractions increased with acceleration from 100.2±28.4 Nm (CON0) to 134.5±31.6 Nm (CON4000) and equaled isometric torque capacity during accelerations $\geq 3000^{\circ}\cdot s^{-2}$. This was accompanied by a reduction in FV from 43.2±25.0 mm·s⁻¹ (CON0) to 24.1±15.1 mm·s⁻¹ (CON4000). Time matched fascicle length and pennation angle showed no significant differences between ISO and CON. Discussion Our results provide novel evidence that acceleration influences the explosive torque capacity during concentric contractions. Enhanced force production with increasing acceleration can be explained by decreasing FV and reduced force depression. Based on model calculations from exemplar data it further was shown that MTU velocity differed from horizontal FV in terms of reduced FV so that tendon shortening likely contributed to overall MTU shortening velocity. These findings demonstrate that there is a crucial influence contraction history and series elasticity on ETC during accelerated concentric contractions. Patrick.Bakenecker@rub.de

MOTOR ADAPTATIONS TO UNILATERAL QUADRICEPS FATIGUE DURING A BILATERAL PEDALING TASK

BRØCHNER NIELSEN, N., HUG, F., GUÉVEL, A., FOHANNO, V., LARDY, J., DOREL, S.

Laboratory « Movement, Interactions, Performance » (EA 4334), UFR STAPS, Université de Nantes, France

Purpose: We aimed to investigate how motor coordination adapts to unilateral fatigue of the quadriceps muscle during a constant-load bilateral pedaling task. We first hypothesized that this local fatigue would induce a decrease in the knee joint power. Then, we aimed to determine whether this decrease would be compensated by i) between-joints compensations within the ipsilateral leg, ii) an increased contribution of the contralateral leg or iii) both. Methods: Fifteen healthy volunteers were tested during 1-min pedaling tasks at 350 W (90 rpm) before and after a fatigue protocol consisting of 15-min of electromyostimulation on the quadriceps muscle. Motor coordination was assessed from myoelectrical activity (22 muscles), pedal forces and joint powers calculated through inverse dynamics. Results: Maximal knee extension force decreased by 28.3±6.8% ($P<0.0005$) immediately after electromyostimulation. A decrease in knee joint extension power produced by the ipsilateral leg during pedaling was observed (-22.8±12.3 W; $P<0.0005$). To maintain the task goal, participants primarily increased the power produced by the contralateral leg during the flexion phase. This was achieved by an increase in hip flexion power (+14.9±8.6 W, $P<0.0005$) confirmed by an increased activation of the tensor fascia latae muscle ($P=0.003$). Within-leg compensations in antiphase (i.e. flexion) were also observed in some, but not all, participants. Conclusion: These results provide evidence that the nervous system readily adapts to unilateral fatigue by preferentially compensating with the contralateral leg during the flexion phase, i.e., synchronously with the decreased knee extension power. This might be explained by both a strong neural coupling between legs and mechanical constraints.

OP-BN02 Neuromuscular

ACUTE WHOLE BODY VIBRATION IS ASSOCIATED WITH SPINAL AND SUPRASPINAL ADAPTATIONS

KRAUSE, A., FREYLER, K., GOLLHOFER, A., RITZMANN, R.

University of Freiburg

Introduction Whole body vibration (WBV) has been demonstrated to improve functional movement control (Rittweger, 2010), but the knowledge about the underlying neurophysiological mechanisms remains fragmentary: Investigations have shown an inhibition of spinal excitability shortly after WBV while corticospinal modulation has been reported to be facilitated – but during WBV, only. Especially evidence regarding the maintenance of adaptations following vibration has not been clarified, yet. Therefore, this study aimed to investigate the acute adaptations of corticospinal and spinal excitability to WBV in one study. Methods In 44 healthy subjects corticospinal (A) and spinal adaptations (B) were tested before (t1), immediately (t2), 2 (t3), 4 (t4) and 10min (t5) after a 1-min-bout of WBV (30Hz, 3mm). (A) Transcranial magnetic and (B) Peripheral nerve stimulation were applied respectively, with the changes in motor evoked potentials (MEP) and H-reflexes being assessed in the m. soleus (SOL) and the m. gastrocnemius medialis (GM) by an rmANOVA. Body position was controlled with background electromyography (EMG) of SOL, GM as well as m. tibialis anterior (TA) and goniometric recordings of ankle and knee joint excursions with equivalence statistics. Results After vibration, (A) MEPs were significantly elevated in SOL compared to baseline values (t2 +15%, t3 +22%, t4 +15%, t5 +20%; P<0.05), but did not change significantly in GM (t2 +32%, t3 +9%, t4 +8%, t5 +22%; P=0.07). In contrast, (B) H-reflexes were diminished for SOL (t2 -19%, t3 -21%, t4 -20%, t5 -14%; P<0.05) as well as GM (t2 -14%, t3 -16%, t4 -18%, t5 -16%; P<0.05). Statistical equivalence was observed for SOL background EMG, ankle and knee joint deflections for (A) as well as SOL and GM background EMG and ankle joint deflections for (B). Discussion After an acute bout of WBV, results revealed (A) a sustaining facilitation of corticospinal pathways concomitant with (B) a suppression in spinal circuits. Those effects persisted for a minimum of 10 minutes and might illustrate increased corticospinal excitability while spinal excitability is inhibited. Functionally, those adaptations may point towards increased voluntary motor control (Chen and Zhou, 2011; Nielsen and Petersen, 1995): Facilitation comprising the origin of supraspinal structures might be associated with greater central movement control. Especially for populations with neurological motor diseases affecting the locomotor system this finding might be beneficial regarding motor learning and voluntary movement execution. THE WILLINGNESS TO TOLERATE HIGHER LEVELS OF PERIPHERAL FATIGUE MIGHT EXPLAIN THE IMPROVED PERFORMANCE DURING HEAD-TO-HEAD CYCLING COMPETITIONS.

KONINGS, M.J.1, PARKINSON, J.1, MICKLEWRIGHT, D.1, ZIJDEWIND, I.2, HETTINGA, F.J.1

University of Essex

1: University of Essex, School of Biological Sciences, Centre for Sports and Exercise Science (Colchester, UK) 2: University of Groningen, UMCG, Center for Human Movement Sciences (Groningen, The Netherlands) Introduction Perceptual affordances provided by the environment could influence the maximal effort an athlete is willing to exert, and alter pacing behavior and performance (Smits et al. 2014). In this perspective, the presence of an opponent has been shown to improve cycling performance as result of a faster initial pace (Corbett et al. 2012). The present study aimed to explore the potential differences in the origin of fatigue that could explain the performance improvement when racing against opponents. Methods Twelve moderately trained participants completed a maximal incremental test and three 4-km time trials (TT) on a VeloTron cycle ergometer. After a familiarization TT (TTfam), participants performed in random order a TT with no opponent (TTno) or a virtual opponent (TToppo). Repeated-measures ANOVAs (p<0.05) were used to examine differences in pacing and performance related to power output, velocity, and finishing times. Measures of neuromuscular function for the assessment of central and peripheral fatigue were evaluated before and after the trial by delivering twin electrical stimuli (200- μ s duration; 10ms interval) to the right femoral nerve during MVC and at rest. In total three variables were obtained to quantify muscle performance; the maximal voluntary contraction (MVC), the voluntary activation (VA) and the potentiated twitch (PT). Results TToppo was completed faster compared to TTno (382.2±31.9s vs. 393.6±21.9s, P=0.022), mainly due to a faster initial pace during TToppo. The reduction in MVC was higher in TToppo compared to TTno (MVCpre-vs-post: -17.5±12.4% vs. -11.4±10.9%, P=0.032). This difference can be assigned to the higher levels of peripheral fatigue found after TToppo compared to TTno (PTpre-vs-post: -23.1±14.0% vs. -16.2±11.4%, P=0.041), while no differences were found for central fatigue (VApre-vs-post: -4.9±6.7% vs. -3.4±5.0%, P=0.274). Discussion The presence of a competitive opponent seems to enable the participants to use a greater degree of their physiologic capacity that is not fully accessed when competing alone. The present study has shown that the improved performance during head-to-head competitions compared to individual cycling time-trials could be assigned to the willingness to tolerate higher levels of peripheral fatigue. INFLUENCE OF ACHILLES TENDON STIFFNESS ON TORQUE STEADINESS IN YOUNG AND OLD ADULTS

JOHANSSON, J.1, JAKOBI, J.2, DUCHATEAU, J.1, BAUDRY, S.1

1 Université Libre de Bruxelles, Belgium 2 UBC, Okanagan, Canada

Introduction When an individual produces a constant torque during an isometric voluntary contraction, torque fluctuates around the target level (2). Those fluctuations decrease non-linearly with the increase in contraction intensity (6), and are greater in old than young adults(3) at low torque levels (<15%)(1). Even though the extent of torque steadiness has been associated with neural mechanisms (2), mechanical properties of the tendon could also influence the finite control of torque output (4), especially in old adults who experience an age-related decrease in tendon stiffness (5). As no study has investigated the influence of tendon stiffness on torque steadiness, the aim of this project was to investigate the influence of Achilles tendon stiffness on torque steadiness during submaximal isometric contractions in young and old adults. Methods 14 young (23.6±3.0yrs) and 14 old (71.3±5.1yrs) adults participated in the study. Torque steadiness was assessed as the coefficient of variation (CV) for torque during voluntary isometric contractions performed with the plantar flexor muscles

at 5, 10, 15, 20 and 30% of maximal torque. Achilles tendon cross-sectional area and stiffness, estimated from the force-elongation relation obtained from the displacement of the muscle-tendon junction of the gastrocnemius lateralis during isometric contractions, were assessed by ultrasonography. Results The CV for torque was greater in old than young adults for the 5% torque ($p=0.032$). Tendon stiffness was greater in young (171.6 ± 56.1 N/mm) than old adults (92.1 ± 35.5 N/mm, $p<0.001$). Stepwise, multiple-regression analysis indicated that maximal torque and age predicted tendon stiffness (adjusted $R^2=0.50$, $p<0.001$). Moreover, tendon stiffness was associated with CV for torque during contractions performed at 5 ($r^2=0.42$), 10 ($r^2=0.18$) and 15% ($r^2=0.10$) of maximal torque. Discussion These results indicate that Achilles tendon stiffness may contribute to plantar flexion torque steadiness, such that a reduction in tendon stiffness promotes greater variability in submaximal force output. This study further suggests that mechanical properties of the muscle-tendon unit should be considered when investigating performances in fine motor tasks and their alteration with ageing. INFLUENCE OF ACETAMINOPHEN INGESTION ON PERFORMANCE DURING INTERMITTENT MAXIMAL VOLUNTARY ISOMETRIC CONTRACTIONS

MORGAN, P.T., VANHATALO, A., JONES, A.M., BOWTELL, J.L., BAILEY, S.J.

University of Exeter

Introduction Acetaminophen (ACT) is the most commonly used medicine for general pain relief with emerging evidence suggesting that ACT can improve endurance exercise performance (e.g., Mauger et al., 2010). The ergogenic effect of ACT ingestion has been attributed to a lower pain and effort sensation permitting a higher power output during exercise. However, the physiological mechanisms that underlie the potential ergogenic effects of ACT ingestion are unclear. The purpose of this study was to explore the potential mechanistic bases for improved fatigue resistance following acute ACT consumption. Methods Following ethical approval and initial familiarisation, and in a randomised, double-blinded, cross-over experimental design, 13 active males completed 60 isometric maximum voluntary contractions (MVCs) of the knee extensor muscles after ingestion of 1g of maltodextrin (placebo) and 1g of ACT. Each MVC was 3-s in duration and interspersed by a 2-s passive recovery, with the critical torque (CT) taken as the mean torque over that last 12 MVCs and W' taken as the total amount of work completed above CT. Electromyography (EMG) was measured continuously during the 60 MVC protocol with peripheral nerve stimulation (PNS) administered every 6th contraction through the protocol for assessment of neuromuscular fatigue development. The compound action-potential (M-wave characteristics) in response to PNS was measured to assess changes in excitability, contractility and voluntary drive. Results The average torque (expressed as a % of the pre-exercise MVC) achieved across the 60 MVCs was greater with ACT ($61 \pm 11\%$) compared to PL ($58 \pm 14\%$; $P<0.05$). Likewise, CT was increased with ACT ($44 \pm 13\%$) compared to PL ($40 \pm 15\%$; $P<0.05$), but W' was not different between ACT and PL ($P>0.05$). Neuromuscular function was not different between the interventions during or following the 60 MVC protocol ($P>0.05$). Discussion Acute ingestion of ACT increased mean MVC torque over the 60 MVC protocol, consistent with findings of improved fatigue resistance during whole body locomotor exercise. The greater exercise capacity afforded by acute ACT ingestion was accompanied by similar end points in voluntary activation and m-wave amplitude, suggestive of a slower rate of neuromuscular fatigue development, and an increased CT. The increase in CT and attenuated decline in neuromuscular function during intense exercise provide novel insights into the mechanisms that underlie improved endurance exercise performance after acute ACT ingestion. TIMING OF MUSCLE ACTIVATION IS ALTERED DURING SINGLE-LEG LANDING TASKS FOLLOWING ACL RECONSTRUCTION AT THE TIME OF RETURN TO SPORT.

ROCCHI, J.E.1,2, LABANCA, L.1, LAUDANI, L.1,3, MARIANI, P.P.2, MACALUSO, A.1

1 University of Rome Foro Italico (Rome, Italy), 2 Villa Stuart Sport Clinic (Rome, Italy), 3 Cardiff Metropolitan University (Cardiff, UK)

INTRODUCTION Several studies showed how the lower limb landing pattern is altered months and years following anterior cruciate ligament reconstruction (ACL). Existing literature is controversial in reporting successful or unsuccessful recovery of the motor control of landings after surgery (Bryant et al., 2009; Gokeler et al., 2010). The aim of this study was to compare the timing of activation of knee extensor and flexor muscles between anterior cruciate ligament reconstructed (ACL-R) and healthy subjects performing single-leg landing tasks at the time of return to sport. METHODS Fifteen male and 8 female patients at an average of 6 months following ACL reconstruction using either patellar tendon or semitendinosus and gracilis autograft were recruited. Fifteen male and 11 female served as the control group. Participants performed a Stop Landing (SL) in which they were asked to land holding a bent knee position of 30° and a Smooth Landing (SML) in which they were asked to land smoothly absorbing the impact. In both tasks they landed on a force plate from a 20 cm height platform. Normalized vertical ground reaction force (vGRF/BW), knee angular displacement and muscle activation of Vastus Lateralis (VL), Vastus Medialis (VM), Rectus Femoris (RF), Biceps Femoris (BF) muscles in the examined limb were recorded during the whole landing phase. One-way ANOVA was used to analyze the differences between the two groups ($p<0.05$). RESULTS ACL-R patients showed longer pre-impact EMG duration of quadriceps and hamstrings muscles in the SL task (VM: 137 ± 49 vs 92 ± 26 ms, RF: 131 ± 51 vs 88 ± 37 ms, VL: 142 ± 56 vs 90 ± 42 ms, BF: 190 ± 42 vs 160 ± 37 ms, ST: 188 ± 45 vs 148 ± 43 ms) and in the SML task (VM: 137 ± 50 vs 81 ± 24 ms, RF: 113 ± 50 vs 85 ± 23 ms, VL: 138 ± 48 vs 75 ± 21 ms, ST: 173 ± 48 vs 143 ± 36 ms) as well as a wider Initial Contact (IC) knee angle (SL: 9 ± 5 vs $16 \pm 9^\circ$; SML: 9 ± 5 vs $17 \pm 10^\circ$) compared with healthy participants. No differences were found for vGRF/BW. DISCUSSION At the time of return to sport ACL-R group underlined longer quadriceps and hamstrings pre-impact EMG duration and a wider IC knee angle showing an altered neuromuscular control of single-leg landing tasks when compared to healthy subjects, thus increasing the risk of re-injury. BIOMECHANICAL CHARACTERISTICS OF VERTICAL DROP JUMP TEST AND THE RISK OF ACL INJURY IN YOUNG FEMALE BASKETBALL AND FLOORBALL PLAYERS

LEPPÄNEN, M., PASANEN, K., KUJALA, U.M., VASANKARI, T., KANNUS, P., PARKKARI, J.

UKK Institute for Health Promoting Research

Introduction Young female athletes participating in sports involving running, pivoting, jumping and landing are at increased risk of sustaining anterior cruciate ligament (ACL) injury. Knee valgus loading plays a critical role in the mechanism of ACL injury. So far, however, few prospective studies have investigated biomechanical risk factors of ACL injury, and only one study has found an association between knee valgus loading and future ACL injury. Thus, the purpose of the study was to investigate the biomechanical risk factors of ACL injuries in young female athletes from basketball and floorball. **Methods** A total of 171 female basketball and floorball players (aged 12–21) participated in a vertical drop jump (VDJ) test using 3D motion analysis. The following biomechanical variables were analyzed in six separate Cox regression models: 1) knee valgus angle at initial contact (IC), 2) peak knee abduction moment, 3) knee flexion angle at IC, 4) peak knee flexion angle, 5) peak vertical ground reaction force (GRF), and 6) medial knee displacement (MKD). We registered new ACL injuries and players' match and training exposure until April 2014 (range, 1–3 years). Cox regression models were used to calculate hazard ratios (HRs) and 95 % confidence intervals (CIs). **Results** Fifteen new ACL injuries occurred during the study period (0.2 injuries / 1 000 player hours). Peak knee flexion angle (HR for 10 unit change 0.47; 95 % CI 0.27 – 0.81) and peak vertical GRF (HR for 100 unit change 1.31; 95 % CI 1.12 – 1.54) were associated with increased risk for ACL injury. Knee valgus angle at IC (HR for 10 unit change 1.89; 95 % CI 0.69 – 5.00), knee flexion angle at IC (HR for 10 unit change 1.31; 95 % CI 0.69 – 2.48), peak knee abduction moment (HR for 10 unit change 1.12; 95 % CI 0.89 to 1.43), and medial knee displacement (HR for 10 unit change 1.95; 95 % CI 0.72 – 1.24) were not significantly associated with ACL injuries. Of the adjustment factors, players' lower height (HR 0.85; 95 % CI 0.74 to 0.98), and playing at adult league level (HR 4.85; 95 % CI 1.14 to 20.62) were risk factors of ACL injury. Age, weight, sport and previous ACL injury were not significantly associated with ACL injuries. **Discussion** This prospective study showed that landing with decreased knee flexion and high vertical ground reaction force were associated with increased risk of ACL injury in young female basketball and floorball players. Our study did not find any significant associations between frontal plane biomechanics and future ACL injury. Based on these findings, preventive training should include neuromuscular training not only to avoid valgus movement but also to avoid stiff landings. **References** Hewett TE, Myer GD, Ford KR, et al. THE EFFECT OF DIFFERENT COLD WATER IMMERSION PROTOCOLS ON RECOVERY FROM EXERCISE-INDUCED MUSCLE DAMAGE

VIEIRA, A., SIQUEIRA A.F., FERREIRA-JUNIOR, J.B., DA CUNHA, E.C., DURIGAN, J., CARMO, J., BLAZEVICH, A., BOTTARO, M.
University of Brasilia

Cryotherapy is widely accepted as recovery strategy to accelerate muscle recovery from strenuous exercise. Cold water immersion (CWI) is one of the most popular cold modality. It has been suggested that the therapeutic effect of CWI begins with water at 15 °C, but it is also assumed that lower temperatures may provide better outcomes (Merrick et al. 2003; Wilcock et al. 2006). However, the optimal temperature of CWI on the time course of muscle damage recovery are still controversial. Therefore, the aim of this study was to compare the effects of CWI at 15°C and CWI at 5°C on recovery from exercise-induced muscle damage. Forty-five college students performed a damaging exercise (5x20 drop jumps) and they were randomly allocated into one of three groups: 1) CWI at 5°C (G5, n=14), 2) CWI at 15°C (G15, n=14) or 3) control (CG, n=14). Individuals from CWI groups had their lower limbs immersed in water for 20 min, whereas those from control group remained seated for the same period. Isometric strength, countermovement jump (CMJ) performance, delayed-onset muscle soreness (DOMS), and serum creatine kinase (CK) activity were measured before, immediately after, 24, 48, 72, 96 and 168 h post-exercise. There was no difference between groups for isometric strength recovery ($p=0.73$). However, both G5 and G15 groups had a quicker recovery in CMJ performance than control group ($p<0.05$). Furthermore, G15 recovered CMJ performance 72 h, whereas G5 recovered only 96 h after EIMD. The control group did not recover CMJ at any time point investigated. G15 also demonstrated no significantly difference on CK activity from baseline after 72 and 168 h post-exercise, whereas the CK from both G5 and GC remained higher than baseline throughout study's period. There was a trend toward lower DOMS ($p=0.06$) in G15 when compared to the GC 24 h post-exercise. CWI hastened CMJ performance recovery, but not the isometric strength recovery. This discrepancy suggest that CWI might enhance aspects of stretch-shortening cycle, such as: utilizing elastic energy of structures of the musculature, activating proprioceptive reflexes, increasing the time to produce force and/or by potentiating sarcomere length (Byrne et al. 2004; White et al. 2014). Furthermore, the groups demonstrated different time course recovery on CMJ. G15 recovered linearly, whereas both G5 and GC demonstrated a further decline in performance. This second drop in performance might be associated with a secondary damage as consequence of excessive inflammatory response (Byrne et al. 2004). In summary, the results of the present study suggest that independent of the temperature CWI may enhance muscle damage recovery. Also, it appears that 15 °C may improve recovery from strenuous exercise when compared to lower temperatures. **References** Merrick MA, Jutte LS, Smith ME. (2003). J Athl Train, 38(1), 28-33. DIFFERENCES IN PLANTAR PRESSURE DISTRIBUTION IN ELITE CYCLISTS WITH OVERUSE INJURIES

NAVARRO, D., ZAHONERO, J., VERA, P., BARRIOS, C., HUERTAS, F.

Catholic University of Valencia

Introduction To date, the relationship of the plantar pressures in cyclists and the occurrence of injuries is not well-defined (Carpes et al., 2010). The purpose of this study was to determine the differences between the plantar pressure pattern of cyclists with patellofemoral

syndrome (PS), iliotibial band syndrome (ITBS) and those with non-overload lower limbs injury (NI). Material and methods: In a sample of 50 professional cyclists, the plantar pressures were recorded while pedalling using the Biofoot / IBV® system. For pressure analysis, the foot was divided into 9 zones: 3 zones for fingers (F1, F2, F3), 3 zones for the metatarsals (C1, C2, C3), 2 zones for the midfoot (M1, M2) and the hindfoot area (H). Setting cadence at 100 rpm, two powers (100 and 200 Wats.) were used. The order of the test conditions was counterbalanced among all participants. Repeated measures ANOVA was performed with 4 intra-subject factors: Group (NI vs. PS or ITBS), power (100 vs. 200 Wats.) x Foot (Left vs. right) x Zones (F, C, MT, or M, L). Results: A significant interaction Group x Zone x Foot was found: $F(1,50,46.66) = 6.07$, $p = .009$, $\eta^2 = .16$, when cyclists with PS and NI were compared. The post hoc analyses indicated that differences occurred between both, right and left feet in cyclist with PS in areas F and C (forefoot). An interaction Group x Zone was also found: $F(1,25) = 3.15$, $p = .088$, $\eta^2 = .11$, comparing ITBS with NI cyclists. Further analysis showed that cyclists with ITBS applied more pressure in the L zone (lateral). Conclusions: As compared to NI cyclists, those with PS show a different plantar pressure pattern with higher pressures in the forefoot areas, in particular on the medial zones as described by other authors (van Zyl et al., 2001; Wanich et al., 2007). Moreover, cyclists with ITBS showed a distinct plantar pressure pattern compared with NI group. It was identified by greater pressure on the lateral foot area. Carpes, F. P., Mota, C. B., & Faria, I. FISH OIL COUPLING WITH THERAPEUTIC ULTRASOUND FACILITATES HEALING OF RUPTURED ACHILLES TENDON

CHAN, K.O.W.1, TONG, H.H.Y.2, NG, G.Y.F.1

1: The Hong Kong Polytechnic University (Hong Kong SAR, China) 2: Macao Polytechnic Institute (Macau SAR, China)

Introduction Achilles tendon rupture is common in athletes but there is no consensus on the optimal treatment. Fish oil is rich in omega-3 fatty acids (n-3) and has been shown to suppress inflammation (Calder, 2013), promote collagen synthesis (Hankenson et al., 2000) and hence enhance connective tissue healing. Therapeutic ultrasound has long been reported to be effective for treating soft tissue injuries. The aims of the present study were to investigate the effect of topical fish oil coupled with ultrasound on healing of partial Achilles tendon rupture in a rat model. Methods Eighty five Sprague-Dawley rats with surgically hemi-transected right Achilles tendons were randomly assigned into four groups ie. topical placebo ointment as control (CON), topical fish oil (FO), ultrasound (US) and combination of ultrasound and fish oil (FU). Half of the animals were treated for 2 weeks while the rest were treated for 4 weeks. The right Achilles tendons were harvested after the treatment period for biomechanical assessments including structural stiffness and ultimate tensile strength (UTS). The values after normalization with the intact Achilles tendon were then compared between groups and treatment duration using two-way analysis of variance (ANOVA). Results The FU group demonstrated significant improvement in structural stiffness and UTS than CON at 4 weeks ($p<0.05$). Significantly higher UTS was observed in US than CON for both treatment periods ($p<0.05$). The FO group had increased structural stiffness at 4 weeks ($p<0.05$) than CON. Discussion Our findings revealed that fish oil either applied alone or incorporated with ultrasound improved biomechanical properties of injured tendon for longer treatment period. Although the actual mechanism behind is not certain, it is possible that the role of n-3 as a cyclooxygenase (COX) inhibitor may contribute to the positive findings as agreed with Virchenko et al. (2004). COX is an enzyme signaling pain and inflammation and hence n-3 suppress inflammation (Calder, 2013). In addition, our findings revealed that therapeutic ultrasound is effective in promoting tendon healing, which is consistent with the previous studies (Ng et al., 2003; Yeung et al., 2006). MOVEMENT DYSFUNCTIONS IN LUMBAR AND HIP AREA RELATED TO OVERUSE INJURIES IN HANDBALL MALE PLAYERS OF THE FIRST NATIONAL LEAGUE.

VALTUEÑA GIMENO, N.

UCH CEU

Introduction In Handball many players train and play with pain during the season. Sometimes overuse injuries are overlooked, and evidence shows that altered movement patterns have a direct influence in this type of lesion. We try to show the direct relationship between movement failures in a specific direction and overuse injuries in first national league handball players. Methods A sample of 22 handball male players (mean age: 25.8 years) was included in the study. The mean period performing as elite athletes was 7.7 years. During two seasons, overuse injuries were recorded. Movement test for lumbar spine and hip control were performed (Comerford et al. 2012). The test were recorded and assessed during its performance and after reviewed by two physical therapists. Every video was assessed with the Kinovea® software to record angles and timing. Injuries over 2.5 on VAS and failure in the tests were compared. Results There 10 cases (45.4%) reporting left knee pain, 4 (18.2%) right knee pain, and 6 (27.3%) referred low back pain. Hip flexion during forward bending showed a mean range of 86.4 ± 12.6 degrees, over the benchmark. Prone knee flexion was 109.5 ± 6.3 on average, failing in 21 cases (95.5%) the benchmark range. During execution of prone knee flexion, the stabilizer disclosed a mean value 73.2 ± 8.9 mmHg of values, being above the benchmark range in 5 cases (22.7%) and below in one case (4.5%). Failure in double knee flexion in prone position was related to the experience of pain in the jumping knee ($p<0.05$). Monopodal squat failure in the jumping knee was related with the experience of low back pain ($p<0.05$). All cases with low back pain displayed failure during Crook lift test. Discussion Failure in crook lift test and prone knee flexion were related to extension and rotation lumbar spine syndromes. Likewise hip position and its range of motion can be linked to low back pain (Van Dillen et al. 2000), as well as with knee pain (Levinger et al. 2007). Overuse pain recorded in lumbar and knee and failed tests on low back spine and hip seem to lead to an extension rotation dysfunction pattern in lumbar spine and lack of rotation control on the hip, especially in the jumping leg. Further studies with an extensive sampling should be performed to understand the role of motion dysfunction on the development of overuse injuries. References Comerford M, Mottram S. PREDICTING TOMMY JOHN SURGERY IN MAJOR LEAGUE BASEBALL: A MACHINE LEARNING APPROACH

WHITESIDE, D.1,2, GOULET, G.3, ZERNICKE, R.3

1 Tennis Australia; 2 Victoria University; 3 University of Michigan

Introduction In the current decade, the number of ulnar collateral ligament reconstruction surgeries (also known as Tommy John surgery—TJS) in Major League Baseball (MLB) has increased 44% compared with the preceding decade, and 305% since the 1990s. With this surgery imposing an average 21 months away from MLB competition (Erickson et al., 2014) and potentially leading to declines in performance (Keller et al., 2014), there is an obvious need to curtail the epidemic. The aim of this study was to develop a machine learning model that could form part of the injury screening process in MLB. Methods 75 MLB relief pitchers who underwent TJS between 2010 and 2015 were identified and an age-matched control group of MLB relief pitchers created. Data relating to demographics, playing activity and 148,301 pitch trajectories were harvested from MLB databases. Two machine learning classifiers—naïve Bayes (NB) and linear support vector machine (SVM)—were constructed and optimized using a brute force approach (i.e., parsing every possible combination of predictor features). The predictive accuracy of each model (i.e., how accurately it predicted whether a pitcher would undergo TJS) was then assessed using six-fold cross-validation. To provide more explicit practical insight into the risk factors for TJS, a logistic regression was performed and odds ratios computed on significant ($P < .05$) features. Results The SVM predicted TJS with an accuracy of 79% and NB with 80%. Optimization procedures revealed pitch speed, spin rate and average days between games to be the most valuable predictors of TJS. According to the odds ratios: (1) each 1 m/s increase in mean pitch speed increased a pitcher's odds of undergoing TJS by 48%; (2) each additional day a pitcher was afforded between consecutive games reduced his odds of TJS by 29%. Discussion Based on their predictive accuracy, the machine learning classifiers developed in this study could be deployed as part of an injury screening program to identify MLB relief pitchers who are at risk of catastrophic UCL injury. While MLB pitchers who throw with greater speed are reportedly more effective (Whiteside et al., 2015) the current data suggest that these pitchers are also more susceptible to TJS—an instructive finding for practitioners. Moreover, these data revealed that pitchers who were afforded more time between consecutive games had significantly lower odds of undergoing TJS—a finding with obvious implications for franchise-level roster management and league-wide policies in MLB. INTRODUCTION Forearm nerve injuries, although rare, can cause significant disability in functional abilities of injured hand. In majority of cases they are caused by cuts made by sharp objects, injuries caused by chainsaw or grinder, falls, gunshot injuries or traffic accidents (Rasulic et al., 2015). They can be associated with other injuries, such as soft tissue lacerations, bone fractures and vascular traumas (Puzovic et al, 2015). Although treatment of peripheral nerve injuries (PNI) significantly advanced during last 60 years, functional outcome still may be unsatisfactory. The aim of this study was to examine hand motor abilities of people surgically treated after median forearm nerve injury. **METHODS** Study included 30 subjects surgically treated because of traumatic median forearm nerve injury. Subjects with peripheral nerve tumors or different entrapment syndromes were excluded from the study, as well as the subjects with associated ulnar and/or radial nerve injury. After signing written information consent subjects performed motor ability testing of the injured and healthy hand. Testing was performed at least 3 years after the surgery. Test battery included: Purdue pegboard testing (PPT), Minnesota rate of manipulation testing (MRMT), hand grip (HGS) and pinch grip strength testing (PGS). Statistical procedures were done using the PASW 18 statistical package. The study was approved by the relevant Ethics Committee and it was part of a doctoral thesis project. **RESULTS** Results show that subjects with median forearm nerve injuries have weaker motor abilities of the injured hand in comparing to the non injured one. Motor abilities of the injured hand are highly influenced by the location of forearm injury, proximal vs distal and severity of the injury. In all the subjects, HGS was significantly lower in injured hand in comparing to non-injured one ($p=0.05$), while with PGS it wasn't the case. PPT also showed significantly lower results of injured hand ($p=0.05$), MRMT showed significant differences in subjects with proximal forearm nerve injuries ($p=0.05$), while in subjects with distal forearm nerve injuries there wasn't significant differences. **DISCUSSION** Muscle denervation as a consequence of PNI causing lower muscle strength tested by hand grip dynamometer and fine hand and fingers coordination tested by PPT. Location of injury is influencing the functional outcome, since in proximal PNI during recovery axon has to bridge longer distance from the site of injury to the end motor organ. **REFERENCES** Rasulic L, Puzovic V, Rotim K, Jovanovic M, Samardzic M, Zivkovic B, Savic A. PHYSIOLOGICAL PATTERNS OF ADAPTATIVE REACTIONS DETERMINE SUCCESS OR FAILURE IN CANADIAN NAT'L BASKETBALL: A 2014-2015 STUDY

FOMIN, R.1, GIBBS, S.2, WEINGROFF, C.2, MALCHEVSKAYA, E.4, NASEDKIN, V.1

1: Omegawave (Portland, USA), 2: Canadian Men's National Basketball Team (Toronto, Canada) 3: Institute for Informatics and Automation (St. Petersburg, Russia).

Introduction: The purpose: identify adaptational patterns in the cardiac system related to success or failure in Olympic level basketball players. **Methods:** The study involved 8 athletes of the Canadian Nat'l Men's Basketball Team. Data were obtained from 2 competitive periods: unsuccessful - 2014 (3 weeks) and successful - 2015 (8 weeks), where the Team was a finalist of the Pan-American games. The physiological parameters of the Central Nervous System (CNS), Autonomic Nervous System (ANS) and Cardiac System (CS) were frequently collected and assessed by Omegawave Team technology (Finland) using ECG and Direct Current Potential (DC) methods. Electrical cardiac activity was recorded using a portable, wireless, single-channel amplifier, located in a special chest belt. Two electrodes were placed

inside the belt in the medium axillary line on the right and left sides at a position close to lead V6 (Wilson). Recording time was 4 minutes and took place before training or competition (5:00 am to 12:00 pm). ECG amplitude analysis and Heart Rate Variability (HRV) methods were utilized. Data were analyzed using SPSS 23 (USA). Descriptive characteristics are presented as mean and standard deviation (SD). Data were checked for normality. Comparisons between two groups were made using Two-Independent-Samples Mann-Whitney U-test. Results: The following changes in data were observed in 2015 (compared to the 2014 period): HRV Parameters reflecting the activity of the parasympathetic division the ANS and autonomic contour of regulation were significantly lower. Vagal activity index (dX) was significantly decreased ($P<0.05$) by 0.024 sec (5.3%), falling to 0.427 ± 0.15 sec. RMSSD was significantly decreased ($P<0.05$) by 36.5 ms (25%), falling to 111 ± 49 ms. High Frequency power significantly decreased ($P<0.05$) by 12 n.u. (21%), falling to 46 ± 20 n.u. Conversely, parameters characterizing the activity of the sympathetic branch of the ANS and central contour regulation increased. Tension Index significantly increased ($P<0.05$) by 13.5 r.u. (72%), rising to 32 ± 41 r.u. Low Frequency/High Frequency Ratio significantly increased ($P<0.05$) by 0.93 r.u. (102.9%) and reached 1.83 ± 1.74 r.u. ECG parameters showed a significant increase (19.3%) in the amplitude of Q, R and S waves. The level of CNS activation also significantly increased. DC potential significantly increased by 5.29 mV (38.6%), rising to 19 ± 9.4 mV. Discussion: Changes in HRV parameters, the increase in DC potential and the increase in the amplitudes of Q, R and S waves seem to have contributed to better results in the 2015 season. EFFECT OF FATIGUE ON JUMP SHOT ACCURACY IN EXPERT AND JUNIOR BASKETBALL PLAYERS

MARCOLIN, G., CAMAZZOLA, N., MORO, T., PAOLI, A.

University of Padova

Introduction Fatigue is a multifactorial mechanism that involves the central nervous system, the peripheral nervous system and the muscular system. Moreover fatigue can also involve physiological factors. Fatigue is part of basketball and can influence the overall level of performance (1, 2). The aim of the present study was to investigate the effect of fatigue on jump shot accuracy in expert and junior basketball players. Methods 11 elite (age 26 ± 6 yrs) and 10 junior (age 18 ± 1 yrs) basketball players were enrolled in the study. After a standardized warm up they were asked to perform 3 series of 20 consecutive jump shots following a low, medium and high fatigue protocol respectively. Rest among the three series of shots was set in 4 minutes. Heart rate was measured continuously and the Borg rating of Perceived Exertion (RPE) Scale was administered at the end of each series of shots. Fatigue protocol consisted on a combination of walking, running and sprinting with side-cutting manoeuvres. All jump shots were performed in correspondence of the free throw line. Results Elite players showed a better shot accuracy with respect to junior players for low (83% vs 64%), medium (75% vs 57%) and high (76% vs 60%) level of fatigue. Statistical analysis showed no effect of fatigue for both elite and junior players considering the whole series of 20 shots. However elite players increased significantly their shot accuracy comparing the first 10 shots and the last 10 shots during the high fatigue protocol. Discussion Elite players showed a better shot accuracy with respect to the junior players at each level of fatigue. However for both groups fatigue didn't influenced the shot accuracy itself. Interestingly, only in the high fatigue condition, the accuracy of elite players referred to the last 10 shots was better than the accuracy referred to the first 10 shots. These findings underlined the importance of proposing levels of intensity as close as possible to those experienced in real matches also in shooting workouts. References 1. JUMP PERFORMANCE AND FORCE-VELOCITY PROFILING IN HIGH-LEVEL VOLLEYBALL PLAYERS: A PILOT STUDY.

BROUSSAL-DERVAL, A.1, DELACOURT, L.1, SAMOZINO, P.2, MORIN, J.B.3

1: French Volleyball Federation (Paris, France), 2: Laboratory of Muscular Biology (Chambéry, France), 3: Laboratory of Human Motricity, Education Sport and Health (Nice, France)

Introduction Jump performance is the most important physical determinant of volleyball (VB) performance, at all levels of play (Ziv and Lidor, 2010). Research and practice have long sought to improve players jump height through specific strength training (Newton et al., 2006). Recently, the concept of optimal force-velocity (FV) profile has been related to jump performance: in addition to maximal lower limbs power (Pmax), a well-balanced FV profile is a key factor (Samozino et al., 2014). We investigated jump performance, Pmax and FV imbalance in pre-professional and professional VB players. Methods Using a simple method based on five loaded squat jumps, we determined Pmax and the FV imbalance (FVimb), i.e. the % difference between a player's actual and optimal FV profiles (Samozino et al., 2014) in the following groups: young elite (32 females, 22 males), professional (6 females, 8 males), professional in beach-VB (5 males). Results In both female and male players, jump height increased with the level of play (from 26.6 cm in young females to 37.8 cm in pro beach-VB males), as did Pmax (from 23.2 to 31.0 W/kg). All the groups tested showed on average a FVimb towards a deficit in maximal force capability. This FVimb was very similar between groups: -37 and -34% for female young and professional players, and -34 and -33% for male young and professional players, respectively. Interestingly, these FVimb were very variable within groups (coefficients of variation of 37 to 150%). Additional computations showed that on average, 10.4 % better jump heights (range: 0-38%) could be expected in these players should FVimb be reduced, all other things (e.g. Pmax) being equal. Discussion This pilot study provides a descriptive reference for young and professional high-level VB players, and paves the way for more individualized training programs. Indeed, we observed that the majority of players had a force deficit (negative FVimb), which means that, *ceteris paribus*, a force-oriented training program would result in improved jump performance in most players. However, the interest of this approach is that some players had an optimal FV profile and even a velocity deficit (high within-group variability), which means they would benefit from a different strength training than the majority of their teammates. This study supports the interest of an individualized FV profiling and strength work to improve jump height in VB players. References Newton RU, Rogers RA, Volek JS, Hakkinen K, Kraemer WJ. (2006). THE ACUTE EFFECTS OF VARYING WHOLE BODY VIBRATION EXPOSURE ON THE JUMP HEIGHT OF CLUB VOLLEYBALL PLAYERS

NAIDOO, R., DLAMINI, K.P.

University of KwaZulu-Natal

Introduction Whole body vibration (WBV) has demonstrated rapid improvement to muscle strength or power when being vibrated on a platform. However, WBV studies have utilised sedentary individuals as participants and limited on athletes whom strength and power are their primary development in sport. There is an opportunity for South African athletes to improve their power output during game time using whole body vibration or as warm up protocol before games. The objective of this study was to measure the acute effects of varying high and low frequencies [0, 30, 35, 40, and 50 Hz] set at high and low displacements of WBV for 30 seconds on the countermovement jump performance in club volleyball players. Methods A single-blinded repeated-measures crossover study design was conducted. Club volleyball players ($n=30$, 27 males (age, 25.33 ± 5.86 years; height, 1.83 ± 0.73 m; weight, 84.06 ± 13.23 kg) completed countermovement jumps (CMJs) of maximal volition to assess peak power pre and post (immediately) randomised WBV stimuli set at varying frequency (0, 30, 35, 40, and 50 Hz), displacement (2-4 vs. 4-6 mm), and duration (30 seconds) combinations. Results Significant main effects were found for power (pre-to-post WBV, $p < 0.048$), with repeated measures analysis of variance (paired sample test) emphasising that there was significant mean improvement of 9.4% in CMJ as a result of WBV at 35Hz but no significant change at other frequencies. Therefore, this study demonstrates that for athletic trained men, an acute 30-second bout of vertical WBV at 35Hz and 4-6mm peak-to-peak displacement significantly improves explosive jumping performance in comparison to other frequencies. Conclusion Acute vertical WBV for 30 seconds at 35Hz may be utilised as part of the warm up session to enhance explosive power in volleyball players; however, the exact mechanisms for improvements still need further well controlled investigations on chronic WBV training utilising strength/ power trained athletes.

MATURATION AND ANTHROPOMETRIC CORRELATES OF AEROBIC CAPACITY IN TOP ELITE YOUNG FEMALE VOLLEY-BALL PLAYERS: PWC170 VS. STEP TEST

NIKOLAIDIS, P.T.1,2, KOSTOULAS, I.1, TASIOPoulos, I.1,3, PADULO, J.4, TORRES-LUQUE, G.5, FERNÁNDEZ-GARCÍA, A.I.6, AFONSO, J.7

Introduction From a physiological point of view, performance in volleyball relies mostly on anaerobic power and anthropometry (1-6). Nonetheless a minimum of aerobic capacity is necessary for volleyball players to cope with the demands of training and certain game situations (e.g. long-lasting rallies). Whether two inexpensive tests of aerobic capacity, the physical working capacity at heart rate 170 bpm (PWC170) and YMCA step test, can be used interchangeably has not been examined yet. The aim of the present study was to examine the relationship between the YMCA step test and PWC170 in top elite young female volleyball players. Methods Forty-three selected female volleyball players (age 13.0 (0.6) yrs, height 171 (6) cm, weight 61.6 (6.6) kg) performed a series of anthropometric and aerobic capacity tests (PWC170 and YMCA step test). Results HR in the end of YMCA test correlated with PWC170 indices ($0.780.087$). Conclusions PWC170 and YMCA test showed very large correlations and their use in young volleyball players is further recommended. The lack of relationship of aerobic capacity with anthropometric and age parameters should be considered in training planning by coaches and fitness trainers. References 1. PERFORMANCE MODELLING IN SWIMMING

RASCHE, C., ENDLER, S., PFEIFFER, M.

Johannes Gutenberg University Mainz

Introduction Modelling the individual load-performance relationship to deduce information about convenient application of load and recovery phases to achieve optimal adaptation processes and estimate fitness and fatigue levels is essential for training theory. The existing linear and non-linear systems models abstract real-world settings and underlying physiology and need to be compared regarding their predictive accuracy, ability to copy adaptations and included variables (Taha & Thomas, 2003). Methods Training load and performance of five elite swimmers (17-27y, 1f/4m) was assessed for 25 weeks by recording swimming kilometers (volume) weighted by different stress levels (intensity) and performing Semi-Tethered-Tests (3x20m freestyle, increasing resistance) twice a week. Data was analyzed and modelled using the Fitness-Fatigue-Model (FF-Modell), the Performance-Potential-Model (PerPot) and the Performance-Potential-Double-Model (PerPot DoMo) (Perl & Pfeiffer, 2011). Mean absolute percentage error (MAPE) and intraclass correlation coefficient (ICC) were computed to estimate the goodness of fit (model-fit) i.e. compare empirical and simulated performance. Results Resulting MAPEs $\pm SD$ and mean ICCs were $3.07 \pm 1.81\%$ and .65 for the FF-Model, $2.94 \pm 1.23\%$ and .72 for PerPot and $2.58 \pm 1.16\%$ and .81 for PerPot DoMo. Discussion The results indicate a slightly better goodness of fit for the PerPot DoMo in comparison to the FF-Model and PerPot, but no significance because of the high variance and small sample size. Two separate inputs (volume/intensity) enable PerPot DoMo to model performance more precisely than with one input (FF-Model, PerPot), though the model fit of all three models is appropriate regarding the performance's dynamics and variations. References Perl, J & Pfeiffer, M (2011). Int J Comp Sci Sport 10 (2), 85-92. Taha, T & Thomas, SG (2003). Sports Medicine, 33(14), 1061-1073. Contact chrasche@uni-mainz.de

OXYGEN UPTAKE RESPONSE AT SUPRAMAXIMAL SWIMMING INTENSITIES – STUDY OF 50, 100 AND 200 METERS TIME TRIALS

ALMEIDA, T.1,2, PESSOA FILHO, D.2, SIMIONATO, A.2, SILVA, J.2, PESTANA, D.3, ESPADA, M.1,2, REIS, J.1, ALVES, F.1

(1)CIPER, BIOLAD–Faculty of Human Kinetics, University of Lisbon, Portugal (2)UNESP, LABOREH–Human Performance Optimization Laboratory, Rio Claro, Brazil (3)ABDA–Assoc Bauruense de Desportos Aquáticos

Introduction: Oxygen uptake kinetics (VO2K) is an important method for sports performance analysis, as faster kinetics seem to delay fatigue and improve performance. In swimming, VO2K studies focus mainly on submaximal transitions, however 95% of swimming events are performed at maximal or supramaximal intensities. This study aimed to describe the VO2K response at 50, 100 and 200 meters front crawl performance. **Methods:** Fourteen well trained male swimmers (age 16.57 ± 1.8 yr.; mass 70.5 ± 9.95 kg; height 1.78 ± 0.08 m) completed a discontinuous incremental test designed with 6x250m plus 1x200m steps for maximal oxygen uptake (VO2peak) assessment, as well as the maximal aerobic swimming velocity (MAV). In complementary days and in randomized order swimmers maximal performance at 50, 100 and 200 meters were evaluated for VO2peak (VO2peak50, VO2peak100, VO2peak200, respectively), oxygen deficit determination and VO2K analysis. VO2K parameters (time delay, time constant and amplitude) were determined using a monoexponential modelling. All tests were conducted using a breath-by-breath apparatus (K4b2, Cosmed, Italy) connected to a swimming snorkel (AquaTrainer, Cosmed, Italy) for pulmonary gas sampling. **Results:** VO2peak (58.1 ± 6.3 ml/kg/min) was significantly different from VO2peak50 and VO2peak100 (49.5 ± 4.9 and 55.6 ± 6.1 ml/kg/min, respectively), but not from VO2peak200 (57.7 ± 6.8 ml/kg/min). MAV (1.31 ± 0.07 m/s) was significantly different from the 50 and 100 m velocity (1.66 ± 0.11 and 1.49 ± 0.08 m/s, respectively), but didn't show significant differences with the 200 m velocity (1.32 ± 0.07 m/s). Time delay and amplitude didn't present any significant differences between distances, but the time constant (tp) does, reducing as the exercise became shorter and more intense (8.1 ± 2.2 s vs 11.2 ± 2.3 s vs 16.3 ± 6.9 s for the 50, 100 and 200 m, respectively). Oxygen deficit didn't show any significant differences. **Discussion:** The VO2peak obtained in the incremental test was only reached in the 200m time trial, however we could say that near maximal values of VO2 (approximately 96%) can be reached within 1 min of strenuous exercise, as seen in the 100m trial. This results are in line with Carter et al (2006) and Hettinga et al (2008) that observe similar results performed in running and cycling, respectively. Despite the VO2 response was faster as the swimming trials became shorter, the differences on oxygen deficit at the onset of each trial was not observed. **References:** Carter, H., Pringle, J.S., Barstow, T.J., Doust, J.H. (2006). Oxygen uptake kinetics during supra VO2max treadmill running in humans. *Int J Sports Med*, 27(2), 149-57. Hettinga, F.J., De Koning JJ., Foster C. (2009). EFFECTS OF CIRCADIAN RHYTHMS ON NIGHT-TIME SWIMMING DURING THE OLYMPICS: WILL PERFORMANCE BE AFFECTED? – A PILOT STUDY FOR RIO 2016

MIGLIACCIO, G.M.1,2, DI NINO, A.3, AVALDI, F.4, BAZZU, A.5, MULLEN, G.6, PADULO, J.7

1: Sport Science Lab (London, UK), 2: CONI Italian Olympic Committee (Sardinia, Italy), 3: A.D.N. Swim Project (Italy), 4: Nutrition Area AC Milan (Milan, Italy), 5: Energy Standard Swimming Club (Ukr)

Introduction The impact of Circadian rhythms (CRs), among other factors, on sporting performance is already known (Cappert T, 1999). Unlike the usual timings for international events, the swimming competitions in the 2016 Olympics will be held between 22.00 and 00.30. Therefore, the aim of this study was to analyse sleep quality (SQ), heart rate variability (HRV), heart rate recovery (HRR) and the total mood disturbance (TMD) index during a week of night-time training and the influence they have on the state of overreaching. **Methods** Three male swimmers, qualified to the 2016 Olympics in Rio, were monitored during a week of night-time training sessions to correspond with the timings of Rio's semi-finals and finals. Assessments of SQ was calculated using actigraphy (Sensewear, Bodymedia USA), HRR, HRV (Minicardio, Hosand – Italy) and TMD were conducted five times during the whole simulation exercise with intervals of two days and once on the habituation day. All athletes answered a "morningness/eveningness" questionnaire in relation to the chronotype profile. The CRs were made to shift by five hours, such that the athletes woke up at 11.00 and retired for the day at 02.00, while their nutritional intake was integrated with Tryptophan in order to improve SQ. Results The Univariate ANOVA showed that, for HRV, which was classified in terms of Very Low Frequency (VLF), Low Frequency (LF) or High Frequency (HF), SQ showed significant effects between each time period (T0-T1-T2-T3-T4): $F=9.481$ and $p=0.002$, $F=6.603$ and $p=0.007$, $F=9.209$ and $p=0.002$, $F=19.189$ and $p<0.0001$, respectively. Conversely, the Univariate ANOVA showed no significant effect on HRR, ($F=0.817$ and $p=0.542$). Finally, TMD was very low at the start (5.50 ± 3.51) respect 81.00 ± 18.90 during the last session ($p=0.031$). **Discussion** The main findings indicated that there are effects on HRV, SQ and TMD. The data suggest that training late at night increased sleep disturbance, fatigue and changes in autonomic functioning hinted at the onset of an overreached state. More than two days under "late night" conditions can inhibit the performance of athletes, with a major impact on their "morningness" profile. In order to reduce such an impact, greater emphasis must be placed on identifying the nutritional and sleep needs of elite swimmers, in order to put together adequate recovery strategies that will help them train effectively to maximize performance outcomes. **References** Sleep in Elite Athletes and Nutritional Interventions to Enhance Sleep – Halson S. – Sports Med. 2014 Review: Time of Day Effect on Athletic Performance: An Update – Cappaert T. – J. OXYGEN UPTAKE AND BLOOD LACTATE IN FULL AND FRACTIONATED SYNCHRONIZED SWIMMING DUET ROUTINES IN ELITE SWIMMERS

RODRÍGUEZ, F.A., CHAVERRI, D., RODRÍGUEZ-ZAMORA, L., CARRASCO, M., IRURTIA, A., IGLESIAS, X.

Institut Nacional d'Educació Física de Catalunya, Universitat de Barcelona

Introduction Synchronized swimming (SS) combines intense muscular exercise with body position changes and prolonged apnoeic periods that impose additional physiological demands (Rodríguez-Zamora et al. 2012). Oxygen uptake (VO2) and blood lactate (Lab) have traditionally been used as key indicators to assess the internal load in sports. No studies have examined VO2 in SS. We aimed to describe the time course of VO2 and Lab across fractionated competitive routines in elite swimmers. **Methods** 16 elite junior and senior swimmers (age 16.5 ± 2.5 years, height 165 ± 7 cm, body mass 53 ± 8 kg) completed eight full duet routines fractionated into two periods in coincidence with prolonged apnoeic periods. Measurements were taken before exercise (PRE) and before and after the full routine (FULL), and before and after the first and second prolonged apnoeic phases (Pre/PostAP1, Pre/PostAP2). Capillary blood samples were obtained from the earlobe at rest and at min 3, 5, (7) after each subroutine. VO2 was estimated from 30-s backward extrapolation of breath-by-

breath postexercise measurements (K4 b2 Cosmed, Italy). RPE was measured with the Borg CR-10 scale. RM-ANOVA and post-hoc Bonferroni tests compared values obtained before and after the five subroutines ($P < \alpha = 0.05$ for significance). Results Exercise duration (s), peak Lab (mmol·l⁻¹), and peak VO₂ (ml·kg⁻¹·min⁻¹) was, respectively: PRE: 0, 1.0±0.5, 10.4±3.4; PreAP1: 67±21, 3.7±1.6, 54.7±6.5; PostAP1: 81±22, 3.8±2.2, 55.5±9.6; PreAP2: 171±25, 4.9±1.9, 60.2±11.1; PostAP2: 183±23, 5.7±2.0, 60.7±10.8; and FULL: 197±10, 5.9±1.4, 61.8±15.1. All postexercise VO₂ and Lab values were different from PRE, but VO₂ was similar among subroutines and compared with FULL ($P > 0.38$). Peak Lab was higher after FULL than after PreAP1 and PostAP1 ($P = 0.04$ and 0.005). Discussion Continuous measurement of VO₂ and Lab during SS routines is not possible due to the frequent immersion phases. The fractionation strategy used here allowed us to build up a picture of the time course of these parameters across competitive duet routines in elite swimmers. VO₂ showed a fast rate of increase during exercise (e.g., ~90% VO₂ peak was attained after ~67 s). Since no differences were noted between any of these parameters before and after prolonged apnoeic phases, we propose that the fast rate of increase of VO₂ and Lab accumulation are essentially caused by the high energy demands of exercise and not by the prolonged hypoxic bouts, despite the dramatic effect on heart rate. SLEEP CHARACTERISTICS IN YOUNG FEMALE SYNCHRONIZED SWIMMERS

DUMORTIER, J.1, BOONE, J.1, MARIMAN, A.2, DELESIE, L.2, TOBACK, E.2, VOGELAERS, D.2, BOURGOIS, J.1,3

1: Department of Movement and Sports Sciences, Ghent University; 2: Department of Internal Diseases, Ghent University Hospital;

3: Centre of Sports Medicine, Ghent University Hospital

Introduction Sleep is considered to be one of the most important recovery techniques for elite athletes in both training and competition periods[1]. Because little is known about the sleep pattern in athlete populations, the aim of this study was to identify sleep patterns in Belgian elite synchronized swimmers (SS). Methods 15 Belgian elite SS (14.5±1.4 years old; 7.4±0.9h of training per week), wherefrom 10 entered a competition, were included in this study. Daily sleep registration was made using a sleep diary, during a 12 week specific training and competition period. Total sleep time (TST) and sleep efficiency (SE = TST/time in bed) were calculated. Week and weekend sleep parameters were compared for all subjects during the entire period using a Paired Samples T-Test. The same statistical analysis was used for comparison between a training and competition period in all competitive athletes. Repeated Measures ANOVA was used to detect both differences in sleep parameters between a training period and the night before a competition and to identify day-to-day variability. Level of significance was set at $p < 0.05$. Results SS went to sleep and got up earlier during week versus weekend nights (22:02±0:29 vs. 22:49±0:41, $p < 0.001$; 7:25±0:14 vs. 8:50±0:26, $p < 0.001$), which led to a shorter TST, but not SE (539±38min vs. 580±46min, $p < 0.001$). In competition periods, SS went to sleep earlier than during training periods, both in week (21:45±0:33 vs. 22:00±0:25, $p = 0.024$) and weekend nights (21:53±0:38 vs. 22:44±0:39, $p = 0.004$). Furthermore, in competition weekends, SS got up earlier than during training weekends (7:35±0:51 vs. 8:51±0:28). No significant differences in TST and SE were observed. The night before the competition, SS went to bed and got up earlier than during a normal weekend night (21:41±0:41 vs. 22:44±0:39). TST was diminished the night before the competition compared to a normal weekend night (509±70min vs. 580±50 min), however, without differences in SE. After a late training session, TST, but not SE, was shorter than during normal week nights (527±39min vs. 543±39min, $p = 0.001$). Discussion SS tend to compensate sleep debts from the previous week during weekends which is not beneficial for recovery, due to a disruption of the sleep/wake cycle[2]. Although SS adapt their sleep/wake rhythm before a competition, no equal TST is obtained compared to a normal night's sleep. Also, an impaired TST was observed in SS the night after a late night training session due to the late bedtime hour. Coach's awareness of the influence of training and competition scheduling on their athlete's sleep seems very important. References 1. EVALUATION OF COACH-ASSISTED TRAINING VERSUS SELF-TRAINING IN AMATEUR SWIMMERS

PINNA, V.1, GIORDO, M.P.2,3, TOCCO, F.1, MULLIRI, G.1, GHIANI, G.1, CRISAFULLI, A.1, MAMELI, O.2, CARIA, M.A.2

1University of Cagliari, 2University of Sassari, 3Fédération Internationale de Natation (FINA)

Introduction There is plenty of study on the quantification of physical performance in competitive athletes. This information is also extended to population over 40 yrs old (Baker and Tang, 2010). However investigations dealing with the effect of self-training procedures in amateurs athletes is not abundant. Aim of the present study was to compare the cardio-metabolic effects of two different training plans: a coach-assisted program followed by master swimmers (MS), and a self-administered program carried out by leisure swimmers (LS). Methods 18 healthy and active males were divided in 2 groups regularly practicing swimming 3 times a week in the last 3 years: MS (age: 48.4±7.4) usually taking part in competitions, and LS (age: 50.3±6.8) with the only aim to keep a good level of physical fitness. MS adhered to a specific training protocol administered by a Certified Coach of Italian Swimming Federation, while LS followed a self-administered workout. The total training distance covered by both groups was equal. Cardiovascular and metabolic parameters at the beginning of the study (T0) and after six months (T6) were assessed by means of a portable metabolic system during an incremental treadmill test, until exhaustion (Pinna et al. 2013). Results The two groups showed a significant increase in total time (TT) performance without any treatment effect (TT; MS=+11.9±13.4% vs. LS=+8.3±15.5%; $p > 0.05$). Likewise, maximum speed reached (Msp) increased without any difference between groups (MS=+6.5±9.3% vs. LS=+2.1±10.6%; $p > 0.05$). Of note, the MS group increased their maximal aerobic capacity with respect to the LS group (VO_{2max}=+12.6±14% and +2.5±5.4% respectively; $p < 0.05$). A similar phenomenon was observed for VO₂ at anaerobic threshold (VO_{2AT}; MS= +16.8±16.8% vs. LS=+2.5±5.4%; $p < 0.05$). Chronotropic response and index of the anaerobic capacity (CO₂ excess) were unmodified in both groups. Conclusions Our results show that only the coach-assisted training was able to evoke significant physiological adjustments in parameters related to aerobic capacity such as VO_{2max} increase and VO_{2AT}. Considering the equivalent amount of work in terms of total distance covered in MS and LS, this different outcome may be due to the training periodization followed by MS. Of note, these improvements can be detected by a specific cardiopulmonary treadmill tests. References Baker AB, Tang YQ. (2010). Exp Aging Res, 36, 453-477. OP-PM58 Gene Networks in Response to Exercise

CHANGES IN ISOMETRIC KNEE FLEXION TORQUE AND HAMSTRINGS EMGS UNDER THE DIFFERENT OF MUSCLE-TENDON LENGTH CONDITIONS

YAMAZAKI, Y.1, KASHIWAGI, Y.1, YAMAGISHI, M.2, FUNATO, K.2

1: Graduate school of Health and Sport Science, Nippon Sport Science University, 2: Nippon Sport Science University, Tokyo, Japan

Introduction Hamstrings muscle group is composed of the biceps femoris long head (BF), semimembranosus (SM), and semitendinosus (ST). The muscle-tendon length (ML) of each muscle is affected by hip and knee angle positions. Previous research reported that the amount of length change was different in each muscle. Kumazaki et al.,(2012) reported that hamstrings generated maximal knee flexion torque where the knee joint was almost fully extended position, but EMG activities during the isometric contraction of hamstrings were maintained a similar level. It's still unclear how the different ML by changing hip and knee angles affects exerting force. The purpose of this study was to compare joint torque and EMG activities of the BF, SM, and ST under different ML conditions. Methods Thirteen healthy young subjects (age:21.1±1.0yrs, BH:173.1±4.4cm, BW:71.1±8.7kg) performed maximal isometric knee flexion by using the dynamometer (CON-TREX). Knee flexion torque data were collected from 10 combinations of hip and knee positions; knee flexion angle (Kangle) at 05, 30, 60, 90, 105 degree for both sitting(S) or prone(P). Surface EMG were recorded from 3 places on same muscle which were at the mid-point, proximal, and distal of the muscle belly in BF, ST and SM. Estimated ML was calculated using the equation from Hawkins and Hull (1990). Results & Discussion In hamstrings, the shortest ML were observed at P-Kangle105 and the longest ML were at S-Kangle05. Relative ranges of changes in ML as compared by thigh length were 0.35, 0.36 and 0.40 for BF, ST and SM, respectively. Higher knee flexion torque were observed at relatively longer ML conditions. Although total EMG activity was almost constant along every ML conditions. EMGs in both BF and SM decreased at both P-Kangle60, S-Kangle60, whereas, EMG in ST maintained steady regardless of changing ML. Conclusion Maximum knee flexion torque was observed under longer ML conditions such as S-Kangle05 posture. On the other hand, EMGs of hamstrings showed almost constant regardless of ML changes. CHANGES OF SKELETAL MUSCLE TRANSCRIPTOME IN ENDURANCE-TRAINED MEN AFTER ACUTE EXERCISE

POPOV, D.V., MAKHNOVSKII, P.A., KUROCHKINA, N.S., LYSENKO, E.A., VEPKHVADZE, T.F., VINOGRADOVA, O.L.

Institute for Biomedical Problems RAS

Changes in the human skeletal muscle transcriptome during early (1-4 h) and late (24-96 h) recovery periods after acute endurance exercise were investigated by DNA microarray in several studies. The goal of our work is to investigate changes of skeletal muscle transcriptome in endurance-trained men 4 h and 8 h after acute exercise using high-throughput RNA sequencing. Ten amateur endurance-trained athletes carried out bout of cycling (65 min, 70% V'02max). Biopsies from the m. vastus lateralis were taken prior to exercise, and at 4 h and 8 h after. Total RNA was taken from samples of two subjects for RNA sequencing by Illumina HiSeqDefault 2000 instrument prior to exercise, and at 4 and 8 h after (six samples in total). The differential expression of individual genes was confirmed by quantitative PCR using samples from all subjects (n=10). 199 and 177 genes changed expression level ($P_{adj} < 0.05$) at the 4 and 8 h after exercise accordingly; and only 68 genes displayed overlap. The expression of genes encoding transcription factors (TFs) increased for 12 genes and decreased for 13 genes after 4 h of recovery. Noteworthy, after 8 h recovery number of genes with decreased expression rose to 22. Well-characterized genes involved in regulation of OXPHOS and metabolic processes were among genes, which demonstrated increased expression, whereas many transcriptional repressors involved in clock and metabolic regulation were among genes, which decreased expression. Using Gene Ontology Enrichment Analysis with Reduce and Visualize Gene Ontology tool we revealed main groups of genes related to "regulation of cellular metabolism" and "response to organic substance" (at 4 h) and to "regulation of transcription" and "response to endogenous stimulus" (at 8 h). Surprisingly, we did not find main groups related to regulation of lipid or carbohydrate metabolism or mitochondrial biogenesis. Moreover, only 12 and 14 genes out of 1100 genes, which encode mitochondrial proteins, increased expression 4 h and 8 h after exercise, accordingly. We speculate that low number of changes in expression of genes, related to regulation of mitochondrial biogenesis, lipid and carbohydrate metabolism, is explained by fitness level of our subjects. Finally, to retrieve TFs that potentially might regulate genes after exercise TRANSCRIPTION FACTOR database was used. The largest number of TFs was associated with up-regulated genes at 4 h of recovery. Considerable part of these TFs consisted of basic-leucine zipper family TFs, namely members of AP-1 and ATF/CREB subfamilies. In conclusion, in endurance trained skeletal muscle acute exercise induced increased expression of genes encoding TFs, which regulate OXPHOS and metabolic processes, and decreased expression of genes, which encode transcription repressors. During early recovery period AP-1 and ATF/CREB related TFs may play an important role in regulation of exercise-induced genes expression. The work was supported by RSF grant № 14-15-00768.

GENE NETWORKS IN HUMAN SKELETAL MUSCLE FOLLOWING ENDURANCE EXERCISE ARE PRESERVED IN BLOOD NEUTROPHILS

NEUBAUER, O.1,3, BROADBENT, J.1, SAMPSON, D.1, SABAPATHY, S.2, WAGNER, K.H.3, HASELER, L.J.2, BULMER, A.C.2, PEAKE, J.M.1

Introduction It remains incompletely understood whether there is an association between exercise-induced transcriptional patterns of skeletal muscle and blood leukocytes (Fehrenbach, 2007). This lack of knowledge is mainly due to the difficulties in comparing gene expression in the muscle and leukocytes between studies, as the studies involved different subjects, exercise protocols and sampling time-points. Using our original data on the changes in muscle and blood neutrophil transcriptomes in the same eight trained men before and 3, 48 and 96 h after 2 h cycling and running (Neubauer et al., 2013, 2014) enabled us to overcome these limitations and to directly compare the muscle and neutrophil transcriptomes. Methods Weighted gene co-expression network analysis (WGCNA), an advanced bioinformatic, network-driven method (Langfelder and Horvath, 2008), was applied for a systematic comparison. WGCNA was used to

verify whether clusters of inter-connected and interacting genes are preserved among skeletal muscle and neutrophils, and to assess correlations of muscle gene networks with blood inflammation and muscle damage markers. Results Three clusters of inter-connected genes were evident in muscle tissue and blood neutrophils, preserved across all time-points before and after exercise and functionally related to mitochondria and cell-physiological processes, including acetylation. Muscle gene sub-networks related to immune responses and acetylation correlated strongly with plasma creatine kinase activity, total leukocyte and neutrophil counts, C-reactive protein and interleukin-6 plasma concentrations. Discussion This is the first study that has identified gene networks that exist in both skeletal muscle and a blood leukocyte subset after acute exercise. These findings are a key step forward towards the potential use of particularly blood neutrophil gene profiling to assess muscle health and disease. Furthermore, the identified links between muscle gene networks and blood variables provide important information for developing blood biomarker panels to track changes in the muscle following exercise or other physiological stresses. Collectively, these findings highlight the value of WGCNA in sport science and physiology to analyze large, high-dimensional datasets. References Fehrenbach E. (2007). J Appl Physiol., 102, 7-8. Introduction The human muscle mass is reduced from 0.5 to 1% per year after 30 years old and this reduction significantly increased after 65 years old which eventually could cause sarcopenia (Nair, 2005). It is well known that the high level of inflammatory cytokines such as (including TNF- α , IL-6) appearing in the middle-aged people is highly relevant to the muscle mass loss of the muscle mass and decreased muscle strength (Visser et al., 2002). It has been reported that pro-inflammatory cytokines have an ability to can increase the protein degradations in skeletal muscle both in vitro and in rodent models (Haddad et al., 2005). We investigated the effects of endurance exercise training on the expression of AMPK catalytic α subunit and mTOR signaling pathway in plantaris muscle of middle-aged rats. Methods Twenty of each age group: 50-week-old male Wistar rats and 8-week-old rats were randomly assigned into two groups: sedentary or exercise group. The exercise groups underwent a motor drive treadmill exercise (22 m/min, 30 min/day, 5 days/week) for 4 weeks. The expression level of AMPK, p-AMPK, AMPK α 1, AMPK α 2, mTOR, p70S6Kinase, 4E-BP1 in plantaris muscle were analyzed by western blotting. Results The AMPK, phospho-AMPK, mTOR, p70S6K protein contents in plantaris muscle were significantly decreased and AMPK α 1, 4E-BP1 protein contents were increased as aging. But AMPK α 2 protein contents were not changed. However after 4 weeks of endurance exercise training, AMPK, AMPK α 2 protein contents were significantly increased and 4E-BP1 level was decreased. The AMPK α 1 protein contents were tend to decreased, but it was not significantly different after exercise training. The p70S6K protein contents also show same level after exercise training. Discussion We thought that a high level of inflammatory cytokine and a lower level of anti-inflammatory cytokine cause the muscle mass loss and declined reaction to exercise training as the aging, which is considered to be influenced by reduced AMPK activity and PGC-1 α expression (Jung et al., 2015). We concluded endurance exercise training increase AMPK protein contents, especially it come from the increase of AMPK α 2 protein. These molecular chages were stimulated mTOR signaling pathway, but it did not show differences in the age. References Haddad F, Zaldivar F, Cooper DM, Adams GR. (2005). J Appl Physiol, 98, 911-917. THE RNA EXPRESSION OF IGF1 ISOFORMS AND MYOMIR FAMILY MEMBERS IN A HYPERTROPHIC MUSCLE RAT MODEL

BORI, Z., KOLTAI, E., CHABERT, C., DUBOUCHAUD, H., RADAK, Z.

University of Physical Education

Introduction Different insulin-like growth factor-1 (IGF-1) splice variants (IGF1, IGF-1Ea, and IGF-1Ec (MGF) is suggested to have different functions in muscle hypertrophy. Besides these growth factors microRNAs as fundamental post-transcriptional regulators also regulate hypertrophy. The myomiR family, miRNAs specifically expressed in muscle tissues, include the miR-1, miR-133, miR-206, which are arranged into homologous genes clusters: the miR-1-2/miR-133a-1, the miR-1-1/miR-133a-2 and the miR-206/miR-133b (1). These genes clusters have been shown to be regulated by IGF1 proteins (2). To gain insight into the mechanism of muscle hypertrophy we investigate their expressions at RNA levels in our muscle overload animal model. Methods Compensatory overload of plantaris was accomplished by the bilateral removal of its synergists. The dorsal muscles of both legs were exposed, and the major portion of the gastrocnemius was excised after a blunt dissection, while the soleus muscle was entirely excised. Total RNA from plantaris skeletal muscle samples (~30 mg) was extracted with NucleoSpin RNA kit. RNA concentration, purity and integrity (RIN) was determined with an Agilent 2100 Bioanalyzer (RINs ranged from 7.1 to 8.9). One microgram of total RNA was used to synthesize cDNA using Tetro cDNA Synthesis Kit. The real-time quantitative PCR analyses were performed on a Rotor-Gene 6000 thermal cycler instrument. Reported values were normalized to the average values of the internal standards (housekeeping gene/miR). Statistical significance was assessed by ANOVA. The significance level was set at $p = 0.05$ (Statistica ver. 12.). Results The mRNA level of all three IGF1 splicing variants was markedly upregulated in hypertrophic muscle: IGF1 3.5-fold, IGF1-Ea 2.7-fold, IGF1-Ec 3.2-fold ($p < 0.01$). In contrast to, the RNA levels of myomiR members were downregulated: miR-1 and miR-133a 2-fold ($p < 0.02$), or unchanged miR-206. The RNA level of both miR-1 miR-133a correlated negatively with that of IGF1-Ea and Ec splice variants ($R = -0.84$, -0.88 and $R = -0.79$, -0.89 respectively, $p = 0.02$). However the RNA level of miR-206 shows no correlation with any of IGF1 splice variants. Discussion In our overload hypertrophic rat model the well-known muscle growth factor IGF1's all splice variants are similarly upregulated. However not every myomiR members show similar expression pattern. The correlation analysis shows a strong relation among IGF1 variants and two member of myomiR gene cluster: miR-1,-133a RNAs expression pattern. However the third member of these gene clusters miR-206 shows no correlation. These expression profiles may reveal the fine regulation of myomiR gene cluster's promoter activity by IGF1 variants in this model. ERYTHROPOIETIN DOES NOT PROMOTE HUMAN SKELETAL MUSCLE PROTEIN SYNTHESIS

LAMON, S., ZACHERWICZ, E., ARENTSON-LANTZ, E., DELLA GATTA, P., GHOBRIAL, L., GARNHAM, A., PADDON-JONES, D., RUSSELL, A.

Deakin University

Introduction: Erythropoietin (EPO) is a glycoproteic hormone produced in response to tissue hypoxia; a process that results in a larger number of circulating erythrocytes and a better oxygenation of the active tissues. We previously showed that the EPO-receptor (EPO-R) is expressed in human skeletal muscle tissue (1). In cell lines expressing high levels of EPO-R, EPO treatment activates the phosphatidylinositol 3-kinase (PI3)/Akt (Akt) pathway and the Ras/mitogen-activated kinase (MAPK) signalling pathways, the 2 major pathways involved in the regulation of protein synthesis in human muscle. We hypothesized that EPO triggers protein synthesis in human skeletal muscle via the activation of Akt and MAPK signalling. **Methods:** Healthy young ($n=10$, 18-30 y) and older ($n=10$, 60-75 y) males received a bolus intravenous injection of 10'000 IU EPO (Recormon®) or placebo while subjected to a primed (0.34 mg/kg) constant infusion (0.0085 mg/kg/min) of L-[ring-13C6] phenylalanine. Venous blood samples were collected every 30 min and vastus lateralis muscle biopsy samples were obtained at rest (2h post-EPO) and 2 h following an acute bout of resistance exercise (3 sets of 14 repetitions of isometric knee extension exercise at 60% 1RM) (4 h post-EPO). Mixed skeletal muscle fractional synthesis rate and phosphorylation levels of the members of the Akt and MAPK pathways were measured in muscle tissue. Muscle intracellular and bound protein [ring-13C6]-L-phenylalanine enrichments were determined by gas chromatography-mass spectrometry (GC-MS) using their tert-butyldimethylsilyl derivative. **Results:** Exercise activated Akt but not MAPK signalling in young subjects only. EPO had no effect on fractional synthesis rate (protein synthesis) or on the activation of Akt or MAPK signalling following exercise. **Conclusion:** An acute EPO injection had no effect on skeletal muscle protein synthesis or markers of anabolic signalling in human skeletal muscle. These results suggest that the reported effects of EPO on human skeletal muscle are likely not due to the direct activation of the EPO-R, but rather a consequence of the well established enhanced oxygen carrying-capacity of the blood. References 1. Lamon S, Zacharewicz E, Stephens AN, Russell AP. EPO-receptor is present in mouse C2C12 and human primary skeletal muscle cells but EPO does not influence myogenesis. Oral presentations**OP-BN18 Sport Technology: Equipment 1****EFFECT OF SLOPE ON DISTANCE TO ZERO SKID AND COEFFICIENT OF FRICTION OF A PUTTED GOLF BALL**

RORY, M.

Swansea University

Introduction A recent study (Griffiths et al. 2016) determined a method of finding the coefficient of kinetic friction for a number of different surfaces with use of a numerical simulation, however this method was only applicable to completely level surfaces. Therefore the aim of this study was to determine the effect that a sloped surface has on a putted golf ball, before finding the mean coefficient of kinetic friction of each variable, using a numerical simulation. **Methods** Twenty valid putts were tracked for the first 40cm of their travel across three different surfaces namely; rubber, a putt mat and MFC, on five different slopes; 0°, 1.2°, -1.2°, 2.2° and -2.2°, using a high speed video camera (360 frames per second). In order for a putt to be selected for analysis it had to fall within the following criteria; Initial ball speed - 3.4mph ± 0.25, Cut/hook spin - <20rpm and Initial launch angle - 0.75°-2.5°. A numerical simulation was created using the work of Penner, 2002 and Hierrezuelo & Carnero, 1995 to determine the coefficient of kinetic friction of each individual putt. **Results** The distance to zero skid was smallest for the 2.2° slope on the rubber, putt mat and MFC surfaces yielding mean values of 2.71", 8.24" and 12.5" respectively, whilst the -2.2° slope yielded the largest mean values of 3.08", 9.14" and 18.34" respectively. Results suggest that the greater the slope, the smaller the distance it takes for a golf ball to achieve pure rolling motion (i.e. negative relationship). The mean coefficient of kinetic friction for the rubber, putt mat and MFC surfaces ranged from $\mu_k=0.74-0.75$, $\mu_k=0.25-0.26$ and $\mu_k=0.15-0.16$ respectively. **Discussion** The simulation was found to be accurate to 0.01 μ in predicting the coefficient of kinetic friction of the three surfaces at different gradients of slope. It would be of interest for future research to investigate the relationship artificial surfaces have with grass (outdoor golf greens). If found to be similar it may be applicable to replicate putting green characteristics away from the golf course, for players to familiarise themselves with the conditions in order to prepare themselves for competition play. EFFECTS OF DIMPLE ON A SOCCER BALL FLIGHT

HONG, S., ASAI, T.

University of Tsukuba

Introduction It has been reported that the aerodynamic force applied to the ball changes in accordance with the number of panels and their orientation, consequently changing the flight trajectory (Goff et al., 2014; Hong & Asai, 2014; Hong et al., 2015). However, as the shapes on the surface of a soccer ball are a combination of various forms of panels and complicated seams, the influence that these shapes have on the aerodynamic force acting on the soccer ball is mostly unclear. Hence, in this study we aerodynamically studied the shape of the panels and the surface design (presence or absence of dimples). **Methods** In this study, we introduced dimples on the surface of a soccer ball and examined their effect on the aerodynamic forces acting on the ball using a wind tunnel. We targeted three types of soccer balls in this study, namely, a soccer balls constructed from 32 panels, 12 panels and 6 panels, all of which are made out of the same material (leather). In addition, for each type of soccer ball, we constructed a type with dimples (dimple width of 3 mm and depth of 1 mm) and a type without dimples, making a total of six types of soccer balls. We then studied and measured the effect of the number of panels and the presence or absence of dimples on these six types of soccer balls using a wind tunnel experiment and revealed the aerodynamic characteristics. **Results** The drag coefficient of soccer balls with dimples in the supercritical region, the soccer ball with 32 panels had the smallest drag value of approximately 0.10 ($Re = 2.3 \times 10^5$) whereas the soccer ball with 12 and 6 panels had a

value of approximately 0.15 ($Re = 2.1 \times 10^5$) and 0.17 ($Re = 2.1 \times 10^5$). However, for the case of soccer balls without dimples, the soccer ball with 32 panels had a drag coefficient value of approximately 0.13 ($Re = 3.5 \times 10^5$) and the soccer ball with 2 and 6 panels had a value of approximately 0.12 ($Re = 3.5 \times 10^5$) and 0.12 ($Re = 3.4 \times 10^5$). Furthermore, in a wind speed of 30 m/s, the variations in the lift and side force in the case of a soccer ball with 32 panels without dimples were 2.5 N and 2.6 N, respectively. Likewise, the dimple soccer balls with 32 panels were 1.3 N and 1.7 N, respectively. Conclusion The presence or absence of dimples on the surface of a soccer ball greatly varied the drag working on the ball. From this, it is plausible that, in the speed range used during a pass and a long kick, soccer balls with dimples have the possibility of flying faster, whereas, in the speed range used during powerful shots, soccer balls without dimples have the possibility of flying faster. In addition, during the flight of a soccer ball, horizontal motion is believed to be more stable for soccer balls with dimples than for soccer balls without dimples. SPIN BOWLING PERFORMANCE PARAMETERS AND ANALYSIS WITH A SMART CRICKET BALL

FUSS, F.K., DOLJIN, B.

RMIT University

Introduction Cricket is the 2nd-most popular sport in the world. In spin bowling, the ball is delivered at a slower speed than fast bowling, with putting a high spin rate on the ball, such that it bounces at an angle to the flight path. The aim of this research is to define and evaluate parameters for performance analysis with a smart cricket ball. Methods The smart cricket ball (Doljin and Fuss, 2015) used in this study is Mark 2 of the first prototype (Fuss et al., 2012). Mark 2 of the smart cricket ball is wireless (data transfer and inductive charging), and contains high-speed gyros, a circular PCB and a battery. The software of the ball calculates a range of performance parameters before release of the ball, among which are: spin rate, angular acceleration, precession speed, and normalised precession, torques and power about the centre of the ball, efficiency, pitch of the spin axis at release, and location and path of the centre of pressure between ball and hand. The data were collected during off- and leg-spin deliveries of 15 bowlers at different performance levels. The data were analysed statistically with regression analyses. Results and Discussion While the pitch of the spin axis at release, which should be 90 deg, i.e. perpendicular to the plane of the seam, indicates the amount of seam wobble, the most important performance parameter is the spin rate – the faster, the better. Yet, the spin rate alone is only an effect and does not explain its cause. The causes identified in this research are the torque imparted on the ball through the centre of pressure, the resulting acceleration and power, as well as precession and efficiency. E.g., two different bowlers produce the same spin rate, however one bowler requires less torque, acceleration and power than the other. The precession rate (speed of the moving spin axis) is caused by a torque that could have been used for improving the spin rate (and the kinetic energy at release) if the precession was avoided. The peak precession rate, the peak normalised precession (angle between spin axis and torque vector at the beginning of imparting spin on the ball; Fuss et al., 2015), and the efficiency (actual angular kinetic energy over ideal one if the precession was avoided) do not correlate well as they are taken at different times) and as they also depend on the spin delivery (wrist-spin and top-spin deliveries are more efficient than finger-spin and back-spin). However, the ratio of maximal acceleration to maximal spin rate correlates well with the peak precession ($r = 0.89$). The greater this ratio is, the more slender is the acceleration spike (shorter time period), and it seems that the precession shortens this time period. References Fuss FK, Smith RM, Subic A. (2012). INTERFACE PRESSURE GENERATED BY SPORTS GLOVES TO THE HAND OF THE WEARER AND ITS IMPACT ON SPORTS GLOVES ENGINEERING.

TROYNIKOV, O., NASIR, S.H., BAFEKPOUR, E.

RMIT University

Functional sporting gloves are commonly used and are often required in a number of sports such as hockey, baseball, lacrosse, cricket, golf and cycling. The main role of sports gloves is functional: protection from impact and abrasion or greater grip or dexterity of the wearer. It is also highly desirable that the sport gloves do not restrict the wearer's grip and dexterity. Glove design should enable dynamic freedom of movement while allowing avoidance of excessive pressure that could impede the grip strength; range of motion; performance of task; and physiological comfort of users [1]. Previous researchers have mainly focused on hand anthropometry data for development of a glove sizing system and on its pattern [2]. An earlier study [3] focused on the skin relaxed-strain ratio at the dorsal side of the hand to determine the skin deformation behaviour during various sports activities and demonstrated that the metacarpal regions had significantly higher skin relaxed-strain ratio than the phalangeal and metacarpal-carpal regions in both dynamic postures. These findings provide valuable information to be incorporated into sports and functional glove pattern design for improving the fit, comfort, performance and functionality of a sport glove. However, further studies are needed to quantify the interface pressure generated by sport gloves to the hand of the wearer in different hand postures and at different hand regions. The current study explores the interface pressure at the dorsal hand side during different dynamic postures which are typical for various sport activities. Fifteen female participants between the ages of 25-35 years with hand size medium (M) wore sports gloves and performed a relaxed hand posture and two dynamic postures. There were significant differences in the interface pressure between the experimental postures, especially in phalangeal and metacarpal regions. It was determined that sports gloves generate significantly larger interface pressure in the metacarpal region than in the phalangeal region and metacarpal-carpal region. This study has further contributed to enhancing the knowledge of the glove's behaviour during various sports activities and the interface pressure generated by them which are important for the engineering of sports and functional gloves with improved fit, comfort, and functionality. OP-PM21 Soccer Assessments

TIME-MOTION ANALYSIS IN ELITE SOCCER PLAYERS: SMALL-SIDED GAMES VS. MATCH PERFORMANCE

RIBOLI, A.1,2, RAMPICHINI, S.1, LIMONTA, E.1, CÈ, E.1, VENTURELLI, M.1, ESPOSITO, F.1

University of Milan

Introduction: Video-analysis and global positioning system (GPS) are used to determine players' loads and drills during soccer activities. Small-sided games (SSGs) are generally utilized as skill-based conditioning drills, the workload intensity of which is a crucial feature. The aim of the study was to compare the equivalent distance (ED, i.e., the distance that a given player would have run, given the actually measured overall energy expenditure, had he been running at constant speed throughout the whole match) (di Prampero et al., 2015) determined during SSG in different pitch dimension with average ED during official matches (EDmatch). For this approach, the interchangeability of video analysis and GPS during SSGs is a crucial issue and was also assessed (Buchheit et al., 2014). **Methods:** Twenty-five elite soccer players (Italian Serie A) performed a total of 1033 and 1532 observations for collective possession plays (SSG-P) and SSGs with goalkeeper (SSG-G), respectively. SSGs were evaluated by GPS (10 Hz; accelerometer: 100 Hz, 16G Tri-Axis). For each player, a median of 39 ± 14 SSG-P (mean \pm SD) and 57 ± 17 SSG-G were examined on different pitch dimensions. Each drill was normalized per meter covered in one minute ($m \cdot \text{min}^{-1}$) and area per player ($m^2 \cdot \text{player}$). In addition, thirty-nine official matches (18 ± 9 observations per player) were monitored by semi-automatic multiple cameras. Lastly, a typical training session with SSGs was monitored with both GPS and video-analysis to assess the interchangeability of the two methodologies. **Results:** A small typical error of the estimate (TEE: 0.07, 95% confidence intervals: 0.04/0.13) and a higher correlation ($r^2=0.99$, $P<0.001$) were found between ED calculated from GPS and video-analysis. A correlation ($r^2=0.788$, $P<0.001$) between ED and area per player was found only for SSG-P. The regression line in SSG-P crossed EDmatch at an average area of $95 \pm 8 m^2 \cdot \text{player}$ with a smaller dimension ($36 \pm 1 m^2 \cdot \text{player}$) for central defenders (CD) than other roles ($P<0.05$). **Discussion:** A small TEE and a higher correlation permitted a comparison between GPS and video-analysis with these technologies. Due to a lower tactical and higher physical involvement than in SSG-G, ED increased with area per player and induced average EDmatch only during SSG-P, with a less area per player in CD. These findings may contribute to better assess workloads using SSG-P with respect to match intensity for each role. **References:** di Prampero PE, Botter A, Osgnach C (2015). CRITERION VALIDITY OF THE LOUGHBOROUGH SOCCER PASSING TEST IN ELITE YOUTH SOCCER

SERPIELLO, F.R.1, COX, A.1, OPPICI, L.1, HOPKINS, W.G.1,2, VARLEY, M.C.1

1 Institute of Sport, Exercise and Active Living (ISEAL), Victoria University, Melbourne, Australia 2 Defence Institute, Oslo, Norway

INTRODUCTION Successful passing is a key component of skilled performance in football, particularly for elite youth players. Owing to the difficulty of assessing passing performance in a controlled environment in games, field tests have been developed to isolate the measurement of this skill. The Loughborough Soccer Passing Test (LSPT) is commonly used to assess passing performance under time pressure. The test is reliable and displays discriminant validity in youth soccer. Here we report its criterion validity with such athletes. **METHODS** Twenty-five players from the U18 state representative team (age 15.1 ± 0.6) performed the LSPT. The first eight games of the season were then recorded and coded for passing ability using a custom-made coding window from commercially-available software (SportsCode, Hudl). Data were coded according to two scenarios. The first reflected overall success rate for all passes within a game. The second scenario represented a high-quality passing situation and passes were included only when they met all the following criteria: the player had performed ≤ 3 touches before the pass, the pass lead to a scoring opportunity or forward movement of a team-mate, the pass occurred across halves or in the opponent's half, and pass direction was forward or sideways. Inter-rater agreement was assessed for overall passing success rate using Cohen's kappa. Criterion validity of the LSPT scores was assessed as the correlation between the players' mean passing score and their LSPT score. The validity correlation coefficient was then adjusted to take into account the error of the criterion using the intraclass correlation coefficient (ICC) for the mean passing score in 8 games. **RESULTS** Inter-rater agreement kappa was 1.00. The ICC for 8-game reliability was 0.67 for overall passing success and 0.75 for the high-quality situation. Overall validity of the LSPT compared to the criterion was very poor for both time-only LSPT (corrected $r=0.59$) and LSPT total time (corrected $r=0.58$). Validity of the LSPT compared to the criterion in the high-quality passing scenario was impractical for both time-only LSPT (corrected $r=0.32$) and LSPT total time (corrected $r=0.18$). **DISCUSSION** This study demonstrated for the first time that the LSPT does not have criterion validity in Australian elite youth football. Despite the strong reliability and discriminant validity, attention must be paid to the interpretation of the test result, as it does not accurately represent in-game passing performance. **CONTACT** Dr Fabio R. HIGH INTENSITY EVENTS AND POST-MATCH FATIGUE IN FOOTBALL

WIIG, H., LUTEBERGET, L., RAASTAD, T., SPENCER, M.

Norwegian School of Sport Sciences

Introduction Football matches produce post-match fatigue and time until full recovery may take several days (Nedelec et al., 2012). The slow recovery, probably related to muscle damage, has been associated to the high intensity activities during the match (e.g. Russel et al., 2016). However, the role of accelerations and decelerations in this relationship is not well understood. Therefore, the aim of this study was to investigate high intensity events (HIE) in football matches using Inertial Measurements Units (IMU) and its interaction on post-match fatigue and indicators of muscle damage. **Methods** Six Norwegian 2. division teams ($n=81$) were recruited to play three matches. IMUs (Catapult Optimeye S5, Australia) with 100Hz accelerometer, magnetometer, and gyroscope were worn in a vest placed on the upper back. HIE, the sum of accelerations, decelerations, change of directions efforts and jumps ($>2.5 m \cdot s^{-1}$), were quantified and expressed as counts per minute. Players were divided into keepers (KE; $n=6$), central defenders (CD; $n=13$), full backs (FB; $n=13$), central midfielders (CM; $n=23$), wide midfielders (WM; $n=16$) and attackers (AT; $n=10$). Countermovement jumps (CMJ; $n=56$) and Creatine Kinase (CK; $n=35$) were measured 1 hour pre and 1, 24, 48 and 72 hours' post-match (KE excluded). Differences were deemed likely (L), very likely (VL) and most likely (ML) when there was a likelihood of $> 75\%$, 95% and 99% of the difference exceeding an effect size of 0.2 respectively. The interaction of HIE on fatigue was investigated using mixed model analysis (fixed effects: time:HIE and random effects: subjects +

teams). Results On average, HIE occurred 2.1 ± 0.7 times per minute (mean \pm SD) including 0.3 ± 0.1 accelerations, 0.5 ± 0.2 decelerations, 1.3 ± 0.5 changes of direction and 0.05 ± 0.03 jumps and were position depended: WM (2.5 ± 0.5), CM (2.4 ± 0.5), AT (2.2 ± 0.5), FB (2.0 ± 0.6), CD (1.8 ± 0.5) and KE (0.8 ± 0.2). Differences ranged from L to VL. The percent changes from pre to +1h, +24h, +48, and +72h were -6.6 (VL), -6.2 (VL), -6.6 (VL) and -4.7 (L) for CMJ height and 69 (ML), 112 (ML), 42 (L), 4.1 (unclear) for CK respectively. Lastly, our model showed no interaction of HIE on neither CMJ nor CK for any of the time points. Discussion HIE were found to be position depended and thus, players from different positions are loaded differently in matches. The match load produced neuromuscular fatigue lasting for 72 hours. However, a direct interaction of total HIE on fatigue or muscle damage was missing, suggesting that the match load and fatigue relationship is more complex. Player fitness, pre-match fatigue, and match effort could possibly interact in this relationship. References Nedelec, M et al. (2012). Sports Medicine, 42, 997-1015 Russel, M et al. (2016). RELATIVE ACCELERATION AS A NEW INDICATOR OF GAME INTENSITY IN SOCCER

SONDEREGGER, K.1,2, RUMO, M.1, TSCHOPP, M.1

1: Swiss Federal Institute of Sport Magglingen (Switzerland); 2: Movement and Sport Science, University of Fribourg (Switzerland)

Introduction Intensity in team sports has been commonly measured on the basis of distances covered in different speed zones. It was recently noted that the problem with this approach is that short acceleration does not contribute to game intensity because the required speed is not achieved. Relative acceleration accounts for these short-term actions and may be therefore a more valid indicator of game intensity. Methods During 14 official games, 90 positional datasets were collected from 69 elite junior players (mean age, 17.0 ± 0.6 y) of the highest and 91 datasets from 69 sub-elite junior players (mean age, 17.9 ± 0.9 y) of the second highest national U18 championship levels, using the Local Position Measurement System. Based on the raw acceleration and speed data, each acceleration peak was identified as a single action. For each action, the relative acceleration was calculated as a ratio between the acceleration of the action and the maximum possible acceleration, dependent of the initial running speed, which was determined in a sprint test conducted prior to the games. All actions were classified into four intensities based on the relative acceleration and the initial running speed. The number of high-, moderate-, low-, and very low-intensity actions were then compared with commonly used speed zones (high-speed running [I_{HSR}] > 19.8 km·h $^{-1}$ and sprinting [$|S| > 25$ km·h $^{-1}$]). Differences between the two performance levels were determined by calculating the effect sizes (ES). Results Elite junior players had more of high- (84 vs 66), moderate- (90 vs 82), and low- (183 vs 176) intensity actions. The difference is larger in high- (ES, 0.91) than in moderate- (0.48) and low- (0.28) intensity actions. The number of high-intensity actions yields a larger ES than the commonly used indicators of game intensity such as distances covered in high-speed zones (I_{HSR} : 522 vs 431 m; ES, 0.50; S: 111 vs 76 m; ES, 0.51). Comparison between the elite and sub-elite players for specific positions yielded a larger ES when number of high-intensity actions rather than common speed zones were used, except for fullbacks (central midfield: ES of 1.38 vs 0.52 [I_{HSR}]/0.09 $|S|$; centre back: ES of 0.68 vs 0.48/0.31; forward: ES of 1.47 vs 0.52/-0.03; wide midfield: 0.64 vs -0.89/0.28; fullbacks: ES of 0.87 vs 1.22/1.88). Discussion and Conclusion The differences in game intensity between elite and sub-elite junior soccer players is larger when expressed by number of high-intensity actions calculated with relative acceleration than by commonly used speed zones. The difference can be explained by the fact that using relative acceleration to determine intensity results in taking high accelerations from low initial running speeds as well as lower accelerations from high initial speeds into account. Therefore, the new indicator proposed here removes the bias introduced by the commonly used speed zones. Contact karin.sonderegger@baspo.admin.ch

COGNIFOOT - ASSESSING THE COGNITIVE-MOTOR PERFORMANCE OF SOCCER PLAYERS: OBJECTIVE MEASUREMENTS VS COACHES' EVALUATION

TAUBE, W., CHASSOT, S., CHENEVIERE, X., HICHEUR, H.

University of Freiburg

The cognitive-motor performance, defined here as the capacity to rapidly use sensory information and transfer it into efficient motor output, represents a major contributor to performance in almost all sports, involving soccer. The difficulty is to assess this complex cognitive-motor performance in a standardized and quantitative manner while preserving the ecological validity of the tested tasks. For this purpose, we used a high-technology system (COGNIFOOT, patent pending) which combines a visual environment simulator fully synchronized with a motion capture system. With this device, objective real-time measurements of several parameters such as response time and kicking accuracy were done in a large (10 x 8 meters – length x width) turf-artificial grass playfield on which players could execute real soccer skills. Forty-six (46) young elite soccer players aged between 11 and 16 years who all belonged to the U12-U13-U14-U15-U16 categories of the same youth soccer academy were tested. Each player had to shoot the ball as fast and as accurately as possible towards a 0.2 meters-diameter visual target projected onto a large screen (4 x 3 meters – width x height) located 5 meters in front of him/her (a short pass situation). The response times were computed as the delay between the appearance of the visual stimulus and the initial movement of the ball, thus, including a motor preparation phase. The response times were found to decrease with increasing age of the players (on average from 1100 ms to 1020 ms for the U12 and U15-U16 categories, respectively) while the kicking accuracy increased linearly with age indicated by smaller spatial errors (from 45 to 29 cm for the U12 and U15-U16 categories). These data were converted into 5 point-scales in order to compare them with the judgement of the coaches, who also used a 5 point-scale to evaluate the reactivity and the kicking accuracy of their players, respectively. The global cognitive-motor performance indices computed from these two types of evaluations were highly correlated when considering every single age category. However, coaches' more subjective evaluations across age groups were not consistent and failed to detect the age effect measured via the COGNIFOOT system. The functional implications of these findings for talents identification will be discussed together with the potential interest of this new type of sport technology for testing/training the cognitive-motor performance.

OP-SH08 Psychology: Burnout & Stress

PERCEIVED COACH AUTONOMY SUPPORT AND ATHLETE BURNOUT: THE MODERATING ROLE OF EXPERIENTIAL AVOIDANCE

CHANG, W.H.1, CHI, L.1, CHEN, L.H.2

National Taiwan Normal University 1, National Taiwan Sport University 2

Introduction Researchers have investigated that perceived coach autonomy support could prevent athlete burnout (Quested & Duda, 2011). However, few studies have investigated the when and whether or not perceived coach autonomy support can alleviate athlete burnout empirically. Therefore, authors draw on an interactionism perspective to suggest low experiential avoidance individuals benefit most from perceived coach autonomy support. Experiential avoidance is a generalized unwillingness to remain in contact with private experiences leading to actions inconsistent with one's values and goals (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996, p. 1153). Therefore, the present study examined the relationship between perceived coach autonomy support and athlete burnout is moderated by experiential avoidance. Methods To allay common-method bias concern, we used a time-lagged design to collect data during two periods. Athletes completed experiential avoidance and athlete burnout instruments at time 1. After 3 months, perceived coach autonomy support and athlete burnout were assessed. To examine our hypothesis, the completed variables collected from 141 athletes with a mean age of 21.14 years. The athletes were recruited from department of athletic performance and physical education. All participants read and signed the informed consent form indicating their ethical rights. Results The results indicated that perceived coach autonomy support was negatively related to athlete burnout. Furthermore, experiential avoidance weakened the relationship between perceived coach autonomy support and athlete burnout. Discussion Our study helps explain that athletes low in experiential avoidance benefit more from perceived coach autonomy support than those high in experiential avoidance. We contribute to the literature by identifying new boundary conditions. Furthermore, the present study contributes to athlete burnout research by adopting an interactionist perspective to understand how perceived coach autonomy support and experiential avoidance jointly shape athlete burnout. THE PREDICTION OF DISEMPowering MOTIVATIONAL CLIMATE ON BURNOUT AMONG YOUTH BADMINTON PLAYERS: THE MEDIATING EFFECTS OF BASIC PSYCHOLOGICAL NEEDS.

TSAI, Y.T., CHI, L.K.

National Taiwan Normal University

Introduction Athletes' burnout has been an important issue which results in dropout the sport. The present study aimed to examine whether the impact of coach's disempowering motivational climate on burnout is mediated by basic psychological needs among youth badminton players. Methods One hundred and fifty-two high school badminton players (males=85, females=67, Mage=16.55) were recruited to this study. Participants were asked to complete questionnaires which include Disempowering Motivational Climate Questionnaire (Appleton, Ntoumanis, Quested, Viladrich, Duda, 2015), Basic Need Satisfaction Scale (Deci, Ryan, Gagné& Kornazheva, 2001), and Athlete Burnout Questionnaire (Raedeke, & Smith, 2001). Results Results showed that disempowering motivation climate positively predicted exercise burnout ($R^2=21\%$). Disempowering motivational climate negatively predicted relatedness, competence, and autonomy. The explained variances were 18%, 6.1% and 3.5% respectively. In addition, in terms of the mediating effect of basic psychological needs, the prediction of disempowering motivational climate on burnout was only mediated by competence but not relatedness and autonomy. Discussion In accord to the previous studies regarding the relationships between motivational climates and burnout (Kang, 2004; Wang, 2008), disempowering motivational climate negatively predicted burnout. Moreover, one of the basic needs – competence played as a mediator. In other words, disempowering motivational climate negatively influence youth badminton players' competence and then negatively predicted their burnout. According to these results, coaches should avoid creating disempowering motivational climate to protect athletes' competence and then reduce the tendency of the burnout. REGULARLY EXERCISING STUDENTS REPORT LESSER EXHAUSTION AND PERCEIVED STRESS, BUT THE WEEKLY VOLUME OF EXERCISE APPEARS TO BE UNIMPORTANT

SZABO, A., STORVIK, V.

Eötvös Loránd University

Introduction Several reports in the scholastic literature suggest that regular physical exercise buffers psychosocial stress. There is also a tendency to prescribe a minimal volume of exercise in detecting measurable effects. However, this presumption was challenged a while ago (Szabo, 2003). In the current study, we tested the perceived stress and burnout in exercising and non-exercising university students to establish whether the claims in the literature materialize in the real life situation. Methods A volunteer sample (n=372) of Norwegian and Hungarian undergraduate and postgraduate university students completed both the 'Maslach Burnout Inventory Student Scale' (MBISS; Schaufeli et al., 2002) and the 'Perceived Stress Scale' (PSS; Cohen et al., 1983). Exercising students also reported the frequency and the best estimated duration of their weekly exercise. Data were analysed with a multivariate analysis of variance. Results While there

was no statistically significant difference in the perceived (reported) burnout and stress between undergraduates and postgraduates, exercisers reported less exhaustion (13.44 ± 5.05 vs. 14.84 ± 5.67 , $p=.034$, $d=.26$) on the MBISS and lower perceived stress (40.39 ± 8.47 vs. 44.05 ± 9.92 , $p=.001$, $d=.37$) on the PSS than non-exercisers. Nevertheless, there was no significant correlation between these two variables (that were correlated with each other, $r = .46$, $p<.001$) and the reported weekly volume of exercise. Discussion The results of this study support the contention in the literature that regular exercise has a protective role in stress and burnout. The lack of correlation between the amount of reported stress or burnout in exercising students and the best estimated volume of exercise, indicates that the fact that one exercises (the involvement itself) is more a determinant of the perceived stress and burnout than the effort invested in exercise. If this is the case, it may be stated that exercise acts as a mental aid in the mental appraisal of the challenges in the life of university students, supporting the role of the placebo effect in exercise behaviour (Szabo, 2013). ACUTE EFFECTS OF YOGA ON CARDIAC AUTONOMIC RESPONSE TO AND RECOVERY FROM MENTAL STRESS

CHU, I.H., LIN, Y.J.

KAOHSIUNG MEDICAL UNIVERSITY

Introduction Mental stress has been shown to be associated with the development of cardiovascular disease (Chida & Steptoe, 2010). Previous research also indicated that individuals with exaggerated cardiovascular response to mental stress had increased risk for hypertension (Carroll et al., 2003). While most studies have investigated the effects of aerobic exercise on cardiovascular reactivity, the effects of other types of exercise, such as yoga, are undetermined. The purpose of this study was to examine the acute effects of yoga on heart rate (HR) and cardiac autonomic response to and recovery from mental stress. Methods A total of 46 participants (mean age 23.25 ± 3.80) were recruited for this study and completed two testing sessions in which participants engaged in either yoga or video watching (VW) conditions randomized for that session. After each condition, participants underwent a Stroop task and mental arithmetic task, which served as mental stressors. Electrocardiogram was used to measure HR throughout the mental stress period until 5 minutes after the end of the stress period. Heart rate variability (HRV) for both stress and recovery periods were analyzed and expressed as low frequency (LF), high frequency (HF), and the ratio of LF to HF (LF/HF). Results The results revealed that there were no significant differences in HR during mental stress and recovery periods after yoga and VW conditions. Similar for HRV, there were no significant differences in LF, HF, and LF/HF during mental stress and recovery periods after the two conditions. Discussion The results of this study showed that HR and HRV during mental stress and recovery after an acute bout of yoga was not significantly different from the VW control condition, suggesting that one bout of yoga practice was not effective in reducing cardiovascular reactivity to mental stress. Future studies may consider investigating individuals demonstrating exaggerated cardiovascular reactivity to mental stress and involve long-term practice of yoga to further examine the potential effect of yoga on cardiovascular reactivity to mental stress. FILM-INDUCED NEGATIVE EMOTIONS INTERFERE WITH CONTROL OF BREATHING DURING PHYSICAL ACTIVITY AND CAUSE HYPERVENTILATION

WÜRTH, S., WILHELM, F.H., MINNIBERGER, M., AMESBERGER, G.

University of Salzburg

Introduction Automatic control of breathing is primarily regulated by the carbon dioxide partial pressure (pCO₂). PCO₂ remains stable at rest as well as during light and moderate physical exercise before it sharply decreases at heavy-exercise intensities (exercise-induced hyperventilation) (Brown, Miller, & Eason, 2006). However, intense negative emotional experiences of individual relevance (e.g., fear) can evoke hyperventilation without any exercise (psychogenic hyperventilation) (Niggemann, 2010). Hence, strong emotion during physical exercise might lead to interfering effects in the control of breathing. Sport injury related stimuli can elicit negative emotions and thus are expected to cause this interference effect and hyperventilation. Methods Twelve volunteers aged 23.9 (20-33) years underwent two graded exercise tests on a cycle-ergometer at intervals of one week. Individual work load started at 0.8 W/kg with increased intensity of 15 W/kg/min. Respiratory gas analysis was carried out via a breath-by-breath-system (© ZAN 600 USB). During exercise tests, participants watched either video clips with neutral emotional valence, or negative emotional video clips depicting sports injuries (order counterbalanced). Heart rate, ratings of perceived exertion (RPE; Borg, 1998), and ratings of negative emotions (10-point Likert scale) were recorded at the end of each stage. Results Negative emotions were significantly higher when watching injury-related clips ($M_{neu} = 1.08$, $SD = 0.09$; $M_{inj} = 5.23$, $SD = 1.94$). Repeated measures ANOVA across the first ten stages of exercise testing revealed a significant Emotion x Stage interaction effect for pCO₂ [$F(9, 99) = 6.39$, $p < .01$, $\eta^2 = .37$]. Follow-up analyses revealed that pCO₂ did not differ between conditions across the first stages of exercise, but then declined in the negative emotion condition resulting in significantly lower pCO₂ at stage ten [$M_{neu} = 43.65$ mmHG, $SD = 2.56$; $M_{inj} = 41.84$ mmHG, $SD = 2.93$]. No significant effects were found for heart rate or perceived exertion, respectively. Discussion Results confirm that negative emotion interferes with control of breathing and pCO₂ maintenance at graded exercise. The decline of pCO₂ while watching aversive injury-related stimuli during graded exercising indicates hyperventilation due to psychogenic rather than exercise-induced factors. Results will be discussed with respect to underlying psychophysiological mechanisms and consequences as well as implications for sports performance and practice. References Borg G (1998). COGNITIVE REACTIONS TO FAILURE IN HEALTHY AND UNHEALTHY PERFECTIONIST INTERCOLLEGIATE ATHLETES

LIZMORE, M., DUNN, J., CAUSGROVE DUNN, J.

University of Alberta

The ability to respond in an adaptive or functional manner following failure in sport is a highly desirable attribute for competitive athletes. This study used the tripartite model of perfectionism (Stoeber & Otto, 2006) to examine the degree to which healthy and unhealthy perfectionist athletes typically respond with adaptive and maladaptive cognitions following poor performances in sport. A sample of 239 male and female intercollegiate team-sport varsity athletes (M age = 20.50, SD = 1.99) from a large Canadian university completed a self-report measure of perfectionism in sport (i.e., the Sport-Multidimensional Perfectionism Scale-2 [Sport-MPS-2]: Gotwals & Dunn, 2009).

Participants also completed three instruments designed to measure athletes' cognitive-response tendencies to poor personal performances in sport across four constructs: self-compassion, optimism, pessimism, and rumination. A non-hierarchical (K-means) cluster analysis was conducted to create groups/clusters of healthy perfectionists (i.e., high strivings and low concerns: n = 102), unhealthy perfectionists (i.e., high strivings and high concerns: n = 71), and non-perfectionists (i.e., low strivings: n = 63). The seed points employed in the K-mean analysis were based on Sport-MPS-2 mean-item subscale scores taken from previously published studies that had also used cluster analysis to create groups (i.e., healthy perfectionists, unhealthy perfectionists, and non-perfectionists) that were interpreted using the tripartite model of perfectionism. A statistically significant MANOVA (Wilks Lambda = .757, F (8,460) = 8.582, p < .001) with follow-up univariate F-tests revealed significant between-group differences on all four dependent variables (i.e., self-compassion, optimism, pessimism, and rumination: all ps < .05). Post-hoc t-tests (with Bonferroni corrections) indicated that healthy perfectionists, on average, experienced significantly higher adaptive cognitions (i.e., self-compassion and optimism) and lower maladaptive cognitions (i.e., pessimism and rumination) following poor performances than unhealthy perfectionists (all ps < .05). Results indicate that coaches and sport psychologists may benefit from knowing an athlete's perfectionism profile in order to better understand (or anticipate) how the athlete might respond following personal failure in competition. OP-PM50 Bed Rest & Inactivity

ONE WEEK OF BED REST LEADS TO SUBSTANTIAL MUSCLE ATROPHY AND INDUCES PERIPHERAL INSULIN RESISTANCE IN THE ABSENCE OF SKELETAL MUSCLE LIPID ACCUMULATION

DIRKS, M.L., WALL, B.T., VAN DE VALK, B., HOLLOWAY, T.M., HOLLOWAY, G.P., GOOSSENS, G.H., VAN LOON, L.J.C.
Maastricht University Medical Centre + (MUMC+)

Short periods of muscle disuse, often necessary for recovery from illness or injury, lead to various negative health consequences. The present study investigated mechanisms underlying disuse-induced peripheral insulin resistance, taking into account muscle atrophy. Ten healthy, young males (age: 23±1 y, BMI: 23.0±0.9 kg·m⁻²) were subjected to 7 days of strict bed rest. Prior to and after bed rest, lean body mass (DXA) and quadriceps cross-sectional area (CSA; CT) were assessed, and VO_{2peak} and leg strength were determined. Peripheral insulin sensitivity was measured using a hyperinsulinemic-euglycemic clamp. Additionally, muscle biopsies were collected to assess muscle lipid (fraction) content and various markers of mitochondrial and vascular content. Bed rest resulted in 1.4±0.2 kg lean tissue loss and a 3.2±0.9% decline in quadriceps CSA (both P<0.01). VO_{2peak} and 1RM had declined by 6.4±2.3 (P<0.05) and 6.9±1.4% (P<0.01), respectively. Bed rest induced a 29±5% decrease in peripheral insulin sensitivity (P<0.01). This was accompanied by a decline in muscle oxidative capacity, without alterations in skeletal muscle lipid content or saturation level, markers of oxidative stress, or capillary density. In conclusion, one week of bed rest substantially reduces skeletal muscle mass and lowers peripheral insulin sensitivity, without affecting mechanisms implicated in high-fat diet-induced insulin resistance.

THE IDENTIFICATION OF FUNCTIONAL AND PHYSIOLOGICAL MARKERS ASSOCIATED WITH SHORT-TERM DЕТRAINING IN A YOUNG HEALTHY POPULATION

GARCIA-HORTAL, M., BRICKLEY, G., BEALE, L., DOUST, J.
University of Brighton

Introduction During the periodised training macrocycle, athletes across all sports experience phases in which training is limited or ceases entirely (Bosquet et al., 2013). To date, detraining literature has not analysed the weekly effects of training stoppage nor determined the reliability of tests used as baseline pre-detraining measurements. A comprehensive understanding of detraining processes is imperative in effective program design, especially during off-season and pre-season periods (Mujika & Padilla, 2001). Therefore, the aim of this study is to assess the change in functional and physiological markers, related to strength and power, associated with short-term detraining in a young healthy population. Methods With institutional ethics approval, eleven healthy participants (5 females; mean ± SD age= 21.6 ± 2.9 yr, height =163.2 ± 13.3 cm, body mass= 68.8 ± 32.3 kg and 6 males; mean ± SD age 21.8 ± 4.7 yr, height = 175.3 ± 7.6 cm, body mass= 72.2 ± 7.6 kg) completed a two weeks stable position (SP) to assure that the baseline values were accurate for each participant. To date, four of the aforementioned participants (1 male, 3 females) have completed four weeks of detraining (DTR). Maximal voluntary isometric contractions (MVIC) coupled with electromyography (EMG) of the vastus medialis (VM) and vastus lateralis (VL) of the quadriceps muscle, countermovement and squat jumps (CMJ, SJ), isokinetic leg press (ILP) and six-second Wingate (6sec-WAnT) tests were carried out each week during the six weeks that formed the study. Results All tests, except 6sec-WAnT, during the SP showed no significant difference between the three trials (MVIC: P=0.165; EMG VM: P=0.707; EMG VL: P=0.538; CMJ: P=0.837; SJ: P=0.520; ILP: P=0.132). 6sec-WAnT (P=0.018) showed that males were more powerful in the third test of the SP. Acute losses in strength tests (ILP, MVIC) and SJ were found in DTR (i.e. 18 and 21% decline at weeks 3 and 4 in ILP); whereas in power based tests (6sec-WAnT, CMJ) the changes were not as significant. Discussion These results suggest that in future studies using the same procedures, familiarisation would be crucial when using 6sec-WAnT. Preliminary results suggest that short-term detraining elicits a loss in voluntary muscle force output and the underlying mechanisms warrant further investigation (Koundourakis et al., 2014). FUNCTIONAL AND METABOLIC ALTERNATIONS IN YOUNGER AND OLDER MEN AFTER 14-DAY BED REST WITH 14-DAY RECOVERY

PIŠOT, R.1, MARUSIC, U.1, BIOLO, G.2, MAZZUCCO, S.2, LAZZER, S.3, GRASSI, B.4, REGGIANI, C., DI PRAMPERO, P.E.3, PASSARO, A.5, NARICI, M.6, RITTWEGER, J.7, GASPARINI, M.8, PARAVLIC, A.1, SIMUNIC, B.1

1:University of Primorska (Slovenia), 2:University of Trieste (Italy), 3:University of Udine (Italy), 4:University of Padua (Italy), 5:University of Ferrara (Italy)

Introduction: Physical inactivity is an increasing problem of modern society and is associated with major health hazards involving loss of muscle mass and function but also changes in cardiovascular function and energy metabolic balance (Brower, 2009; Kortebein et al., 2007; Knudsen et al., 2012). Given the paucity of literature on this topic, we aimed to investigate the functional and metabolic responses to bed rest and subsequent recovery of younger and older adult men. **Methods:** Sixteen old (OM: 55-65 years) and seven young men (YM: 18-30 years) were exposed to 14-day bed rest (BR) followed by 14-day active recovery (R). Quadriceps muscle volume (QVOL), force (QF) and explosive power (QP) of leg extensors, single fiber isometric force (Fo), peak aerobic power (VO_{2peak}), gait stride length, and three metabolic parameters, Matsuda index for insulin sensitivity, postprandial lipid curve and homocysteine plasma level, were measured before and after BR and after R. **Results:** Following BR, QVOL declined more in OM than in YM ($P=0.031$), QF ($P=0.001$), QP ($P=0.001$) and gait stride length ($P=0.002$) declined only in OM. Fo significantly declined in both YM -32.0% and OM -16.4% without significant differences between groups. VO_{2peak} declined more in OM than in YM ($P<0.001$). To the opposite, metabolic parameters showed greater decline in YM than in OM for Matsuda index ($P=0.003$), while increase in AUC of triglycerides ($P=0.013$) and homocysteine concentration ($P=0.027$) were observed only in YM. Finally, after 14 days R, several parameters, among them QVOL, QP and VO_{2peak} did not recover in OM, while Fo did not recover in both age groups. **Discussion:** These results are of considerable clinical relevance as they show the greater impact of inactivity on muscle mass and function in OM, while the metabolic alterations are greater in YM. Furthermore, they point to a greater difficulty of OM in regaining the pre-inactivity conditions. Finally, due to greater detrimental effect of bed rest and delayed recovery in OM our study suggests that minimizing of hospitalization periods should be of greater importance particularly for OM. **References:** Brower RG. EFFICACY OF A REACTIVE JUMP TRAINING PROGRAM DURING 60 DAYS OF BED REST

KRAMER, A., KÜMMEL, J., GOLLHOFER, A., GRUBER, M.

University of Konstanz

Background: In spite of extensive training regimens during long-term space missions with existing training devices, astronauts suffer from muscle and bone loss. Reactive jumps have been shown to exert very high forces on the leg muscles and bones, resulting in high strains and strain rates (Milgrom 2000). Therefore, reactive jumps seem to be a promising candidate for an effective and also efficient countermeasure. A training device that allows reactive jumps in the absence of gravitational forces has already been validated in previous studies (Kramer 2010; Kramer 2012). The aim of the present study was to evaluate if a training program using this sledge jump system (SJS) can prevent or at least greatly reduce the deteriorating effects of bed rest on the human body. **Methods:** After a familiarization and measurement phase of two weeks, 24 male participants (30 ± 6 y, 181 ± 6 cm, 77 ± 7 kg) were randomly allocated to the training or control group. In the following 60 days, all participants were confined to strict six-degree head-down tilt (HDT) bed rest. During this HDT phase, members of the training group had to perform reactive jumps in the SJS 5-6x per week, each training session lasting ten minutes on average. Two types of jumps were performed: series of usually 15 repetitive hops and series of 2-30 countermovement jumps. The amount and type of jumps was varied between training sessions, on average about 70 jumps were performed during each session. All the jumps in the SJS were recorded using force plates located at the bottom of the SJS. The 60 days of HDT were followed by a two-week recovery phase that included the same measurements as before HDT. **Results:** Adherence to the training sessions was 100%. The subjects in the training group were able to maintain their high initial peak ground reaction forces during the jumps throughout the 60 days of HDT: starting with 3300 ± 370 N during the first training session, this level could be maintained until the last training session on HDT 60 (3400 ± 440 N). Mean countermovement jump height one day before HDT for jumps on the ground was 43 ± 5 cm for the training group and 40 ± 3 cm for the control group. On the first day after the end of the HDT phase, jump height was 23 ± 4 cm for the control group and 44 ± 6 cm for the training group. In other words, a decrease of 42% for the control group, whereas the training group even increased their jump height a bit. Note that these results refer to the first 12 subjects of the study. The results for subjects 13 to 24 will be added after the end of the second phase of the bed rest study in April 2016. **Conclusion:** Reactive jumps seem to be a very effective and efficient countermeasure for deteriorating neuromuscular performance during long-term bed rest. Further analyses of the remaining data (e.g., pQCT, VO_{2max}) will show if it is just as effective for bone health and even the cardiovascular system. **References:** Kramer A et al (2010) J Biom 43(14), 2672-7 Kramer A et al (2012) J Biom 45(10), 1816-22 Milgrom C et al (2000) Br J Sports Med 34, 195-9

OP-SH19 Persons in Sport Organisations

ARE PROACTIVE SPORT EMPLOYEES MORE SATISFIED WITH THEIR JOB? AN INTERACTIONISM PERSPECTIVE

KUO, C.C.1, CHEN, L.H.1, CHEN, M.Y.2

1: National Taiwan Sport University (Taoyuan, Taiwan), 2: National Taiwan Normal University (Taipei, Taiwan)

Introduction Due to the highly competitive in the sport service market (Chanavata & Bodet, 2014), employees are ideal to be proactive to create conducive and satisfactory work experiences to conquer the environmental challenges (Li, Liang, & Crant, 2010). Nevertheless, based on interactionism hypothesis, employees with higher proactive tendency might not always lead to greater satisfaction at work because of the potential effect of situational forces. Accordingly, the present study proposed the psychological safety as an important boundary condition. **Methods** Data was collected from employees in 12 sport centers in Taiwan through a two-wave, time-lagged design. In the first wave, participants were invited to report the measures of proactive personality, psychological safety, and job satisfaction.

A follow up survey containing job satisfaction scale was distributed to participants again as second wave investigation. A total of 240 respondents completing questionnaires were retained as our final sample. In the data analysis, we conducted a hierarchical regression analysis to test our hypothesis. Results revealed that proactive personality significantly predicted the change in job satisfaction ($B = .15$, $p < .01$). In addition, proactive personality and psychological safety have a significant interaction effect in predicting the change in job satisfaction ($B = -.10$, $p < .05$). Specifically, the positive relationship between proactive personality and the change in job satisfaction was increased especially when employees who perceived lower than higher psychological safety. Discussion Although situational strength hypothesis of interactionism assumed that personality matters most in weak situations (Cooper & Withey, 2009), our findings, partly supporting this notion, suggested that proactive employees are not only beneficial from supportive environments but also unconstrained by unfavorable contexts to shape their job satisfaction over time. Overall, the current findings further provided practical implications for human resource management in sport organizations. Reference Chanavata, N., & Bodet, G. (2014). INVESTIGATION OF RELATIONSHIP BETWEEN ORGANIZATIONAL COMMITMENT AND JOB SATISFACTION IN YOUTH TEAM FOOTBALL COACHES IN TURKEY

YAŞAR, M.O., SUNAY, H.

UNVERST OF ANKARA FACULTY OF SPORT SCIENCES

To develop qualified football players, youth team process has a critical importance. During this process youth team coaches is the key factor. In this point of view the job satisfaction and organizational commitment levels of the youth team coaches are significant to achieve success (Topkaya, 2013). Job satisfaction is, an emotional reaction towards, comparison of the job expectation and what has been acquired the job (Sarminah, 2006). Organizational commitment is definition of employees psychological point of view and relationship between employee and organization. Both of these factors directly influences efficiency of the job. The sample of the study is consisted of 212 youth team coaches who work in Turkey. Coaches were selected by purpose sampling method. The job satisfaction survey which was developed by Spector (1985) and the organizational commitment survey which was developed by Porter et al. (1974) was used. The Cronbach Alpha value of job satisfaction survey was .80 calculated. In addition, non-parametric tests which are Kruskall-Wallis and Mann Whitney-U were used. Job satisfaction and organizational commitment levels of the coaches who participated in this study was found average. There are two remarkable results in this study. When coaches are compared by their education status, it was seen that, higher educated coaches' job satisfaction levels were detected lower. Moreover, when coaches are compared by their football club types, it was found that, professional club coaches, job satisfaction and organizational commitment levels were reached higher than amateur club coaches. It was seen that when age gets older, job satisfaction and organizational commitment levels increase. Also Hickson and Obsehgemi(1999) were found that there was a positive relationship between job satisfaction. According to Ketchan(2001), age and organizational commitment also has a positive relationship. In financial parameters, unexperienced and young coaches satisfaction levels were higher than older experienced coaches. But general results about experience parameter; as the experience gets more the job satisfaction levels increase. In Orhan's study same results were found. In parallel to these results, when experience is more, the organizational commitment level also increases. VOLUNTEERS, MOTIVATION AND REWARDS – A STUDY ON VOLUNTEERISM IN SPORT EVENTS

STRAALMAN, O.

Karlstad university

Background: The European Indoor Athletics Championships (iEM) were accomplished in 2013 at the Scandinavium Arena in Gothenburg, Sweden. About 600 top athletes participated and around 23.000 spectators watched the championship live. To accomplish the championships, the organizers had to procure about 800 volunteers to carry out important duties of the event. These individuals had assignments to work with competition, accreditation, security, transportation, media, communications, hosting, and support areas. The aims with this study of the volunteers in the European Indoor Athletics Championships (iEM) are to describe what kind of individual rewards volunteering in a sport event provides and how that could be theoretically explained. Method: A questionnaire was sent out to the volunteers. The questionnaire had questions about what kind of individual benefits volunteering provides and if those were related to motivation aspects of the volunteer. In all, 411 respondents (54,8% of the sample) answered the questionnaire. Of those, 234 were women and 177 were men. Results: The results shows that behavioural factors such as motivational lure for volunteer work appear regardless of gender and participation level. The first conclusion is that volunteer work has a general impact in most countries and cultures in the world. The second conclusion is that volunteering is a give-and-take relation between organizers and volunteers and especially the organizers has to ensure that it is a win-win situation. To retain volunteers to assign for further jobs requires matching between duty and personal motivation. The third conclusion is that there has to be both intrinsic and extrinsic gains that motivate volunteer work. Discussion: Motivation theory is an important foundation to explain and understand volunteering. It seems to be a persons' desire to do something for someone else that makes them participates as volunteers and to make them feel good with what they had accomplished. The respondents in the study experienced both personal and situational factors while fulfilling different goals, needs or interests. Gagné and Deci (2005) found that there has to be both internal (intrinsic) and external (extrinsic) motivation, and underpin Self-Determination Theory (SDT) as a useful tool for further analysis. AGE-RELATED CHANGES IN THE RESPONSE OF THE NEUROMUSCULAR SYSTEM TO CONTRACTILE ACTIVITY.ALR

JACKSON, M.

University of Liverpool

Ageing of the neuromuscular system is associated with loss of skeletal muscle mass and degeneration of peripheral axons and neuromuscular junctions. Increased oxidative damage has been reported to occur in many tissues of older subjects and experimental models, but whether these changes play a causative role in age-related decline in function of tissues has become controversial. We have utilized a variety of approaches to determine the activities of reactive oxygen species (ROS) in skeletal muscle tissue at rest, the changes that occur in response to contractile activity and how these are modified during ageing. These data indicate that skeletal muscle tissue from older animals and man shows an increased activity of ROS at rest that is associated with increased measurements of oxidative damage, but that the ROS generated in response to contractile activity is attenuated in older animals and man. In recent comparative studies we have used an electron paramagnetic resonance-based approach to examine ROS activities in mouse sciatic nerve during ageing in comparison with skeletal muscle. Substantial age-related degenerative changes in the nerve were seen, but this was not associated with an age-related increase in oxidative damage. In contrast there was evidence for a disruption of redox signaling pathways in neurons. Our data therefore show significant differences of the effects of age on motor nerves and the muscles innervated by the nerve. Supported by the Medical Research Council and Biotechnology and Biological Sciences Research Council.

THE EFFECT OF SHORT-TERM DISUSE AND SUBSEQUENT RETRAINING ON MOLECULAR SIGNALING AND MUSCLE SIZE IN OLD VS YOUNG ADULTS

SUETTA, C.

Rigshospitalet, University of Copenhagen

Human skeletal muscle is a highly plastic tissue, which is reflected by its ability to rapidly adapt to short-term changes in habitual loading intensity. However, it has been demonstrated that elderly individuals require a prolonged recovery phase in order to return to initial muscle mass levels following short-term immobilisation. Yet, there is a paucity of studies examining the cellular mechanisms responsible for the attenuated re-growth and associated molecular signalling processes in ageing human skeletal muscle. The age-related impairment in muscle re-growth following disuse could, at least in part, reside in an impaired capacity for myogenic stem cell proliferation and activation in aged myofibres, but it is not known whether such changes are related to muscle fibre phenotype. Further, systemic factors appear to play an important role in explaining the impaired proliferative capacity of SCs cultured from old vs. young human adults. There is, however, also evidence of local mechanisms influencing satellite cell and recent data suggest a close relation between various systemic and local factors in the regulation of SC function *in vivo*.

EXERCISE IN CACHEXIA: THE ROLE OF REDOX HOMEOSTASIS

CAPOROSSI, D.

University of Rome Foro Italico

Muscle wasting is a life-threatening condition leading to weakness and poor quality of life. It is common in most organ failure diseases and in some types of cancer. In such settings, it is known as cachexia, a complex metabolic syndrome characterized by loss of muscle with or without loss of fat mass. Beside some pharmaceutical interventions, the only promising treatment for sarcopenia or cachexia is exercise training (ExT) in combination with adequate dietary intake. This approach proven to be very efficacious in the low number of clinical trials available so far, although the inadequate understanding of its underlying biological mechanisms prevents the identification of robust biomarkers of efficacy. This presentation aims at giving an overview of the state of the art on the exercise-related molecular mechanisms able to counteract muscle wasting in cachexia. In this respect, we present results of a national multicenter research project funded by the Italian Government (PRIN2012 – prot. 2012N8YJC3) that applies a multidisciplinary, translational approach aiming at revealing the interconnection between the improvement of muscle function and performance, elicited in cachexia by exercise, and the molecular pathways relevant in muscle wasting conditions focusing on the control of systemic and muscle tissue redox homeostasis (1). Results from human and animal protocols pointed out the role of exercise in the induction of regenerative potential, as well as of HSP60 and a B crystalline (2, 3, 4), while findings from cellular models demonstrated that redox imbalance has a direct role in the c-JUN and Nrf2 mediated CRYAB gene upregulation in myogenic cells (5) and in the p38 MAPK mediated triggering of ARS-mediated apoptosis in embryonal rhabdomyosarcoma cells (6). In colon carcinoma (C26)-bearing mice, we found that wheel running leads to increased survival. Our findings correlate autophagic flux alteration and muscle wasting in cancer cachexia, thus implying a novel, regulatory role for this pathway. Since both drugs, as wheel running, affect the autophagic system and counteract cachexia, we foresee the potential use of autophagy-triggering drugs to treat cachexia in conditions in which exercise cannot be prescribed (7). 1) Vaughan et al., J Cachexia Sarcopenia Muscle (2013) 4:95–109 2) Pietrangelo et al., Front. IS-PM09 A close look at skeletal muscle plasticity - the dynamics of skeletal muscle cell interactions

SKELETAL MUSCLE HETEROGENEITY, PLASTICITY AND 3-DIMENSIONAL ORGANIZATION

PRATS, C.

The Panum Institute, University of Copenhagen

Skeletal muscle is an extremely heterogenic and plastic tissue that continuously adapts to metabolic and physiologic demands. This talk will review some of the cellular and molecular mechanisms involved in skeletal muscle adaptations to physical activity/inactivity and, obesity; from muscle fibre type adaptations to dynamic rearrangement of intracellular compartments. During the last years we have collected evidence supporting a key role of intracellular compartmentalisation as a regulator of skeletal muscle metabolism and, identified obesity-and physical inactivity-induced metabolic and structural alterations in skeletal muscle, which coincide with tissue insulin resistance development.

NON-MUSCLE CELLS IN SKELETAL MUSCLE - CO-REGULATION OR JUST FRIENDLY NEIGHBOURS?

CHAZAUD, B.

Université Claude Bernard Lyon 1

Adult skeletal muscle regenerates after an injury. This is possible thanks to the muscle stem cells, or satellite cells, which activate and recapitulate a myogenic program that eventually leads to the formation of new functional myofibers. There is increasing evidence that non-muscle cells play important roles in skeletal muscle regeneration, among which immune cells, and particularly macrophages, as well as vessel cells (endothelial and peri-endothelial cells) and fibroblasts. The various roles of these cell types in skeletal muscle regeneration will be presented. The role of these interactions will be discussed in the context of exercise-induced muscle damage. In light of these recent biological advances, the question of early treatment aiming at blunting inflammation after exercise-induced muscle injury will be discussed.

TARGETING SATELLITE CELLS TO OPTIMISE MUSCLE ADAPTATION - IS EXERCISE ENOUGH?

MACKY, A.L., KJAER, M.

University of Copenhagen and Bispebjerg Hospital

This talk will address the issue of whether satellite cell activation through exercise alone is sufficient for muscle adaptation in situations where regeneration may not be complete or where full restoration of muscle mass and function is paramount, such as after periods of muscle disuse encountered during hospitalisation. The issue is that often full restoration of muscle mass is not achieved through regular rehabilitation, especially in elderly individuals, who therefore will more rapidly fall below the threshold for independent living. It has also been shown that elderly individuals are also poorer at mounting a satellite cell response during such situations. Thus it may be that pharmacological intervention is required and appropriate, at least in the short term, simply to enhance satellite cell activation. Several such agents will be considered, including non-steroidal anti-inflammatory medication, where there is ample evidence for and against a beneficial effect on muscle adaptation, and Angiotensin II receptor blockers, which is a relatively unexplored field in human skeletal muscle.

IS-PM10 New discoveries in cellular cross-talk between skeletal muscle, its microvascular endothelium and vital organs underpin the importance of an active lifestyle

METABOLIC CONSEQUENCES OF IMPAIRED INSULIN AND VEGF SIGNALING IN SEDENTARY, OBESE AND AGED INDIVIDUALS

WAGENMAKERS, A.

Liverpool John Moores University

Introduction: A sedentary lifestyle, obesity and ageing (SLOA) impair the insulin and VEGFA induced vasodilator response of the skeletal muscle (SkM) microvasculature and reduce capillary density¹. This lecture is aiming to explain the underlying mechanisms and metabolic consequences. Impaired capillary recruitment: Meal-induced increases in plasma insulin activate the insulin-signaling cascade in endothelial cells (ECs) of SkM terminal arterioles (TAs). This leads to activation of eNOS, increases in NO production and vasomotion frequency (oscillations in capillary blood flow attributable to TA dilatation) and a 50% increase in microvascular blood volume. All increases and eNOS protein expression are reduced in SLOA, while expression of ET-1 (vasoconstrictor) and superoxide production by NOX2 (quenching NO) is increased. As a result less EC surface area is recruited after meal ingestion and this limits transendothelial transport (TET) of insulin and glucose, thus reducing SkM glucose uptake and increasing post-meal glucose concentrations. Reduction in capillary density: Exercise training via the resultant VEGFA pulses leads to capillary growth. Sedentary SLOA individuals will miss these VEGFA pulses. Also the low eNOS and increased ET-1 and NOX2 expression are likely to reduce NO production during exercise (eNOS is activated by shear stress and VEGFA pulses), as angiogenesis depends on increased NO production during the exercise bouts¹. TET of insulin, glucose and FA: Insulin stimulates its own TET. The mechanism involves eNOS activation and S-nitrosylation of the protein tyrosine phosphatase PTP1B leading to PTP1B inactivation and, therefore, increased insulin signaling. GLUT1 is the only glucose transporter present in SkM ECs and is insulin independent. FAT/CD361, FATP-3 and -42 mediate FA-transport across the luminal and abluminal EC-membrane. FABP-4 and -51 bind FA during transcellular EC transport¹. In mice with knockouts for these FA transporter and binding proteins SkM fatty acid uptake is

reduced, while glucose uptake is increased^{1,2}. Important is the recent suggestion in mice that increased VEGF-B release from SkM controls the expression of FATPs2 in capillary ECs and thus links endothelial FA uptake to the oxidative capacity of SkM. This mechanism may contribute to the high fat oxidation capacity during endurance exercise in trained athletes. VEGF-B KO mice showed less uptake and accumulation of lipids in SkM, and instead shunted lipids into white adipose tissue leading to obesity and insulin resistance. Interestingly trained athletes combine preferential storage of meal derived fat in SkM with the highest possible insulin sensitivity, while in SLOA individuals meal derived fats are primarily stored in adipose tissue and ectopic lipid stores and lead to obesity, inflammation, insulin resistance and atherosclerosis. References: Wagenmakers et al. J Physiol 2015. doi: 10.1113/jphysiol.2014.284513 Hagberg et al. Nature 464, 917-921 (2010)

ROLE OF VEGF-A IN EXERCISE INDUCED CAPILLARY GROWTH AND NUTRIENT DELIVERY TO SKELETAL MUSCLE

HELLSTEN, Y., HOIER, B.

University of Copenhagen

Capillarization in skeletal muscle correlates well with the level of oxidative capacity of the muscle and is readily altered in relation to the level of physical activity and inactivity. At a functional level, the size of the capillary net in skeletal muscle is important for optimal exchange of oxygen and nutrients and for insulin sensitivity. The process of capillary growth, or angiogenesis, is complex and involves orchestration of a number of proangiogenic and antiangiogenic factors of which vascular endothelial growth factor-A (VEGF-A) is known to be a central proangiogenic factor. VEGF-A is stored in relatively large amounts in skeletal muscle cells in vesicle-like structures. Upon muscle contraction or passive movement the VEGF-A containing vesicles are translocated to the muscle membrane for release to the extracellular space. Accordingly, in healthy young individuals, muscle interstitial levels of VEGF-A increase markedly during exercise and passive movement. This mechanism, which is thought to be an important step in the regulation of capillary growth in skeletal muscle, is impaired in aging and life style related disease and may be one of the underlying causes of microvascular rarefaction. VEGF-A is also present in capillary endothelial cells and pericytes and recent evidence suggests that pericytes also may contribute to angiogenesis in skeletal muscle. It is clear that capillary growth and oxygen and nutrient delivery depend on an interaction of endothelial cells with skeletal muscle cells and pericytes and future research should aim at addressing the precise mechanisms underlying this cellular cross-talk.

EXOSOMES AS MEDIATORS OF THE SYSTEMIC EFFECTS OF ENDURANCE EXERCISE.

TARNOPOLSKY, M.

McMaster University

Exosomes are small (30 – 110 nm) microparticles that are formed from the endosome and either fuse with lysosomes or are released to the plasma. They are known to contain a variety of proteins and nucleic acids including; mRNA, miRNA, and mitochondrial DNA; consequently, they are a form of inter-cellular communication. Skeletal muscle is known to secrete a variety of proteins and miRNA in response to contraction and the proteins have been termed, "myokines". Given that tissues other than muscle can secrete proteins and nucleic acids in response to exercise, we have coined the term "exerkines". Preliminary work from our laboratory found that acute exercise led to an increase IL-6 immunoreactivity within ~ 80 nm particles within skeletal muscle. The latter work was confirmed by showing a massive reduction in alix (an exosome marker) immunoreactivity in skeletal muscle following an acute bout of exercise. We then developed methods to isolate exosomes from other microparticles called microvesicles (100 – 1000 nm) and found that most of the known "myokines" are found within exosomes including VEGF-A and VEGF-B. We have been able to passively transfer many of the mitochondrial and exercise capacity adaptations seen with endurance exercise training to sedentary mice through 5 months of allogenic "exersome" transfusions. The latter adaptations were blocked in exercise-trained mice by inhibiting exosome release. We have also been able to allogenically transfer exosomes from endurance exercise trained mice to confer insulin sensitivity and attenuate obesity in the sedentary high-fat fed mouse model. Collectively, our data suggest that the multi-systemic benefits of endurance exercise are mediated by inter-tissue/organ exchange of exosomes containing exerkines.

Oral presentations

OP-BN21 Biomechanics: Muscle & Tendon

ATHLETIC TRAINING AFFECTS THE HOMOGENEITY OF MUSCLE AND TENDON ADAPTATION DURING ADOLESCENCE

MERSMANN, F.1,2, BOHM, S.1, SCHROLL, A.1, MARZILGER, R.1,2, ARAMPATZIS, A.1,2

Humboldt-Universität zu Berlin

Introduction The different temporal dynamics in the adaptation of muscle and tendon can result in an imbalanced development of muscle strength and tendon mechanical properties in adults (Kubo et al., 2011) and recent evidence suggests that this might affect adolescent athletes as well (Mersmann et al., 2014). To date, however, no detailed information exists on the time-course of muscle-tendon unit adaptation during adolescence and the effect of athletic training. Consequently, this issue was addressed in the present longitudinal study. Methods Twelve elite athletes (A; 16±1 yrs) and eight age-matched controls (C; 16±1 yrs) participated in five ultrasound-dynamometry sessions over one year in three-month intervals. Knee extensor muscle strength was measured combining dynamometry, inverse dynamics and electromyography. Patellar tendon mechanical properties, derived from the force-elongation relationship during isometric knee extension contractions, were assessed integrating ultrasonography. A linear mixed-effects model (LMM) was used to analyse time-dependent changes of muscle and tendon properties and the mean absolute residuals (RES) to the respective model fit served as a measure of non-linearity of parameter development. Homogeneity of the development of tendon force and stiffness (in terms of uniformity in direction and relative magnitude) was investigated by calculating the cosine similarity (CS) of the relative changes between measurement sessions. Results The increases in muscle strength (~11%) and tendon stiffness (~14%) over time were significant ($p<0.01$) in both groups. However, the non-linearity of the development of muscle strength was greater (RES A: 17±7 Nm, C: 6±2 Nm, $p<0.05$) and the homogeneity of changes of tendon force and stiffness was lower in athletes compared to controls (CS A: -0.02±0.5, C: 0.5±0.4, $p<0.05$). Further, the athletes demonstrated greater maximum tendon strain (A: 7.6±1.7 %, C: 5.5±0.9 %, $p<0.05$) and greater non-linearity of tendon strain over time (RES A: 0.9±0.4, C: 0.3±0.1, $p<0.05$). Discussion The results of the present study provide evidence that

athletic training in adolescence may disrupt the homogeneous development of muscle and tendon. The non-uniform adaptation increases the demand on the tendon of adolescent athletes and results in episodes of individual excessive strain with potential implications for tendon injury. PREFERRED VERSUS NON-PREFERRED LEG DIFFERENCES IN MEDIAL GASTROCNEMIUS FASCICLE LENGTH ARE NOT GREATER IN HIGH- AND LONG-JUMP ATHLETES AS COMPARED TO CONTROL SUBJECTS.

AELES, J., LENCHANT, S., VANLOMMEL, L., VANWANSEELE, B.

KU Leuven

Aim: To evaluate the effect of long-term training on muscle architecture a comparison was made between preferred (Pf) and non-preferred (NPf) leg fascicle lengths in athletes that have clear differences in amount of loading between legs and in control subjects. We hypothesised that these athletes would show greater differences in fascicle lengths between legs than the control subjects. Methods: 16 well-trained male and female athletes (high-jump and long-jump) and 9 control subjects were included. Muscle architecture (i.e. fascicle length, pennation angle, muscle thickness) data was collected for the Medial Gastrocnemius muscle in various conditions (i.e. 90° ankle angle, tendon-slack length (TSL) angle, during passive rotations and ankle joint plantar flexion MVC) using ultrasonography (B-mode; 30 Hz). In this abstract the results are restricted to fascicle length data at TSL angle. TSL angle was defined for each subject individually as the ankle joint angle at which the fascicles are at a length where tendon slack has been taken up and thus force from muscle fascicles is directly transferred to the segment. The intra-researcher reliability showed a low error (0.93 ± 0.36 mm). Subjects were asked about their preferred leg for jumping and a two-way ANOVA was used to test for main and interaction effects of the difference in Pf and NPf for the two groups, gender and track event. Significance level of $p < 0.05$ was used. Results: 4 control subjects reported not to have a preferred jumping leg. Athletes had longer fascicle lengths ($l_f = 57.63 \pm 6.96$ mm) than control subjects ($l_f = 52.27 \pm 5.30$ mm) when both legs for each subject were used in the analysis. A difference was found between Pf and NPf for all subjects combined ($n = 21$; mean difference: 2.31 ± 3.87 mm; $p = 0.013$). No difference ($p = 0.122$) was found between athletes (mean difference: 2.80 ± 3.56 mm) and controls (mean difference: 0.76 ± 4.04 mm) in fascicle length difference between Pf and NPf. Visual inspection of the data showed that even the 4 control subjects with no preferred jumping leg showed large differences between both legs in fascicle lengths. Discussion: Although high- and long-jump athletes report to have a clearly preferred leg for jumping and loading during training is higher on the jumping leg, this does not result in greater fascicle length differences in that leg as compared to control subjects. This may indicate that fascicle length does not necessarily change more under this long-term training but that other parameters (for example pennation angle, tendon stiffness) might be more subjective to change.

RATE OF FORCE DEVELOPMENT AND ELECTROMECHANICAL DELAY ARE NEGATIVELY IMPACTED BY 6 WEEKS OF STRETCH TRAINING

BRAY, N.W., SIMPSON, C.L., JAKOBI, J.M.

University of British Columbia - Okanagan

Rate of force development and electromechanical delay are negatively impacted by 6 weeks of stretch training Bray, N.W., Simpson, C.L., Jakobi, J.M. University of British Columbia Okanagan (Kelowna, Canada) Introduction Previous literature has shown a negative impact on rate of force development (RFD) and electromechanical delay (EMD) of a maximal voluntary contraction (MVC) that follows acute bouts of static stretching (Costa et al., 2010, Esposito et al., 2011). It is unknown whether chronic stretch training similarly impacts the neural and mechanical components of force development. The purpose of this study was to evaluate the effects of 6 weeks of chronic stretch training of the plantar flexors and Achilles tendon on RFD and EMD of plantar flexion MVCs. Methods Five days per week for 6 consecutive weeks, the non-dominant leg of 11 males (age 22 ± 3 years) was rotated to maximal dorsiflexion and passively stretched against a progressively increased load (20–60% MVC) for 3 minutes. At baseline, three weeks, six weeks and one week post training electromyography (EMG) was collected from the lateral and medial gastrocnemius and soleus while plantar flexor force was measured on a dynamometer with the ankle angle set to 10° of dorsiflexion. Supramaximal stimuli was administered during contraction to assess voluntary activation. EMD, RFD, EMG and the H/M Ratio (H-reflex/M-wave) were assessed from the force and EMG tracings. Results Thirty sessions of stretch training of the plantar flexors and Achilles tendon resulted in a significant slowing of the RFD (time main effect: $F(3,102) = 2.280$, $p = 0.04$) from baseline at week 6 ($p = 0.01$) and post training ($p = 0.02$). The EMD of MVC increased (time main effect: $F(33,57) = 3.354$, $p = 0.03$) post training when compared to baseline ($p = 0.006$) and week 3 ($p = 0.05$). There was a time main effect ($F(1,632,386.888) = 11.617$, $p < 0.001$) for normalized EMG as the amplitude decreased from baseline at week 3 ($p = 0.001$), week 6 ($p < 0.001$) and post training ($p = 0.006$). There were no interactions or main effects for H/M ratio. There were no changes in the control leg ($p > 0.08$). Discussion Six weeks of progressively loaded chronic stretch training slowed the RFD and normalized EMG while increasing EMD of the plantar flexors during plantar flexion MVC. These results suggest that chronic stretch training interrupted activation patterns of the plantar flexors and slowed signal transmission in the muscle while leaving neural mechanisms, reflex activity and voluntary activation, unaffected. Meaning, alterations in RFD and EMD post-intervention are the result of mechanical adaptations in the muscle-tendon unit (MTU). References Costa, P. B. et al. (2009). THE ACUTE EFFECTS OF DYNAMIC STRETCHING ON THE SENSORIMOTOR AND MECHANICAL PERFORMANCE OF THE TRICEPS SURAE MUSCLES.

PAMBORIS, G.I., MOHAGHEGH, A.I., BALTZOPOULOS, V.2

1: Brunel University London, 2: Liverpool John Moores University

Introduction Dynamic stretching (DS) is commonly used in warm-up routines prior to athletic activities. Even though several positive effects of dynamic stretching have been reported, the effects on different muscle contraction modes and proprioceptive ability are still unclear. The present study aims to determine whether acute responses to different dynamic stretching velocities affect the maximum voluntary torque and proprioceptive performance of the ankle plantarflexors. Methods A repeated measures experimental design was used where 18 healthy university students and staff (9 male and 9 female) (age = 28.33 ± 4.75 years, height = 1.73 ± 1.00 m, mass = 70.58 ± 11.38 kg) were randomly assigned into slow dynamic stretching at 50 b/min (SDS) and fast dynamic stretching at 100 b/min (FDS). Outcome measures were assessed pre- and post-2 minutes after both interventions using an isokinetic dynamometer and ultrasonography.

Outcome measures included maximum isometric torque at neutral ankle position (90°), maximum concentric and eccentric torque through the available ankle range of motion, and sensorimotor indices such as a force matching task and a joint position sense of the ankle at neutral position. Medial gastrocnemius fascicle length was calculated at passive maximum dorsiflexion angle. Results A mixed model analysis of co-variance (ANCOVA) for interaction of acute responses demonstrated that neither conditions, SDS or FDS elicited any improvement in ankle passive flexibility compared to baseline performance levels ($F(1,32) = 2.763$; $p = 0.106$). Preservation of strength in isometric ($F(1,32) = 0.006$; $p = 0.937$), concentric ($F(1,32) = 2.897$; $p = 0.098$) or eccentric ($F(1,32) = 0.926$; $p = 0.343$) contractions and sensorimotor performance (force ($F(1,32) = 0.003$; $p = 0.959$) and positional ($F(1,32) = 0.011$; $p = 0.919$) errors) in DS has been demonstrated. Passive muscle fascicle length did not show any change from pre- to post stretch for both interventions ($F(1,14) = 0.075$; $p = 0.788$). Note: Only 8 participants in the analysis. Discussion The findings in the current study indicate that an acute bout of DS of either velocity does not lessen a person's mechanical and sensorimotor capability to perform and control movements effectively. Thus DS is not contraindicated for inclusion in a warm-up session. Contact George.Pamboris@brunel.ac.uk

POTENTIATION OF THE FIRST AND SECOND PHASES OF THE MWAVE AFTER VOLUNTARY CONTRACTIONS OF DIFFERENT DURATIONS AND INTENSITIES IN THE TIBIALIS ANTERIOR

RODRIGUEZ-FALCES, J., PLACE, N.

Public University of Navarra

Objective: To investigate the extent and time-course of potentiation of the muscle compound action potential (M wave) after conditioning contractions of different durations and intensities. Methods: M-wave potentiation was studied in the tibialis anterior of 11 young subjects. M waves were evoked before and after isometric maximal voluntary contraction (MVC) of different durations (1, 3, 6, 10, 30 and 60 s), and after 4-s contractions of different intensities (10, 30, 50, 70, and 90% MVC). The amplitude, area, and duration of the first and second phases of the M wave, together with the median frequency (Fmedian) and muscle fibre conduction velocity (MFCV) were measured. For each parameter, potentiation was assessed as the ratio of the values measured after and before the conditioning contraction. Results: Regardless of the duration and intensity of the conditioning contractions, the amplitude of the M-wave first phase was not potentiated, whereas the second phase underwent a marked increase. The potentiation of the M-wave second phase augmented progressively with contraction intensity from 30% to 70% MVC and was similar for MVC durations ranging from 1 to 10s. After these conditioning contractions, the duration and area of the first and second phases was significantly decreased ($P<0.05$), whereas MFCV and Fmedian were increased ($P<0.05$). Changes in MFCV after the contractions were correlated with those in M-wave second phase amplitude ($r^2=0.42$; $P<0.05$) and Fmedian ($r^2=0.53$; $P<0.05$). For all the studied parameters, the greatest changes occurred 1 s after each contraction and these changes were abolished within 30 s following the conditioning contraction. Interestingly, these changes were observed at a time when muscle architecture did not differ from the pre-contraction conditions Conclusions: Our study indicates that only the amplitude of the M-wave second phase (but not the first phase) was enlarged after conditioning contractions shorter than 60s. In view of the unequal degree of potentiation for the first and second phases and the rapid recovery of M-wave characteristics after a contraction, it is unlikely that the enhanced electrogenic Na⁺-K⁺ pumping could account solely for M-wave potentiation. In a wider perspective, the results provide further support to the idea that only the amplitude of the M-wave first phase, but not the second, can be used reliably to monitor possible changes in membrane excitability

STATIC STRETCHING INFLUENCES STRETCH REFLEX AND HAVE NO EFFECTS ON NEURONAL REFLEX PATHWAYS OR CORTICAL ACTIVATION

BUDINI, F., RAUSCHER, B., RAFOLT, D., GALLASCH, E., CHRISTOVA, M., TILP, M.

Institute for Sport Science

Do not insert authors here! Introduction In sport and rehabilitation, muscle stretching is a common practice known to induce several short and long term adaptations. Some of these, as range of motion (Radford 2006) muscular performance (Behm 2011) and morphological parameters (Konrad 2015) have been widely studied. Compared to these topics, the neural implications of muscle stretching have been certainly underinvestigated. In the present work we examined the effects of 60 seconds of triceps surae static stretching (SS) on stretch reflex (SR), H reflex (HR) and motor evoked potentials (MEP) Methods Eight individuals took part in the study. Measurements were always performed with the volunteers sitting on a dynamometer chair, leg fully extended at knee joint and ankle joint at 10° plantarflexion (PF) (neutral ankle position at 90°). Baseline measurement consisted on averaging 15 HR, 15 SR and 30 MEP responses; the same procedures were repeated immediately, five and ten minutes after 60 seconds control time during which the subjects remained seated with the knee extended and the ankle at 10° PF. Following baseline and control recordings measurements were further repeated immediately, five and ten min after 60 seconds SS at maximal individual dorsiflexion. Results SR reflex resulted strongly inhibited immediately after stretching (-78%) and it did not recover to baseline values neither at 5 (-56%) nor 10 min (-60%) after termination of stretching. However significant results in comparison to control were only found at immediate ($P=.0008$) and 10 min after ($P=.0028$) stretching. HR and MEPs did not significantly change. Discussion The results of the present work seem to indicate that SS only influences muscle spindles sensitivity, with no effects on neuronal reflex pathways or cortical activation. Inhibition of the SR reflex can be attributed to formation of slack within the spindles. Results related to HR and MEP are partially in agreement (Guissard 2001) and partially in disagreement (Olivieri 2012) with literature. This controversy can be attributed to the time delay between the end of the stretching and the termination of the measurements. In fact, due to the protocol, the values reported are an average value of several reflexes collected within 150 seconds from the termination of the conditioning manoeuvre. IS-BN07 INNOVATIVE TECHNOLOGY FOR ANALYZING, IMPROVING AND ENCOURAGING ATHLETES' PERFORMANCE

VIRTUAL REALITY TECHNOLOGY: HOW CAN IT HELP US UNDERSTAND DECISION-MAKING IN SPORT?

CRAIG, C., CUMMINS, A.

Queen's University Belfast

To properly understand expertise and decision-making in sport we need a methodology that can adequately and accurately recreate the perception/action cycle and allow us to measure and understand decision-making from the player's perspective. In other words, we need to use technology that allows us to recreate an athlete's (egocentric) 3D perspective of an unfolding sports related event that can be updated in real time (Bideau et al, 2010). At the same time it has to also offer the possibility of precisely controlling the perceptual information presented to the observer immersed in the environment and reliably reproduce these conditions across trials. The experience has to also be interactive, so that we can record how the observer interacts or responds to the information presented in the environment. Immersive, interactive virtual reality technology offers an exciting new way of studying decision making in sport where the perception/action cycle is maintained (Craig, 2014). The versatility of this technology means it can be easily applied to many different sports (e.g. rugby (Brault et al, 2012), soccer (Dessing & Craig, 2010), cricket (Dhawan et al, 2015)). In this talk I will present different examples from different sports and show systematically how the dynamics of the visual information presented to players influences decisions about when and how to act. I will also explore how an in-depth analysis of the movement of a player as an event unfolds provides valuable insight into expert/novice differences in the decision-making process (Craig & Watson, 2011). ADVANCED TECHNOLOGIES FOR BETTER PERFORMANCE AND INJURY PREVENTION IN SNOW SPORTS

SENNER, V.

TUM - Technical University of Munich

Snow sports and in particular skiing and snowboarding are expensive entertainments not only because of the necessary investment in equipment. It may surprise that -in spite of this- an estimated total of 350 million people worldwide are performing these sports. Not only this considerable number of participants and the economic power of the subsequent sporting goods (and tourist) market justify big efforts in research and development. Even more important however seems the prevention of snow sports related injuries. Against this background it is clear that innovative technologies are not only a stimulation for additional market shares in this segment. They also offer a chance to improve protection by new and better safety gear. The talk will explain the background, illustrate the current state of research and finally formulate visions in this field. This will be done by giving five examples of our and other researchers' work: 1) Digital skiing coach for faster learning and better performance. 2) Prevention of jump-landing accidents in snow parks 3) Prevention of deep burying in an avalanche and of alpine ski race injuries 4) Prevention of overloads of artificial hip joints in skiing 5) Prevention of knee injuries by mechatronic ski bindings While the first three examples have almost achieved the state of market introduction, the fourth and fifth are still in the phase of investigation with special focus on biomechanical issues. With explaining these examples, this talk will also give an impression on actual measurement technologies applied under difficult boundary condition, such as skiing.

THE USE OF PERFORMANCE MEASUREMENT SYSTEMS FOR BOTH ELITE AND RECREATIONAL ATHLETES

KERSTING, U.

Aalborg University

Introduction Classical biomechanical measurement methods have long been validated and provide valid results for performance testing of athletes. They are typically applied in laboratory settings to identify factors which improve movement execution. In conjunction with modelling approaches, principles for human performance can be derived, suggestions for alterations may be examined to further optimize sports techniques and potentially reduce overloading or injury risks. Recent advances on camera and sensor performance, miniaturization, wireless technology, batteries, and modern communication systems have vastly broadened the spectrum for applications in, but most importantly outside, the laboratory. These developments offer new perspectives for testing in the sports environment including real-time feedback to athletes which can be immediate or continuous. The data provided by such approaches may cover a multitude of situations or a whole sports performance session. However, the nature of the new sensor information collected may differ substantially from laboratory-based evaluations providing new metrics for movement analysis. We are currently in a transition phase where we need to explore these new metrics and relate them back to existent knowledge. Example Applications In this symposium, we will present how our earlier ambitions of providing feedback from laboratory tests have developed to field-based assessments that we contend afford a substantial step forward in the improvement of performance. Applications include Cricket, Rowing, Skiing, Soccer, Running and Sprinting. Discussion There is no doubt that these new technologies will provide a much greater ecological validity than laboratory-based measurements. Based on the examples presented, current and future applications as well as fundamental strengths and limitations will be discussed in a discipline specific context. It will be exciting to see how we will move towards even more comprehensive field-based athlete assessments.

Invited symposia

IS-BN08 THE SEQUENCE OF INJURY PREVENTION WITHIN AN INTERNATIONAL SPORT FEDERATION - ELITE ALPINE SKI RACING AS AN EXAMPLE

INJURY DATA FROM THE FIRST SIX SEASONS <2006-2012> OF THE FIS INJURY SURVEILLANCE SYSTEM IN WORLD CUP ALPINE SKIING

STEENSTRUP, S.

Norwegian School of Sports Sciences

FIS established in collaboration with the Oslo Sports Trauma Research Center (OSTRC) a continuous injury reporting system for all FIS events, the FIS Injury Surveillance System (ISS), prior to the 2006/07-season. The objective of the FIS ISS is to provide data on injury trends in international skiing and snowboarding at the elite level with the long-term goal of reducing injury risk. During the 2006/07-season, Flørenes et al. (2011) investigated in a methodological study which method would produce the most complete and accurate record of injuries to World Cup (WC) skiers. They found that retrospective interviews with athletes/coaches gave the most complete picture of injuries in this setting. Therefore, retrospective interviews are conducted by physicians or physiotherapists from the OSTRC at the WC finals at the end of each winter season. All athletes who are present in person are interviewed, while coaches or medical staff are interviewed if the athlete is not present (due to injury or for other reasons). Athletes, coaches and medical staff are asked to recall any acute injury requiring medical attention, occurring in training or competition during the WC season. Injury reporting from the first six (2006-12) seasons of the FIS ISS showed that the risk of injury among WC alpine skiers was even higher than expected. The most frequently injured body part was the knee, and over 50% of these knee injuries were severe (Flørenes et al. 2009). Bere et al. (2014) reported that men had a higher rate of injury than women. These sex differences were even more pronounced during WC races. However, there was no sex difference in the risk of knee or ACL injuries (Bere et al. 2014). The injury rate was highest in downhill (17.2 injuries per 1000 runs), followed by super-G (11.0), giant slalom (9.2) and slalom (4.9) (Flørenes et al. 2009). Based on the high injury rates and severity of these injuries, FIS initiated several steps to improve athlete safety in the following seasons. References: Bere T, Flørenes TW, Nordsletten N, Bahr R. EQUIPMENT REGULATION AS A PREVENTION MEASURE FOR ACUTE KNEE INJURIES IN ALPINE SKI RACING

KRÖLL, J., SPÖRRI, J., GILGIEN, M., SCHWAMEDER, H., MÜLLER, E.

University of Salzburg

Within the classification of severe injuries, the most frequently injured body part was the knee (62,3%),^[1] with a rupture of the anterior cruciate ligament (ACL) as being the most frequent diagnosis.^[2] The majority of knee injuries occurred while the skier was still skiing the course (83%).^[3] The so-called self-steering effect of the ski, which enables athletes to perform turns with high amount of carving, favours a 'catch of the edge' in the event of an out-of-balance situation. As a result, the athlete is unable to control the ski and the ski's behaviour becomes unpredictable.^[4] In such cases, the skis' behaviour is perceived to be aggressive at the ski snow interaction, which has been suggested by expert stakeholders to represent one of the main contributors to typical mechanisms of knee injuries.^[5] Consequently, efforts were made to (i) design, (ii) evaluate and (iii) finally implement equipment which reduces the risk of severe knee injuries: (i) By reducing the self-steering effect of the equipment, a reduction of the aggressiveness at the ski snow interaction was hypothesised, particularly in out-of-balance situations. Potential equipment interventions were ski sidecut radius and standing height of the athlete.^[5] (ii) Across several independent field experiments the effect of different equipment interventions on relevant biomechanical variables were investigated. It was for instance experimentally shown, that skiing on skis with greater sidecut radius results in an increased ski turn radius and, therefore, provides evidence for reduced self-steering of the ski.^[6] Another study depicted that skis with greater sidecut radius potentially reduce the kinetic variables related to, as well as the athletes' perception of, aggressive ski behaviour.^[7] (iii) However, it was also shown that skis with a substantially greater sidecut radius might lead to a significant loss of attractiveness for spectators.^[7] Therefore, potential benefits (injury prevention) and costs (attractiveness) have to be weighed against each other when implementing new specification on equipment within the International Ski Federation's (FIS) competition rules. BACK OVERUSE INJURIES IN ALPINE SKI RACING – WHAT DO WE KNOW AND HOW TO PREVENT THEM?

SPÖRRI, J.1, KRÖLL, J.1, FASEL, B.2, AMINIAN, K.2, MÜLLER, E.1

1: University of Salzburg (Austria), 2: EPFL Lausanne (Switzerland)

Overall, this talk aims to (1) provide an overview of what is known about back overuse injuries in alpine ski racing, and (2) add (new) data/perspectives on how to prevent them. The back is one of the most vulnerable body parts for overuse injuries, particularly in the sport of alpine ski racing.^[1] As early as adolescence, competitive skiers have a significantly higher rate of anterior endplate lesions than age-matched controls.^[2] These types of spine deteriorations are known to increase the risk of developing low back pain at follow-up.^[3] Specifically, the strongly forward/sideward bent and twisted postures of the spine while skiing are considered a major cause of back overuse injuries.^[4] Combined with loads of up to 2.9 times body weight, these postures might lead to adversely high spinal torques.^[4] Therefore, prevention measures should aim to control/reduce the magnitude of frontal bending, lateral bending and torsion in the trunk, while avoiding an immoderate exposure to high peak loads during skiing.^[4] By means of three biomechanical field experiments, we investigated the effects of different equipment and course setting interventions on the aforementioned back loading relevant variables. Briefly stated, in both giant slalom and slalom, decreased standing height due to the ski-plate-binding-boot unit can indirectly be associated with decreased overall back loading (unpublished data), while increased gate offset might primarily help to avoid adverse back

loading patterns in slalom.[5] Alterations in sidecut had no effect on back loading relevant variables.[4] However, whether the investigated measures are effective to prevent back overuse injuries in alpine ski racing remains to be verified by epidemiological studies. INJURY RATE AND INJURY PATTERNS IN FIS WORLD CUP ALPINE SKIING: HAVE THE NEW SKI REGULATIONS MADE AN IMPACT?

HAALAND, B., STEENSTRUP, E., BERE, T., BAHR, R., NORDSLETTEN, L.

Norwegian School of Sports Sciences

Background: New regulations for ski equipment were implemented prior to the 2012/2013 season in the International Ski Federation (FIS) Alpine World Cup (WC). **Objective:** To investigate the effect of the new ski regulations on the rate and pattern of injuries by comparing data before (2006–2012) and after (2012–2015) the implementation. **Methods:** Injuries were recorded on the basis of the FIS Injury Surveillance System (FIS ISS) through retrospective interviews at the end of each of the nine WC seasons. All acute injuries that required medical attention were registered. Exposure was calculated on the basis of the official result lists. **Results:** The absolute injury rate (injuries/100 athletes/season) was lower in the three seasons after the new ski regulations compared with the six seasons before (risk ratio (RR) 0.74, 95% CI 0.63 to 0.87). This was also the case for the relative injury rate (injuries/1000 runs) (RR 0.76, 95% CI 0.59 to 0.98). However, these changes were only evident for male skiers, not for female skiers. There was a lower absolute injury rate for upper body injuries (RR 0.56, 95% CI 0.43 to 0.77), while no difference was found for lower extremity injuries (RR 0.84, 95% CI 0.70 to 1.01). **Conclusions:** We found a lower rate of injuries in the three seasons after the new ski regulation compared with the six seasons before. However, the ability to draw conclusions on the effects of the equipment change in subgroups of sex, discipline or body part is restricted by the limited statistical power.

IS-SH07 TEAM SPORT AND ACCULTURATION DYNAMICS IN MULTICULTURAL SOCIETIES

TEAM SPORT AND ACCULTURATION DYNAMICS IN MULTICULTURAL SOCIETIES – THEORETICAL FRAMEWORK

SANCHEZ, X., MORELA, E., HATZIGEORGIAKIDIS, A.

University of Cumbria, Lancaster

Sport has been recognised as an important socialising agent given the large number of participants it attracts. Team sports bring together individuals from different backgrounds and thus can, potentially, smooth social and cultural barriers. Nevertheless, sport participation is not per se an effective instrument towards the goal of integration. In fact, team sports may reinforce existing ethnic/cultural identities; individuals may not seek to socialise with other 'group' members but rather find shelter within a group of similar ethnic/cultural background, strengthening their own identity. Therefore, organised attempts to promote integration are required whereby sporting environments specifically designed to address the objective of integration are developed. The present symposium provides an overview of our ongoing research programme on team sports and acculturation. In the present talk we discuss a theoretical framework to examine the role of team sports in the acculturation process. Research on the role of sport as a social integration agent in multicultural societies has been scant. The adaptation of relevant theoretical frameworks to sport shall help the development of systematic research and enhance our understanding on the role of sport in the acculturation process. This presentation addresses the theoretical approach we have adopted in our research programme. Acculturation is a two-sided process, involving both the incoming population and their non-dominant culture, and the host population and their dominant culture. The preferences but also the fit between attitudes and strategies adopted by these two parties determine the outcome of the acculturation process. The two-dimensional model of acculturation (Berry, 1997) describes the acculturation strategies of the ethno-cultural groups and the larger society. For both its versions (non-dominant/-dominant culture), the model is based on the interaction of individuals' desire to (a) preserve their cultural heritage and identity, and (b) interact and seek relationships with other groups. Buhris et al. (1997) extended this model by considering the fit between the goals of the two populations. The interactive acculturation model suggests that the interaction of these goals can lead to consensual, conflictual, or problematic acculturation. Based on the conceptualization of these models our currently ongoing research line sheds some light onto the role of team sports in the acculturation process of young migrants.

TEAM SPORT AND ACCULTURATION IN MULTICULTURAL SOCIETIES: THE PERSPECTIVE OF THE HOST POPULATION

HATZIGEORGIAKIDIS, A., MORELA, E., SANCHEZ, X., ELBE, A.M.

University of Thessaly

The process of acculturation is of fundamental importance for both intergroup relations and migrants' adaptation to the society of settlement. Sport has been considered as an appropriate context for promoting cultural contact and integration. Research on the role of sport as an integrative agent is scant and has mainly focused on migrant populations. Considering that acculturation is a two-way process involving both the migrant and the host populations, research investigating the perspective of the hosts will enhance our understanding of the acculturation process. The purpose of the present study was to explore acculturation attitudes of adolescents from the host population as a function of sport participation, and to investigate the role of motivational environment, within those participating in team sports. Participants were 626 Greek adolescents high school students (316 girls and 314 boys), with a mean age of 13.88 (S.D. =1.01). Among

them, 175 were athletes competing in team sports. Participants completed questionnaires assessing acculturation attitudes and variables describing the motivational environment of their sport team. Analysis of variance revealed that athletes scored higher than non-athletes on attitudes towards multicultural contact. A structural equation path model was tested to test the degree to which motivational environment could predict host community acculturation attitudes. The analysis revealed that a motivational environment characterised by a mastery oriented climate, supportive of the needs of autonomy, competence, and relatedness, was positively linked to multiculturalism attitudes, whereas a motivational environment characterised by performance oriented climate and controlling coaching behaviour was negatively linked to multiculturalism attitudes. The findings provide useful insights for the perspective of the host population regarding migrants' acculturation and the role of the sport environment for the promotion of integration. The present study encourage further research onto the role of sport for the effective acculturation of migrants that can help inform interventions and contribute to the development of appropriate policies.

TEAM SPORT INTERVENTIONS PROMOTING INCLUSION OF MIGRANTS IN THE SCHOOL SETTING

ELBE, A.M.1, DANKERS, S.1,2, SANCHEZ, X.3

(1) University of Copenhagen (2) University of Groningen (3) Cumbria University

Today's school environments are getting increasingly culturally diverse and educational institutions are faced with the important question of how cultural diversity in school environments can be utilized in a positive manner. This lecture will present the results of a team sport based intervention aimed at promoting inclusion as well as the students' identification with their school class and Danish society. This intervention study was conducted in 7th, 8th and 9th grade multicultural physical education (PE) classes (n=132) at a school in Silkeborg, Denmark. For this purpose, specific teaching methods focusing on cooperation and aiming at creating an inclusive PE environment were developed, implemented and evaluated. More specifically, lesson plans were directed towards the promotion of a mastery motivational climate within PE classes. A mastery motivational climate is believed to translate into an increase in students' perceived feelings of school class inclusion, school class identification and/or identification with Danish society as a whole. Research has identified six specific sport contextual teaching structures as being salient to the development of a mastery climate in classrooms (Ames, 1992). These TARGET structures are connected to both the content of each lesson (Task, Authority, Grouping, and Time) and specific teaching behaviors which are to be executed during each lesson (Evaluation and Reward). Both quantitative as well as qualitative data were collected from both the intervention as well as the control classes. Results indicated that the intervention group experienced an increase of mastery climate as well as higher levels of perceived inclusion. The present study indicates that implementation of team sport activities conducted within a mastery motivational PE class climate can be a way forward in order to positively deal with cultural diversity in the school environment.

IS-SH08 THE CULTURES OF BOXING

BOXING AND URBAN CULTURE

LEWANDOWSKI, J.

University of Central Missouri

Professional boxing may not be an exclusively urban sport, but at least in the US, it is a quintessentially urban one. For US-based boxing clubs are not merely physical places typically located within cities. More fundamentally, boxing clubs in the US characteristically constitute part of a physically precarious but historical and socio-economically durable landscape of deprivation, disrespect, and disorder commonly known as the 'the hood'. Given the distinctly urban inflection of US boxing, one needs to understand how the attitudes and choices of urban boxers intersect with the larger forces and constraints that define 'the hood' and inform the culture of boxing in America. Drawing on several years as an active member of a Kansas City boxing gym, in this presentation I seek to explore some of the complex ways in which various forces and constraints of life in 'the hood' shape the reflexive agency and self-understandings of those individuals who opt to pursue a professional boxing career in the States.

BOXING: THE ART OF FIGHTING

NEAD, L.

Birkbeck University of London

The aesthetics and visual cultures of sport are strangely neglected within the arts and humanities. It is hard to understand why or to account for this lacuna. Whilst the financial, social and cultural power of sport is fully acknowledged, the place that beauty, ugliness and visual impact play in the exercise of that power remains relatively under theorised or historicised. Perhaps as much as any other sport, boxing has held a particular and enduring fascination for visual artists, including sculptors, painters, photographers and filmmakers. This paper will argue that, unlike other sports that celebrate an idealised male body, boxing images disseminate a different image of masculinity, which represents the physical and emotional pain of defeat and the wounded, damaged body. Using a small number of case-studies, from across a broad chronological period, the paper will examine this subject matter and just what constitutes the visual power of the image in this context. It will suggest that the image of the wounded boxer does offer a type of male beauty, but one that can only be taken on with enormous difficulty by female athletes for whom the battered body tests the limits of mainstream femininity to their utmost.

BOXING: FROM MALE VOCATION TO NEUROTIC MASCULINITY

SCOTT, D.

Trinity College Dublin

Do not insert authors here This paper explores the cultural significance of boxing in its relationship to concepts and practices of masculinity as they have emerged in writing from the time of the mid-18th century revival of the sport in England. Focussing on key moments of

change in boxing's significance in relation to male vocation, the paper will in particular investigate the extent to which literary and cultural responses to the sport cast light on the crisis masculinity has undergone since the start of the 20th century. Changing attitudes to boxing will thus be interpreted as symptoms of modification in the concept and practice of manliness, successively from boxing as rite of passage, as profession or occupation, as idea, as fantasy, and finally as image or neurosis. Early modern European literary writers as diverse as Maurice Maeterlinck, Arthur Cravan, Robert Musil, and Malcolm Lowry together provide evidence of symptoms that will subsequently be clarified in the light of contemporary American authors, whether of fiction (Chuck Palahniuk), or of socio-psychological study (Gerald Early, Carlos Rotella). The paper will close by briefly connecting the modern figure of the boxer as 'man without qualities' with the figure of the contemporary 'golden boy', showing how both manifest essential features of neurotic masculinity.

Invited symposia

IS-EX03 JSPFSM-ECSS Exchange Symposium: Genetics of sports performance and its applications to health science

GENETICS OF SPORTS PERFORMANCE IN ASIAN ATHLETES

FUKU, N.

Juntendo University

A number of familial and twin studies have assessed the relative contribution of genetic and environmental factors to physical performance or its-related traits and have estimated that there is a significant genetic component to their phenotypes. In addition, aerobic capacity has been found to have stronger maternal inheritance than paternal. These findings indicate that functional differences in maternally inherited mitochondrial DNA (mtDNA)-encoded proteins involved in oxidative phosphorylation as well as nuclear DNA polymorphisms affect aerobic performance. To date, over 100 genes in both nuclear DNA and mitochondrial DNA (mtDNA) have been reported to be associated with physical performance. However, most studies have been reported in European populations. In the Asian population, only 5 genetic loci have been linked to physical performance, including angiotensin I-converting enzyme, α -actinin-3, insulin-like growth factor 2, and ciliary neurotrophic factor receptor nuclear genetic polymorphisms and mtDNA polymorphisms (mitochondrial haplogroups). We recently investigated the association between the ACTN3 R577X polymorphism and elite Japanese athlete status in a large cohort of Japanese track and field athletes and controls. We found that sprinters with the RR+RX genotype had faster personal best times for the 100-m event than those with the XX genotype. Interestingly, all 7 male sprinters who had achieved the London 2012 Olympic qualifying standard for the 100-m event (B standard: 10.24 s) possessed the RR or RX genotypes, which was not observed in those qualifying for the 400-m event. Interestingly, the ACTN3 R577X polymorphism accounted for 12% of the variability in the personal best times for the 100-m run. However, there is not enough evidence to explain, in detail, the relationship between genetic factors and elite athlete status. Current studies of athletic performance-associated polymorphisms, which were previously identified through candidate gene-association studies, have revealed the polygenic profile for determining athletic performance; however, additional studies are needed to explain the genetic component. The strong genetic contributions to physical performance and/or its-related traits indicate the possibility of using genetic approaches to individualize training approaches for enhancing competitive abilities in sports or even to help select appropriate athletic events by using genetic screening for extending the personal limit of athletes (i.e., talent identification and/or talent transfer to other events). Further studies in sports science should include more detailed analyses of genetic polymorphisms detected in both mtDNA and nuclear DNA. Investigators in the field of sports science are now focusing on more detailed analysis of genetic polymorphisms, e.g., genome-wide association studies (GWAS) or whole genome sequencing. In this symposium, I will introduce the evidence of genetic polymorphisms to determine physical performance in Asian athletes from both candidate gene-association studies and GWAS.

GENOME-WIDE ASSOCIATION STUDIES INVOLVING RUSSIAN ENDURANCE AND POWER/STRENGTH ATHLETES

AHMETOV, I., ISCHENKO, D., KULEMIN, N., POPOV, D., KOSTRYUKOVA, E., ALEXEEV, D., EGOROVA, E., GABDRAKHMANOVA, L., LARIN, A., GENEROZOV, E., PAVLENKO, A., AKIMOV, E., VINOGRADOVA, O., GOVORUN, V.

Volga Region State Academy of Physical Culture, Sport and Tourism

Humans vary in their ability to achieve success in sports and this variability majorly depends on genetic factors. In the past 19 years, at least 156 genetic markers (located within almost all chromosomes and mtDNA) were found to be linked to elite athlete status (94 endurance-related genetic markers and 62 power/strength-related genetic markers). Importantly, 42 markers were identified within the last two years by performing genome-wide association studies (GWASs) of athletes from Canada, Finland, Germany, Jamaica, Japan, Russia and the USA. GWAS is a new approach that involves rapidly scanning millions of markers across the complete sets of DNA by microchips of many people to find DNA polymorphisms associated with a particular trait. In our first study involving Russian athletes, we examined the association between 1,140,419 SNPs and relative maximal oxygen consumption rate (VO_{2max}) in 80 international-level Russian endurance athletes, and identified six suggestive 'endurance alleles' (with $P<10^{-5}$ - 10^{-8}) which were replicated both in female and male subgroups. To validate obtained results, we further performed case-control studies by comparing the frequencies of six SNPs between 218 endurance athletes (or 100 elite endurance athletes) and opposite cohorts (192 Russian controls and 230 Russian power athletes). It was assumed that the 'endurance allele' should be under-represented in at least one opposite cohort (Russian controls or Russian power athletes) when compared to endurance athletes. This approach resulted in the remaining three SNPs (NFIA-AS2 rs1572312 C, TSHR rs7144481 C, RBOX1 rs7191721 G) associated with endurance athlete status (Ahmetov et al. 2015). One of the most interested genes, namely NFIA-AS2, is involved in the regulation of expression of the nuclear factor I A (NFIA) gene (transcription factor that induces erythropoiesis). We also found that the NFIA-AS2 C allele was associated with high level of hemoglobin, high number of reticulocytes and erythrocytes. In another study, the comparison of genetic profiles of 492 elite Russian power/strength and 227 endurance athletes and controls revealed that the rare DMD rs939787 T allele was over-represented in power/strength athletes (25.0%) compared to endurance athletes (8.8%; $P=3.9*10^{-9}$) and controls (16.3%; $P=0.0354$), indicating that the DMD T allele is favourable for power/strength performance (Naumov et al. 2014). The dystrophin (DMD) gene is a large, rod-like cytoskeletal protein which is found at the inner surface of muscle fibers. Future research including multicenter GWASs and whole-genome sequencing in large cohorts of athletes with further validation and replication will substantially contribute to the discovery of large number of the causal genetic variants (mutations and DNA polymor-

phisms) that would partly explain the heritability of athlete status and related phenotypes. References Ahmetov et al. Biol Sport 2015;32:3-9. Naumov et al. Eur J Hum Genet 2014;22(Suppl. 1):502.

FITNESS-RELATED GENES AND EXCEPTIONAL LONGEVITY

LUCIA, A.

Universidad Europea

The oldest old population (≥ 85 years) is rapidly expanding among westerners. However, advanced aging comes at a price, i.e., it is associated with an increased risk of loss of functional independence. In this regard, centenarians (people aged 100+ years) are the paradigm of healthy aging, as they have usually postponed (or even avoided, in some cases) major age-related diseases, as well as the onset of disability, until they were well into their nineties. Thus, the search for the gene variants that might influence the likelihood of reaching exceptional longevity (EL, i.e., becoming a centenarian) might help identify targets of "anti-aging" interventions. In old people, functional independence is highly dependent on physical fitness, which in turn is determined by several phenotypes such as mainly cardiorespiratory fitness and muscle performance. Aging is inevitably associated with a decline in muscle mass and function, i.e., sarcopenia, with an acceleration of this process increasing the risk of mortality. Thus, those gene variants that can be associated with preservation of muscle mass/function at advanced ages, e.g., the K153R polymorphism in the myostatin (MSTN) gene or the I/D polymorphism in the angiotensin converting enzyme (ACE) as well as other genetic variations linked with muscle aerobic capacity (e.g., the R577X mutation in the α -actinin-3 (ACTN3) gene), might also influence the likelihood of reaching EL. Here we summarize current body of knowledge regarding the possible influence of fitness-related genotypes and EL in different cohorts of various ethnic backgrounds. Interestingly, some genes might have a pleiotropic effect, as the theoretically 'unfavorable' allele in midlife (e.g., the D-allele of the ACE gene) might play a protective role at the end of the human lifespan.

OP-BN05 Sport Technology: Equipment 2

TRANSFER OF FORCE-VELOCITY CHARACTERISTICS AND MUSCLE POWER IN BMX RACERS

GROSS, M.1, LÜTHI, G.1, GROSS, T.1,2

1Swiss Federal Institute of Sport, 2Department of Medicine, Movement and Sport Sciences, University of Fribourg

Introduction In competitive BMX racing, a fast start is crucial for success and requires good explosive strength through a wide movement velocity range. On the bike, and especially on the supercross starting ramp used in international competitions, technical demands increase compared to movements typically used for force-velocity (F-v) assessment, like jumping. This study investigated the transfer of F-v characteristics from jumping to two on-bike conditions varying in speed and technical difficulty, and their influence on starting speed. **Methods** Muscular power and F-v characteristics (Pmax: peak of P-v relationship; F0, v0, sF-v: intercepts and slope of F-v relationship) were obtained using squat jumps with various additional loads. Pedaling power and torque-cadence (T-Cad) characteristics (Pmax: peak of P-Cad relationship; T0, Cad0, sT-Cad: intercepts and slope of T-Cad relationship) were obtained with a modified, crank-based powermeter, under two conditions: • self-initiated sprint to maximum speed on flat ground • simulated supercross race start with randomized gate. Various correlation analyses and t-tests were performed. **Results** • Data were collected from 13 junior or senior national team pool riders. • Absolute Pmax jumping and sprinting were highly correlated, as were absolute F0 and T0. Among other F-v characteristics, and when normalized to body weight, no significant correlations were observed. • Absolute F0 was highly correlated with mean P and v over the first 30 m while sprinting. When F-v characteristics were normalized, the only significant correlation was between F0 and vmean. • Mean P and v on the starting ramp were highly correlated. Ppeak and Pmean for sprints and starts were highly correlated and values did not differ significantly between the two conditions. • For all T-Cad characteristics, significant correlations between sprinting and starting were revealed. However, all values differed significantly between the two conditions. • In absolute terms, all T-Cad characteristics correlated significantly with mean P and v on the starting ramp. When normalized, T0, Cad0 and Pmax correlated significantly with both mean P and v, however sT-Cad did not. **Discussion** In this study, nationally selected BMX racers could transfer muscular power quite well from simple jumping to complex sport-specific tasks. This confirms that good overall explosive strength is beneficial for pedaling power and most importantly, mean starting speed. However, neither F nor v confines of the F-v profile seemed to be limiting for sprint or start P and v, as the transfer of F-v characteristics was not uniform (involves additional skill). On the other hand, transfer of F-v characteristics from sprints to starts was rather uniform. Finally, since Pmax correlated most strongly of the T-Cad characteristics to mean starting v, whereas normalized sT-Cad did not, a preferable tendency toward particularly steep or flat T-Cad profiles is not apparent. Rather, absolute cycling peak P and Cad0 of around 250 rpm seem to be the most crucial determinants of starting speed.

IT IS REALLY A GRADUAL COMPRESSION IN THE COMPRESSIVE GARMENTS?

APARICIO, I.1,2, JULIÁN-ROCHINA, I.3, BLANES, M.2, TORMO-MAICAS, V.3, PÉREZ-SORIANO, P.2

UNIVERSITY OF VALENCIA

Introduction Compressive stockings (CS) are widely used in sport. However it is unknown the best compression parameters. Most of the studies have not measured interface pressure (pressure) applied by the sports garments being investigated (Diriller & Halson, 2013) Pressure applied by sport CS is affected by garment type, size and posture. (Brophy-Williams et al, 2015). The objective of the study is to determine the interface pressure (pressure) applied using two CS: medium compression (MCS) and strong compression stocking (SCS), in three conditions: before, while and after the running test. **Methods** 10 male runners (age $[35 \pm 5$ years]) carried out 2 laboratory tests (1.without any stocking; 2.MCS in a leg and SCS in the other leg, in a randomized way). At each test participants ran for 35 minutes on treadmill (5 min at 8km/h + 30 min at 75% of their maximal aerobic speed, previously measured in an incremental running test). Pressure was measured by Pico Press® in four regions (two on the maximum perimeter of the calves, one on the external supramalleolar and one on anterior tibial area). Measurements were taken in static before and after test and in dynamics, every 5 minutes of running. The factor 'compression type' was analyzed by the T test. The factor 'running' by the U test of Mann-Whitney. The factor 'sensors' by ANOVA and the

post-hoc Tukey test. ($P < 0.05$) Results In static, all pressure sensors reported lower parameters after running test ($p < 0.001$). Mean pressure was greater in MCS (20.95 ± 6.17 mmHg) compared to SCS (18.98 ± 6.08 mmHg) ($p < 0.05$). In both conditions MCS ($p < 0.05$) and SCS ($P < 0.001$), pressure was higher in proximal than distal sensors. In dynamic mean pressure was greater in proximal sensor ($p < 0.001$) at both "compression type". Discussion The optimal method of applying compression to increase blood flow is by highest pressure exerted at the distal end of the limb decreasing to a lower pressure at the proximal end of the limb (Bochmann et al, 2005). Manufacturer of studied CS exposes their gradual decreasing compression In contrast with our results that, CS pressure is higher in the proximal than the distal area (MCS and SCS) in dynamic and static conditions. It is important to reconsider the principles used to predict the final compression in these garments. Exercise showed mechanical fatigue characteristics of the CS evaluated on the calf muscle, or maybe it is due to changes in the behaviour of the muscle. This lower pressure at the end of the test is important to take into account by manufacturers. In conclusion, although CS exert different pressures, optimal pressure to induce the greatest increase in venous flow is yet to be determined, and it is also interesting to know if companies measure the pressure. EFFECTS OF CALF COMPRESSION SLEEVES ON PHYSIOLOGICAL AND BIOMECHANICAL ADAPTATIONS TO TRAIL RUNNING

KERHERVÉ, H.1, SAMOZINO, P.1, DESCOMBE, F.2, PINAY, M.1, MILLET, G.Y.3, PASQUALINI, M.4, RUPP, T.1

1.IIBM, University Savoie Mont Blanc, Chambéry, France; 2.Medipôle, Challes-les-Eaux, France 3.NMFL, University of Calgary, Canada; 4.Thuasne, St-Etienne, France.

Introduction Calf compression sleeves (CS) are increasingly used in off-road exercises, however, no analyses have been conducted so far on the impact of wearing CS on simultaneous physiological and biomechanical adaptations during prolonged (>2 h) outdoor trail running. The aim of this study was therefore to analyse whether CS may modify muscle oxygenation, running biomechanics and performance during a prolonged trail running. Methods Fourteen healthy trained males [21.7 ± 3.0 yr, 180 ± 5 cm, 72 ± 7 kg] took part in a randomised, cross-over study consisting in two identical 25-km trail running sessions (positive elevation change of 1020 m), >3 weeks apart (same weather conditions). One trial was performed with degressive CS (UP®, Thuasne®, 23 ± 2 mmHg) and the other with control sleeves (CON, <4 mmHg). Oxygenation of the medial gastrocnemius muscle (Mox) was monitored continuously by portable near-infrared spectroscopy (Portalite, Netherland). Biomechanical parameters as ground-contact (Tc) and aerial (Ta) times, duty factor ($DF = Tc/(Tc+Ta)$), leg stiffness (Kleg) and peak force applied to the ground (Fmax) were determined at 12 km.h⁻¹ using an 8-m long optical system (Optojump, Italy) at the beginning, during, and at the end of both sessions. Exercise-induced Achilles tendon pain (PAT) and delayed onset calf-muscles soreness (DOMS) were assessed using visual analogue scales. Results Mox increased significantly in CS compared to CON at baseline and immediately after exercise ($P < 0.05$), without any difference in deoxygenation kinetics during the run, irrespective of the slopes (e.g. downhill or uphill sections), and without any significant change in run times (~0.9%). Tc and DF were significantly lower in CS vs. CON and Fmax and Kleg were higher in CS at the beginning and throughout the run. CS and CON induced significant DOMS (> 6 on a 10-cm scale) with no difference between conditions, but PAT after the trial was significantly lesser in CS than CON ($P < 0.05$). Discussion Calf compression did not modify the 'metabolic' state of the muscle during prolonged trail running and exercise-induced DOMS, but minimized Achilles tendon pain at the same level of performance. For the first time, we provided evidence that running mechanics at the beginning and throughout the run are strongly affected by CS. Future research should explore the relationship between such optimisation of the fatigue-induced stride parameters, the reduced pain over the Achilles tendon and performance over longer and/or repeated (chronic) trail running events. EFFECTS OF A NEW RUNNING SHOE DESIGN ON THE LANDING PATTERN AND ENERGY LOSS

ZHANG, J.1, MCPHAIL, A.2, AN, W.1, NAQVI, W.3, CHAN, D.1, AU, I.1, LUK, A.1, CHEN, T.1, CHEUNG, R.1

The Hong Kong Polytechnic University

Introduction Minimalist running shoes have an increased popularity as it may simulate barefoot running (Altman and Davis, 2012; Pohl et al., 2008; Squadrone and Gallozzi, 2009) and reduce running economy (Cheung and Ngai, 2015). A newly designed minimalist with lug platform claims to promote running performance by simulating barefoot running mechanics and lowering the energy loss during impact. This study sought to compare the landing pattern, vertical loading rates, energy loss, and initial vertical body stiffness in a group of habitual shod runners who ran with this new footwear model. Methods Fifteen habitual shod runners conducted two 10-minute treadmill running bouts with their usual running shoes and the minimalists with lug platform in a randomized order. Kinematics and kinetics data were collected from last 20 consecutive steps of each trial. Heel-strike ratio, vertical average (VALR) and instantaneous (VILR) loading rates, energy loss, and initial vertical body stiffness were compared between two shoe conditions using paired-t tests. Results Runners demonstrated significant lower heelstrike ratio while running in minimalists with lug platform than usual shoes (Cohen's $d=0.62$; $p=0.032$). However, only one out of 15 participants completely modified the landing pattern with the minimalists. VALR and VILR between two footwear conditions showed no significant difference (Cohen's $d=0.30-0.36$; $p=0.191-0.258$). Initial vertical body stiffness (Cohen's $d=0.67$; $p=0.032$) and energy loss (Cohen's $d=0.57$; $p=0.044$) were found greater when running in minimalists with lug platform than in traditional running shoes. Discussions Minimalists with lug platform promote non-heelstrike landing but not lead to lower vertical loading rates. Interestingly, the new shoe design does not enhance energy exchange. Instead, it leads to a greater energy loss than traditional running shoes, which could be explained by a higher initial vertical body stiffness. References Altman, A.R., Davis, I.S., 2012. OP-PM22 Soccer Fitness Parameters

FITNESS PARAMETERS IN PROFESSIONAL FOOTBALL PLAYERS AMONG DIFFERENT DIVISIONS

MICHAELIDES, M., KOULLA, P., EVRIPIDOU, D., ZACHARIA, A., PETOUSIS, C.

UCLAN Cyprus

The purpose of the study was to determine aspects of fitness that differentiate first division professional football players from players of second and third divisions in Cypriot football leagues. METHODS: Four hundred and twenty seven professional male football players (age = 25 ± 5 years) performed an isokinetic knee test using the Humac Norm dynamometer at two angular velocities (60°s^{-1} , 300°s^{-1}). On a different occasion, they performed an incremental cardiopulmonary exercise testing (CPET) on a treadmill. Furthermore, anthropometric and flexibility (sit and reach) measurements were recorded. RESULTS: Results were analyzed using one-way ANOVA, between subjects design revealing significant effects for division. Tukey's HSD tests demonstrated that players from division 1 scored significant higher on maximal oxygen consumption ($\text{VO}_2 \text{ max}$) and lasted significantly longer on the treadmill than participants of division 2 and 3 ($p<0.05$). Similar findings were demonstrated when division 2 was contrasted against division 3 players. Marginal or no significant differences were recorded among players from the three different divisions on anthropometric measurements, flexibility and isokinetic parameters (muscular strength and muscular endurance). The marginal differences observed were mainly between first and third division players. CONCLUSION: The findings of this study clearly demonstrated that cardiovascular fitness as determined by CPET is the most important fitness parameter that differentiates professional football players who play at a more advanced championships. Although, strength and muscular endurance of the knee joint as well as low back- hamstring flexibility parameters are crucial for performance and injury prevention in football, they appear to be similar in players from smaller divisions too.

AGE RELATED EFFECT ON YO-YO TEST PERFORMANCE AND HEART RATE ANALYSIS ON TURKISH SOCCER REFEREES

KIZILET BOZDOGAN, T., KIZILET, A., EROL, M.

Marmara University, Boğazici University

INTRODUCTION Referees are responsible apply the rules for such as played on lounge area and sport large areas and while maintaining the compliance with the rules of players. Moreover, during the match play for the success of the referee, they must maintain competencies to meet the physical and physiological demands and the competence to make decisions under intense pace for high level (Helsen and Bultynck, 2004). Also elite soccer referees, because of their careers later in life manage more high level match, it is more important that their physical and physiological competence. In several studies (Castagna, et al., 2005) regarding of game action profile of football referees and physiological effect on the evaluation of the game, it is reported that the referees are done an average of 2200 meters high intensity running in a match. This results are explained that the importance of running distance on YO-YO IRL1 test performance during to their all career and also it reveals the importance of performing at a high level until the end of the their years (Weston, et al.2010). The aim of this study was to investigate the effect of ageing on fitness performance on elite-level soccer referees. METHODS 131 elite level and national soccer referees (age range 27–45 years) are participated in study. All referees are performed YO-YO IRL1 (Yo-Yo Intermittent Test Recovery Level 1) (Bangsbo, et al., 2008). All polar datas are recorded every each 1 seconds (HRload, MaxHR, Mean HR and After 1 minute recovery) (polar team system, Polar electro, Finland). Data are presented as mean and SD. Comparisons between more than 2 means were performed using one-way analysis of variance. Post hoc testing was carried out using Tukey's test. Relations between variables of interest were detected using Pearson's correlation coefficient (r) ($p < 0.05$). RESULTS Advancing age, it is seen that all physical and physiological results are development. It is reported that there is statistically significant difference in HRmax and HRmean ($p=0.00$), but there is no statistically significant difference HRload ($p=.874$) and after 1 minute recovery heart rate ($p=.541$). ($p<0.05$). On YO-YO IRL1 test running distance is better on elderly referees than young, average ve old referees but it is not seen statistically significant difference ($p=.88$). According to correlation analysis, there is negative correlation between body fat and YO-YO IRL1 test ($r=-.341$) ($p<0.05$) DISCUSSION Physiological values are better when they are advancing age. So it reveals that the importance of involve in systematic training program when they are younger. Thus, aerobic and anaerobic be able to meet demands for a match at a younger age. INFLUENCE OF THE NUMBER OF PLAYERS DURING SAME- VS. MIXED-GENDER FOOTBALL SESSIONS ON HEART RATE FOR 12 TO 16-YEAR-OLD SCHOOL CHILDREN

PÓVOAS, S.1,2, RANDERS, M.3,4, SOARES, D.2, FARIA, G.2, SANTOS, T.2, SILVA, P.2,5, KRISTRUP, P.3,6

1:CIDESD,2:ISMAI (Maia,PT),3:Copenhagen C. TS & Health, Dep. Nutr, Ex. & Sports, U.Copenhagen (Copenhagen,DK),4: AaB A/S (Aalborg,DK),5:CIAFEL (Porto,PT),6:Sport & Health Sci., U.Exeter (Exeter,UK).

Introduction Recently, football has been established as a health promoting and performance enhancing activity in several populations (1). Nevertheless, the physiological demands of football played as small or large-sided games in school children is not known, as well as the intensity of various types of small-sided games played as same gender or mixed genders for girls and boys. This study aim was to compare the physiological demands of football sessions for 12-16-year-old school children using small-sided (2v2 and 4v4) and large-sided games (12v12) in same gender and mixed gender game formats. Methods A total of 134 pupils (50 girls and 84 boys) were randomly assigned to same gender and mixed genders game formats, and each of the gender groups played 2x15 min artificial turf football games 2v2, 4v4 and 12v12, on separate days in a random order, using the same area per player and length to width ratio. Heart rates (HR) were determined for all game formats. Results Higher mean HR was found in 2v2 and 4v4 games compared to 12v12 for girls in mixed gender games ($77 \pm 10\%$ ($\pm \text{SD}$) and $73 \pm 12\%$ vs. $63 \pm 11\%$ HRpeak; $p<0.01$), as well as for boys playing same gender ($81 \pm 6\%$ and $79 \pm 5\%$ vs. $73 \pm 9\%$ HRpeak; $p<0.05$) and mixed gender games ($76 \pm 9\%$ and $77 \pm 8\%$ vs. $69 \pm 8\%$ HRpeak; $p<0.05$). Correspondingly, more time was spent with HR above 80%HRmax in 2v2 and 4v4 games compared to 12v12 for girls in mixed gender games (42 \pm 34% and $37 \pm 36\%$ vs. $9 \pm 19\%$; $p<0.01$), as for boys playing same gender ($50 \pm 27\%$ and $43 \pm 24\%$ vs. $24 \pm 29\%$; $p<0.05$) and mixed gender games

($38 \pm 35\%$ and $38 \pm 32\%$ vs. $20 \pm 19\%$; $p < 0.05$). Discussion In accordance with previous studies (2-4), these study results showed that HRs are high for school children playing small-sided games. Furthermore, the present study revealed that when girls are playing mixed gender games and when boys are playing mixed as well as same gender games, the aerobic exercise intensity is much higher during small-sided games 2v2 and 4v4 compared to large-sided games (12v12). FAT OXIDATION RATES IN PROFESSIONAL FOOTBALL PLAYERS

RANDELL, R.K.1, ROLLO, I.I., MEDINA, D.2, LIZARRAGA, M.A.2, JEUKENDRUP, A.E.3, CARTER, J.M.1

1Gatorade Sports Science Institute, PepsiCo Global Nutrition R&D; 2FC Barcelona Medical department, FC Barcelona, Spain; 3School of Sports Exercise and Health Sciences, Loughborough University UK.

Introduction The rates of maximal fat oxidation (MFO) and the exercise intensity at which it occurs (FATMAX), has been reported in obese, sedentary, lean and endurance trained populations. To date there are no data available describing fat oxidation rates in professional football players. **Methods** During pre-season medical testing (2014 – 2015 season) 28 players (age 24 ± 4 y; body mass 74.3 ± 6.1 kg; stature 178.8 ± 7.0 cm; body fat $13.8 \pm 2.6\%$) from the professional football team at FC Barcelona completed a FATMAX test. Performed in a fasted state (> 5 h) on a treadmill, the test started at 5 km/h at a gradient of 1% for 3 min. The speed increased to 8 km/h and, thereafter, increased by 2 km/h until a respiratory exchange ratio (RER) of 1 was reached. The speed then remained constant and the gradient was increased by 1% every 1 min to determine peak oxygen uptake (VO_{2peak}). Respiratory gas measurements (VO₂ and VCO₂) and heart rate (HR) were measured continuously. Stoichiometric equations [1] were used to calculate fat oxidation rates during each 3 min stage of the test to determine MFO. Heart rate max (HRmax) and VO_{2peak} were measured in order to calculate FATMAX. **Results** The average MFO of professional football players was $0.75 \text{ g} \cdot \text{min}^{-1} \pm 0.18$. The lowest absolute MFO rate was $0.45 \text{ g} \cdot \text{min}^{-1}$, whereas the highest MFO measured was $1.18 \text{ g} \cdot \text{min}^{-1}$. FATMAX occurred at an average exercise intensity of $51 \pm 7\%$ VO_{2peak} (range 27 – 60% VO_{2peak}), equating to $66\% \pm 5$ of maximal HR (range 56 – 77% maximal HR). **Conclusion** Our results show that, on average, professional football players have a high capacity to oxidise fat during exercise. However, there is a wide range in MFO and the exercise intensity at which it occurs, potentially emphasizing the importance of personalized nutrition strategies. Further investigation is required to determine the importance and the implications of accounting for substrate oxidation rates, and their interaction with exercise intensity, with regard to football specific training, performance and nutrition recommendations. DIAGNOSTIC OF THE HIGH-ENERGY SYSTEM IN FEMALE SOCCER

WÖRDEHOFF, A., MEINERZ, S., HEINE, O., KNIGGE, H.

German Sport University Cologne

Introduction: Despite of several diagnostic tools in sport, test results do not determine team line-up. There are obviously factors influencing match performance that cannot be measured yet. Nevertheless, diagnostics are essential for systematic training and its evaluation. In female soccer, a lack of money is responsible for insufficient testing. A sprint test with changes in direction is a typical test for team sport attendees and does not require an expensive setup. The aim of the current study was to modify a common sprint test setup by adding information about the speed profile. This could allow assumptions about the demands on the energy system and lower limb strength. **Methods:** 26 female soccer players (playing in second or third German league) participated voluntarily in this study. As pretests, a field level test protocol, a treadmill ramp test protocol and a Counter-Movement-Jump (CMJ) were conducted. After a warm-up the participants performed an 80 m sprint with two changes in direction of 180 degrees. A LAVEG laser gun was used to gauge the speed profile and the alactice time was determined based on the model of Heck and Schulz (2002). Further parameters measured were heart rate, blood lactate concentration, maximal velocity and interims of the sprint. **Results:** The analysis showed a correlation between the interims of the sprint and the generated W/kg in the CMJ. A linear regression showed that at least 30 % of the variance of the sprint interims could be explained by the generated W/kg. In addition large differences between the alactic time could be observed. **Discussion:** The influence of the physical precondition seems to play a significant role concerning the sprint performance. Adapting a common sprint test protocol could easily help diagnosticians to get more information at lower expenses. Future research may enable scientists to identify different types of athletes concerning especially the use of the energy system. Therefore they could provide more appropriate training recommendations for coaches. **References:** Heck, H., Schulz, H. (2002). Deutsche Zeitschrift für Sportmedizin, 53, 202-212. SEQUENCING EFFECTS OF BALANCE AND PLYOMETRIC TRAINING ON PHYSICAL PERFORMANCE IN YOUTH SOCCER ATHLETES

CHAOUACHI, A.1, HAMMAMI, R.1, GRANACHER, U.2, BEHM, D.G.3

Tunisian research laboratory Sports Performance Optimisation

Introduction While there seems to be an advantage for including balance exercises within strength or power training programs (Chaouachi et al. 2014), it is not known whether the sequencing of balance and plyometric training has additional training benefits in youth. The objective was to examine the effect of sequencing balance and plyometric training on the performance of 12-13-years-old athletes. Based on a similar study (balance and strength) conducted with young adults (Bruhn 2006), it was hypothesized that balance training prior to plyometric training would provide greater gains in balance, power, sprint and agility performance. **Methods** Twenty-four young elite soccer players trained twice per week for eight weeks either with an initial four weeks of balance training followed by four weeks of plyometric training (BPT) or four weeks of plyometric training proceeded by four weeks of balance training (PBT). Testing was conducted pre- and post-training and included medicine ball throw, horizontal and vertical jumps, reactive strength, and leg stiffness, agility, 10, 20, 30-m sprints, Standing Stork-balance and Y-Balance-Test. **Results** Results indicated that BPT provided significantly greater improvements with reactive strength index, absolute and relative leg stiffness, triple hop test and a trend for the Y balance test ($p=0.054$) compared to PBT. While all other measures had similar changes for both groups, the average relative improvement for the BPT was 22.4% ($d=1.5$) versus 15% ($d=1.1$) for the PBT. BPT effect sizes were greater with 8 of 13 measures. **Discussion** Behm et al. (2008) recommended that balance training should precede plyometric training since balance and coordination are immature in children, and balance

is essential for optimal performance and the prevention of athletic injuries. Bruhn et al. (2006) suggested that in young-adults, balance training could have a preconditioning effect on subsequent resistance training. The present study provides experimental data corroborating this recommendation. Since the adolescent growth-spurt can adversely affect balance, coordination, and movement patterns, initially implementing balance training can improve anticipatory postural adjustments and motor coordination, possibly decreasing the likelihood of injuries from unstable landings and positions. Based on the present findings, it would be more effective for coaches and fitness conditioning professionals to institute at least four-weeks of initial balance-training prior to plyometric training for their youth-athletes. The balance training should progress from less demanding stationary activities to more complex dynamic balance activities. Such a program should enhance the subsequent plyometric training adaptations. References Behm DG, Drinkwater EJ, Willardson JM, Cowley PM. Appl Physiol Nutr Metab 35: 11-14, 2010. OP-PM78 Coaching: Coaches

PISTEMOLOGICAL BELIEFS OF PROSPECTIVE TURKISH COACHES

YILDIZER, G.

Anadolu University

Introduction Beliefs that individuals hold about knowledge and knowing, or what has been termed "personal epistemology" (EB), are related to learning and achievement in complex ways (Hofer, 2000). It is important to understand EB of individuals in order to explicate their perception through learning and knowledge which are basic components of educational process. It even becomes more important for educators such as physical education teachers and coaches, as they are not only active learners but also source of knowledge for their athletes or students. Grecic & Collins, lastly highlighted importance of EB in coaching process. Method The participants of this study was 124 students of coaching education programs of 3 different universities in Turkey. Schommers' (1990), 5-Likert type, , Personal Epistemological Belief Questionnaire was used as data collection tool. Turkish version of questionnaire consisted of 3 subscales, like orginal questionnaire. The first factor of the scale, depends on effort (LDE) , consists of 18 items. The second factor, depends on ability (LDA) , consists of 9 items. s. Additionally, the low average scores of the factors were evaluated as non-developed epistemological belief and the high average scores were evaluated as developed beliefs on that sub-scale. Results Independent Samples t-test results indicated that there is no significant differences between male and female prospective sport coaches for all three factors ($p>.05$). Similarly, independent samples t-test results indicated no difference between EBs of prospective coaches with coaching experience and no experience ($p>.05$). EB of prospective were also in significant in terms of their class level in all three factors. ($p>.05$). Dependent samples t-test results indicated that prospective coaches have significantly developed EB in LDE subscale comparing to EB in LDA subscale. Discussion The reason of similarities between coaching education students might caused by their insufficient experiences in coaching proffesion. As almost all of them have little or no experiences in the field and they have the same educational background, their epistemological beliefs are similar.Grecic& Collins () indicated the importance of personal epistemology in coaching proffesion. Therefore it is important to investigate personal epistemology on experienced coaches to explicate whether experiences in the field effective on personal epistemolgy among sport coaches. David Grecic & Dave Collins (2013) The Epistemological Chain: Practical Applications in Sports, Quest, 65:2, 151-168 Schommer, M. A. (1990). MAKE IT OR BREAK IT: CONFLICT IN COACH-ATHLETE RELATIONSHIPS

WACHSMUTH, S., JOWETT, S., HARWOOD, C.

Loughborough University

Introduction The coach-athlete relationship plays a central role in sport performance (Jowett & Shanmugam, in press). However, as in every relationship, conflict is inevitable and needs to be managed effectively. Despite its practical relevance in everyday coaching, research has failed to contribute a systematic scientific basis from which to examine conflict processes, determinants and consequences of interpersonal conflict. Recently, empirical efforts to study conflict have been noted around conflicts within sport teams (Partridge et al., 2015); organizations (Kerwin et al., 2011) or fan groups (Schumacher Dimech et al., 2016). The current study aims to provide a comprehensive account of interpersonal conflict within coach-athlete dyads through elite coaches' perspectives. Methods A total of eleven coaches from team (n=8) and individual (n=3) sports participated in the study. Coaches' performance level ranged from national (n=5) to international (n=6). The interview guide consisted of 26 open-ended questions that were classified in four categories: 1) Introduction/ Coaching Experience (5); 2) Interpersonal Conflict/ Concept (2); 3) Conflict Experience (9); and 4) Determining Factors/ Outcomes (10). The semi-structured interviews lasted from 48 minutes to over 2 hours and 14 minutes. All interviews were transcribed verbatim and a cross-case content analyses was conducted (Krippendorff, 1989). Ethical approval for carrying out the study was obtained from the researchers' institution. Results In total, three higher-order themes were derived from the data, covering the following areas: 1) Determining Factors and Conflict Circumstances; 2) Interpersonal Conflict as a Process; and 3) Conflict Consequences. Discussion This study provides an in-depth insight into the experiences of conflict within the context of the coach-athlete relationship. The results shed light in the ways coaches perceive interpersonal conflict as well as the influences of conflict in their emotions, thought processes and behaviors. Moreover, the results suggest that conflict can be both a facilitative and a debilitating process. Finally, the results provide initial practical suggestions concerning strategies that may minimize the negative effects of interpersonal conflict. The current study paves the way for more research in a significant yet underdeveloped psychosocial area. References Jowett S, Shanmugam V (in press). PERCEIVED HINDRANCES EXPERIENCED BY SPORT COACHES IN SOUTH AFRICA

KUBAYI, A.

Tshwane university of technology

Introduction Despite the fact that there is a high turnover of sport coaches in South Africa, very little is known about the impediments encountered by sport coaches in the country. Thus, the present study attempts to fill the void in the literature as such information could help sport organisations to design strategies that could help to retain sport coaches in the country. Therefore, the present study was carried out to ascertain perceived hindrances experienced by sport coaches in South Africa. Methods A total of 224 South African sport coaches (122 males and 102 females) participated in this study. The participants represented a variety of sports: soccer ($n = 87$), athletics ($n = 45$), netball ($n = 44$), cricket ($n = 19$), rugby ($n = 12$), swimming ($n = 10$), boxing ($n = 4$); three coaches did not indicate their sports. Forty-five per cent of the coaches were in the 18–25 years age group, 30% in the 26–35 years age group, 20% in the 36–45 years age group, 4% in the 46–65 years age group and 1% older than 65 years of age. The Perceived Hindrance Scale (PHS) developed by Kamphoff and Gill (2008) was used to collect data. The questionnaire comprised 34 items measured on a 9-point Likert scale ranging from 1 (not at all a hindrance) to 9 (completely a hindrance). Participants were asked to rate the most important hindrances in their coaching profession. A Cronbach alpha coefficient of 0.947 was obtained for the entire questionnaire. Results The major hindrances experienced by sport coaches were "Lack of support systems for women players" ($M = 5.39$, $SD = 2.93$); "Lack of support for women coaches from superiors" ($M = 5.35$, $SD = 2.89$); "Low salary" ($M = 5.23$, $SD = 3.16$); "Lack of opportunities for promotion" ($M = 5.13$, $SD = 3.02$); "Difficulties with parents/spectators" ($M = 5.10$, $SD = 2.70$) and "Lack of job security" ($M = 4.98$, $SD = 3.07$). Discussion Based on the results of this study, the following recommendations are proffered. First, mentoring programmes which could provide encouragement and support for female coaches should be enacted. Second, female coaches, who are role models, should be invited to discuss challenges facing female athletes and coaches, respectively, and how they can be addressed. Third, coach-parent meetings should be organised regularly by teams as this will minimise conflicts between coaches and parents, thus maximising children's participation in sports. Finally, a sport association for coaches should be formed. This will ensure equitable salaries and guarantee that the needs of the sport coaches are well catered for. PERCEPTIONS, AWARENESS AND KNOWLEDGE OF THE FEMALE ATHLETE TRIAD AMONGST COACHES – ARE WE MEETING THE EXPECTATIONS FOR ATHLETE SAFETY?

MUKHERJEE, S.

National Institute of Education, Nanyang Technological University, Singapore

Introduction Female Athlete Triad (FATr) is a condition with the potential of long-term adverse effects on health and sports performance in female athletes. Coaches' awareness and knowledge can play a critical role for primary prevention, early detection and management of the triad. The primary objective of this study was to investigate the awareness, knowledge and perceptions of Singaporean coaches on FATr. Methods The study was a cross-sectional survey with 106 participant coaches (81 males; 25 females) from the Singapore National Registry of Coaches. A 31 item questionnaire was developed to determine the perceptions, awareness and knowledge on FATr. The coaches' responses were obtained in the presence of the research team. Data analyzed included demographic and coaching practice information, awareness and knowledge levels, gender differences in knowledge and differences in awareness and knowledge between participants with different levels of coaching qualification. Results A 100% response rate was achieved. The knowledge levels were found to be low with 85% coaches not having heard of the FATr, 89% coaches not able to identify at least one component of the triad and only 2 coaches being able to correctly identify the three components of FATr. A significant proportion of coaches had misperceptions related to low body fat, leanness, menstrual irregularity and bone health in female athletes. There was no significant difference in knowledge based on gender, level of coaching qualification and years of coaching experience. Discussion Coaches have low levels of awareness and knowledge on FATr. The misperceptions and knowledge gaps need to be addressed through multifaceted coach education programs developing the awareness and knowledge on FATr, skills for early recognition of red flags, athlete referral to health professionals and attitudes and skills for regular communication with the athletes on nutrition, menstrual history and bone health. OP-PM53 Nutrition & Dietetics

DIETARY COUNSELING INTERVENTION FOR FEMALE HEAVYWEIGHT JUDO ATHLETES DECREASED CARDIOMETABOLIC RISK

MURATA, H., OSHIMA, S., TORII, S., SAKAMOTO, S., TAGUCHI, M., HIGUCHI, M.

Waseda University, Sport Sciences

Introduction There is a concern that some heavyweight (HW) Judo athletes have high cardiometabolic risk (CMR) due to excess body fat mass (FM) along with their large body mass (BM). Our previous study showed that female HW Judo athletes had high FM and some of them developed insulin resistance (IR) (Murata, et al., 2013). Visceral fat (VF) and IR have been shown as main contributors of CMR (Despres, et al., 2008) and our previous study showed that a dietary counseling intervention (DCI) for male HW Judo athletes decreased CMR by decreasing VF (Murata, et al, 2015). Therefore, the purpose of this study was to examine whether DCI for female HW Judo athletes can effectively decrease CMR without reducing their physical performance. Methods Fourteen female Judo athletes who belonged to 78kg and over 78kg classes participated in this study. They were divided into 2 groups such as DCI group ($n=7$; age: 20.1 ± 1.3 years, BM: $80.3(78.7-107.3)\text{kg}$) and control (CONT) group ($n=7$; 20.1 ± 0.6 years, $82.8(78.0-92.0)\text{kg}$). DCI group completed a 10-week DCI using e-mail and personal interview by the certified Sports Dietitian which instructed them to have a well-balanced diet with proper caloric intake. VF

and body composition were assessed by magnetic resonance imaging and dual energy X-ray absorptiometry, respectively. Physical fitness was also examined by hand grip strength (HGS) and the 20-m shuttle run (SR) test. Results After DCI, reductions of %BF (from $29.3 \pm 5.8\%$ to $27.8 \pm 6.1\%$) and FM in DCI group were significantly larger than CONT group ($p < 0.05$), whereas increases of total fat-free mass (FFM), HGS and the number of SR in DCI group were significantly larger than CONT group. HOMA-IR in DCI group was also significantly decreased compared to CONT group ($p < 0.01$). Discussion It was found that the 10-week DCI for female HW Judo athletes significantly lowered %BF, FM and HOMA-IR with increasing FFM, muscle strength as well as cardiorespiratory fitness. Interestingly DCI group did not significantly decrease VF. Previous study showed that overweight men deceased larger VF than overweight women in calorie restriction with exercise (Redman, et al., 2007). Therefore, although DCI effectively reduces CMR for female HW Judo athletes, it may have less effect on reducing VF for female HW Judo athletes. Conclusion DCI for female HW Judo athletes reduced CMR without reducing their physical performance. References Despres JP, Lemieux I, Bergeron J, et al. (2008). PREVALENCE OF OMNIVORES, VEGETARIANS AND VEGANS IN RUNNING EVENTS: THE NURMI STUDY

WIRNITZER, K.C.1, KNECHTLE, B.2, NIKOLAIDIS, P.T.3

1: PHT Innsbruck, Austria; 2: UZH Zürich, Switzerland; 3: HAA Athens, Greece

Introduction Considering the growing background numbers of vegetarians and vegans (Craig et al., 2009; Stahler, 2011), the number of vegetarian and vegan runners is likely to rise, too. Therefore, the aim of the Nutrition and Running High Mileage (NURMI) Study was to investigate the prevalence of omnivores, vegetarians, and vegans in running events in the first step. Methods The NURMI Study was conducted following a cross-sectional design. The present study determined epidemiological aspects of runners. Data collection (1/10/2014 to 31/12/2015) was accomplished using a standardized questionnaire. Analysis was performed using SPSS software package. All data derived from the statistical methods were presented as mean \pm standard deviation. Results Data collected built a basic sample size of 3163 runners (1779 women: 56.2%; 1384 men: 43.8%) predominantly from German-speaking countries (Austria, Germany, Switzerland: 2788) with lower numbers from the rest of Europe (375). The prevalence of omnivores, vegetarians and vegans in running events was 1434 (45.3%), 665 (21.0%) and 1065 (33.7%), respectively. An association between sex and diet was observed ($p < 0.001$): the prevalence for female and male runners was 673 (37.8%) vs. 761 (55.0%) in omnivores, 431 (24.2%) vs. 234 (16.9%) in vegetarians, and 675 (37.9%) vs. 389 (28.1%) in vegans. Omnivorous runners were found to be older and heavier (age: 39.2 ± 11.1 y; body weight: 69.0 ± 10.9 kg; body mass index (BMI): 22.7 ± 2.5 kg.m $^{-2}$; $p < 0.001$) compared to vegetarians and vegans (age: 36.2 ± 11.0 vs. 35.2 ± 10.2 y; body weight (BW): 65.0 ± 10.5 vs. 65.3 ± 10.4 kg; BMI: 21.8 ± 2.4 vs. 21.9 ± 2.5 kg.m $^{-2}$; $p < 0.001$). A sex-diet interaction was found on BW ($p = 0.022$, $n_2 = 0.002$) and BMI ($p < 0.001$, $n_2 = 0.007$). Discussion The main findings of the present study were (1) almost equal numbers of female omnivorous and vegan runners, whereas the major count of male runners were omnivores; and (2) omnivorous runners were older and heavier than non-omnivores in this study. However, beneficial and detrimental effects of vegetarian and vegan diets on the health status are well known (Cullum-Dugan et al., 2015). Since scientific data about endurance athletes following a vegetarian and particularly vegan diet is limited (Wirnitzer & Kornexl, 2014; Leischik & Spelsberg, 2014), the NURMI Study is the first to assess this issue considering a bigger sample size. Therefore, these results provide a major contribution by adding knowledge to overcome the lack of data on the prevalence and demographics of vegetarians and vegans in running events (Scheerer et al., 2015), and might be helpful as reference data for future studies. This further may help to augment the body of science on the limited data of vegan athletes in general (Fuhrmann & Ferreri, 2010). References Craig WJ, Mangels AR (2009). DIETARY HABITS AND SUPPLEMENT USE OF ELITE ADOLESCENT CYCLISTS

MAYHO, H., NICHOLAS, C., MITCHELL, N.

University of Chester

Introduction Diet is key to health and athletic performance. Dietary intake of British Cycling Olympic Development Programme (ODP) athletes was assessed and compared in 1st and 2nd year cyclists. Supplement use of these athletes was also determined. Methods Forty adolescent cyclists, 25 male and 15 female (mean age 16.2 years) completed a Dietary Habits Questionnaire (DHQ) that included a Food Frequency Questionnaire (FFQ) and questions to assess monthly supplement use. Dietary analysis was conducted with a sample of 21 FFQ, using Microdiet™ software. Supplement use was calculated for all 40 participants. Energy and macronutrient intake was compared to UK dietary reference values (DRVs). Results ODP cyclists achieved DRVs for energy, carbohydrate and saturated fat (SF), but both males and females consumed more protein than recommended, exceeding DRV by 137.1g and 111.6g respectively ($Z = 3.180$, $p = 0.001$, $n = 13$; $Z = 2.521$, $p = 0.012$, $n = 8$). Dietary intake of 1st and 2nd year cyclists did not differ. Supplement use did not differ between 1st and 2nd year cyclists ($\chi^2 = 0.231$, $df = 1$, $p = 0.631$) but were used at least once a week by 95% of ODP athletes. Average intake per rider per month was 78.2 items, although there were large range values of total monthly use per rider (0-272). Use was more prevalent in male athletes than females (96 vs. 49 items per month) ($\chi^2 = 15.234$, $df = 1$, $p < 0.001$) and compared to other squads, the sprint athletes (TS) used significantly more (122 vs. 75 (Endurance), 24 (BMX), 77 (MTB)), ($\chi^2 = 64.60$, $df = 3$, $p < 0.001$). The most popular supplements amongst the 40 athletes were protein/recovery drinks, multivitamins, fish oil/omega 3, vitamin C and carbohydrate (CHO) bars. Discussion Dietary intake appeared to be adequate, but further research is needed using DRVs specific to young athletes. Small improvements in dietary composition appeared in 2nd year athletes although these were not significant. 2nd year athletes consumed more of their total energy from CHO (+1.76%) and protein (+0.82%) and less from fat (-2.45%), suggesting nutrition education may have had a small impact. The high prevalence of supplement use found among these young athletes is consistent with previous findings from young UK athletes from other sports (Petróczki et al., 2008). However, these results are concerning as young athletes are advised against using supplements by the IOC (2011) due to the associated risks. Further research is needed in order to develop an athlete-specific, validated FFQ and also to determine reasons for supplement use. References IOC consensus statement on sports nutrition 2010. (2011). Journal of Sports Sciences, 29, S3-S4 Petróczki, A, Naughton, DP, Pearce, G, Bailey, R, Bloodworth, A, McNamee, MJ. (2008). DIETARY CALCIUM AND VITAMIN D ADEQUACY IN UNIVERSITY-LEVEL ATHLETES: INITIAL FINDINGS FROM THE D-BIICEP STUDY

WILSON-BARNES, S.J., HUNT, J., WAINWRIGHT, J., WILD, S., LANHAM-NEW, R.

University of Surrey

Introduction: Vitamin D (VitD) and calcium (Ca) are essential for the maintenance of musculoskeletal health. Athletes residing in countries at higher latitudes, and specifically those who train or compete indoors, are at risk of VitD inadequacy (Close, 2013). This is because VitD is primarily synthesized following cutaneous exposure to ultraviolet B (UVB) irradiation, with dietary VitD as a secondary source. Method: We recruited 58 healthy participants (21 women & 37 men) who compete in a range of sports from the University of Surrey. Subjects were investigated to determine dietary intake, anthropometrics, bone health and blood parameters. All subjects completed a total body composition analysis using bioelectrical impedance (TANITA) and a bone density scan of the radius using peripheral quantitative computed tomography (pQCT). Participants also completed a 5-d food diary and under-reporting of dietary intake was determined by calculating energy intake to basal metabolic rate ratio (Goldberg, 1991). Dietary and statistical analysis were carried out using DietPlan6 (2013) and SPSS21(2013), respectively. Results: Average age of participants was 20 ± 1 y. Men had higher BMI and FFM compared to women; 24.8 ± 3.1 , 22.6 ± 3.2 kg/m²; 67.5 ± 8.8 , 49.2 ± 5.6 kg, respectively ($p < 0.05$). Radial bone mass at 4% site averaged: 1.54 ± 0.29 , 1.14 ± 0.20 mg ($p < 0.001$); Radial Mass at 66%: 1.21 ± 0.53 , 1.20 ± 0.40 mg, respectively for men and women. There was a trend for energy intake (EI) to be higher in men compared to women: 2352 ± 754 , 1942 ± 544 kcal/d ($p = 0.076$) respectively. Ca intake was higher in men: 1046 ± 370 mg, 866 ± 517 mg. VitD intake however, did not differ between genders 2.7 ± 1.8 , 2.8 ± 2.9 µg. Positive correlations were observed between 4% radial site and Ca intake; $r = .356$ ($p < .05$), specifically within females; $r = .562$ ($p < .05$). Under-reporting of dietary intakes (EI: BMR ratios: 0.79 ± 0.22) were present in 100% of the cohort (range: 0.42-1.28). Conclusions: Dietary Ca exceeded the RNI (700mg/d; DOH, 1991) within this cohort. However, both groups did not achieve a sufficient VitD intake of 15µg, as recommended by the Institute of Medicine (2010), on average achieving a restrictive intake of 2.75µg/d. Under-reporting could be a contributing factor to these lower intakes; hence further investigation is therefore warranted in this active sub-population. From these results it can be suggested that UK dwelling non-supplemented university athletes are at risk of VitD insufficiency. Further analysis of this dataset is underway, with specific focus on summer and winter VitD status and physical performance.

ASSOCIATIONS BETWEEN BREAKFAST FREQUENCY AND OBJECTIVELY-MEASURED PHYSICAL ACTIVITY AND SEDENTARY TIME IN CHILDREN FROM 12 COUNTRIES

ZAKRZEWSKI-FRUER, J.K.1, GILLISON, F.B.2, CUMMING, S.2, KATZMARZYK, P.T.3, STANDAGE, M.2 ET AL.

1: University of Bedfordshire (Bedford, UK), 2: University of Bath (Bath, UK), 3: Pennington Biomedical Research Center (Baton Rouge, USA).

Introduction There is limited support for an association between breakfast frequency and physical activity (PA) or sedentary time in samples of children from high-income countries with limited socioeconomic diversity. Using data from the International Study of Childhood Obesity, Lifestyle and the Environment (ISCOLE), associations between breakfast frequency and objectively-measured physical activity and sedentary time were examined in 9–11-year-old children from 12 countries representing a wide range of geographic and socio-cultural variability. Methods Multilevel statistical models with participants (level 1) nested within schools (level 2) and country (level 3) were used to examine associations between breakfast frequency and accelerometry-derived PA and sedentary time in 6163 children from 12 ISCOLE study sites. Model 1 adjusted for age, sex and parental education; Model 2 also adjusted for body mass index (BMI) z-score. Results Models 1 and 2 showed rare breakfast consumption to be associated with more sedentary time than occasional (Model 2: $P=0.045$, 95% confidence intervals (CI): 0.22 to 18.61) and frequent (Model 2: $P=0.041$, 95% CI: 0.35 to 16.37) consumption; Model 2 also showed less light PA for rare compared to occasional consumption ($P=0.049$, 95% CI: -14.35 to -0.02). Using Model 1, moderate-to-vigorous PA was higher for frequent compared with rare consumption ($P=0.035$, 95% CI: -5.35 to -0.19), and the higher moderate-to-vigorous PA for frequent vs. occasional consumption neared significance ($P=0.055$, 95% CI: -3.34 to 0.03). Similarly, moderate PA was higher for frequent compared with occasional consumption ($P=0.049$, 95% CI: -2.11 to -0.00) and vigorous PA for frequent compared with rare consumption ($P=0.050$, 95% CI: -2.47 to -0.00). No associations for moderate-to-vigorous, moderate or vigorous PA were found when adjusting for BMI z-score (Model 2). No interactions with study site were found. Discussion In a multinational sample of children, more frequent breakfast consumption was associated with less sedentary time, independent of age, sex, parental education and BMI z-score. Additionally, occasional breakfast consumption was associated more time in light PA than rare consumption. Although we found some evidence of more moderate-to-vigorous PA with more frequent breakfast consumption, these associations became non-significant when controlling for BMI z-score. Experimental research is required to determine the possible causal role of frequent breakfast consumption in reducing sedentary time and increasing PA in globally representative samples of children.

OP-PM41 Exercise & Health

THE IMPACT OF EXERCISE AND FAT TYPE ON HYPERTRIGLYCERIDEMIA IN HEALTHY MALES

FOGARTY, M.C.1, BRAY, J.W.1, O' DOHERTY, A.1, EVANS, W.1, SCOTT, C.1

University of Hull

INTRODUCTION A substantial body of literature postulates that high levels of postprandial blood triglycerides (TG) can promote and environment for the facilitation of atherosclerosis and cardiovascular disease mediated by oxidative stress (OS). Contemporary research has raised interest in food sources of medium-chain triglycerides (MCTs) and their prevalence for a reduced TG response post consumption. Although a bout of moderate exercise prior to a high fat meal has been shown to support the removal of TG postprandial less is known about the impact of exercise in the hours following fat consumption, and the role of the type of fat ingested. Therefore the aim of the present investigation was to determine the influence of fat source, acute exercise, and OS on postprandial hypertriglyceridemia (PHTG). METHODS Nine healthy male participants ($26.0 \text{ y} \pm 4.6$;) completed in a randomised crossover design: (1) high-fat meal alone (HF) (2) high-fat meal with one hour of moderate exercise (60% VO_{2max}) two hours postprandial (HF-EX) (3) high-fat meal of virgin coconut oil

(VCO) with one hour of moderate exercise (60% VO_{2max}) two hours postprandial (HF_EXVCO). The high fat meals consisted of 0.6g of fat (76% energy intake), 0.2g of carbohydrates (15% energy intake) and 0.1g of protein (9% energy intake) per kg of body mass. TG was measured in venous blood at baseline, 2 and 4 hour postprandial. Other supporting biochemical markers were also collected and will be presented in full at the conference (LDL, HDL, TC & LOOH). Following failure of normal distribution data was analysed using area under the curve (AUC) for a non-parametric comparison of the three conditions. Pairwise comparisons were performed with a Bonferroni correction for multiple comparisons. Data is presented as median [IQR] and median difference (MD). RESULTS AUC for TG was statistically significantly different between the three conditions ($X^2(2) = 14.889$, $P = 0.001$). TG was statistically significantly lower for HF_EXVCO (2.4 [1.6]) compared to HF_EX (3.2 [1.7]) (MD = -0.8 mM.L, $P = 0.029$) and HF_only (3.6 [1.07]) (MD = -1.2 mM.L, $P = 0.0001$). However, there was no statistically significant difference between HF_EX vs. HF_only (MD = -0.4 mM.L, $P = 0.716$). CONCLUSION These results propose that a single session of moderate aerobic exercise can decrease TG levels succeeding a high-fat meal. Furthermore, VCO TG response is lowered earlier with exercise potentially due to a more direct oxidation mechanism at the liver. The data correlating the PHTG with lipid markers of oxidative stress is currently undergoing analysis and will add an additional level of analysis to these novel findings.

COMPARISON BETWEEN DESCENDING VERSUS ASCENDING STAIR WALKING INTERVENTION FOR INSULIN SENSITIVITY, LIPID PROFILES AND FUNCTIONAL PHYSICAL FITNESS OF ELDERLY OVERWEIGHT WOMEN

NOSAKA, K.1, TSENG, K.W.2, HSIEH, C.C.2, CHEN, T.C.3

1: ECU (Australia), 2: UT (Taiwan), 3: NTNU (Taiwan)

Introduction Repeating maximal eccentric exercise of the knee extensors once a week for 8 weeks has been shown to improve blood lipid profile and insulin sensitivity of young women (1). Our previous study (ECSS2013) showed greater improvement of fitness and health after progressive eccentric than concentric exercise training of the knee extensors performed once a week for 12 weeks by elderly men. One of the simplest eccentric exercises is descending stairs (DS). The present study investigated the hypothesis that repeating DS would improve lipid profile, insulin sensitivity and functional physical fitness (FPF) greater than ascending stairs (AS). Methods Overweight women (≥ 60 y) were assigned to either DS or AS group ($n=8$ /group). An elevator was used to take the participants from the 1st to 5th floor for DS, and the 5th to 1st floor for AS, and DS and AS were performed twice a week for 12 weeks by increasing the volume gradually (1st wk:2 reps/session, 12th wk:24 reps/session, 1 rep=110 stairs). Overnight fasting blood samples were taken 5 days before the first training session and 4 days after the last training session, and analysed for serum triacylglycerols (TG), total (TC), high-density lipoprotein (HDLC) and low-density lipoprotein cholesterol (LDHC), glucose, insulin, homeostasis model assessment (HOMA) and whole blood glycosylated hemoglobin (HbA1C), and 2-h oral glucose tolerance test (OGTT) was performed. Resting heart rate, systolic (SBP) and diastolic blood pressure (DBP), maximal voluntary isometric contraction strength of the knee extensors (MVC) and FPF tests for older adults (9 tests, e.g. 30-s chair stand: CS, 6-minute walk) were measured before and after the training period. Results The average HR during DS (90 beats/min) was lower ($P<0.05$) than that of AS (111 beats/min). Resting HR (-8%) and SBP (-7%) decreased greater after DS than AS (-3%). Most blood variables changed significantly from baseline to post-training, but decreases in glucose, insulin, HOMA, HbA1C, TG, TC, LDLC and OGTT (area under the curve), and increases in HDLC were greater ($P<0.05$) after DS than AS. Most of FPF tests improved greater ($P<0.05$) for DS (e.g. CS:39%) than AS (16%), and MVC also increased greater for DS (35%) than AS (19%). Discussion These results supported the hypothesis that DS would improve lipid profile, insulin sensitivity and fitness of elderly overweight women better than AS. It is important to note that DS is less metabolically demanding than AS. It is concluded that DS can be used as effective exercise intervention for less-fit individuals to improve their health and fitness. References 1. Paschalis et al. STRENUOUS PHYSICAL EXERCISE ACCELERATES THE LIPID PEROXIDE CLEARING TRANSPORT BY HDL

VÄLIMÄKI, I., VASANKARI, T., VUORIMAA, T., AHOTUPA, M.

Paavo Nurmi keskus

Purpose Physical exercise has cardioprotective functions, which have been partly linked to high-density lipoprotein (HDL), and its functions. We studied the effects of endogenous oxidative stress, induced by acute exhaustive physical exercise, on concentration of oxidized HDL lipids. Methods Twenty-four male national top-level endurance runners, 12 middle-distance runners and 12 marathon runners, performed a maximal run on a treadmill until exhaustion. We analysed concentrations of oxidized HDL (oxHDLlipids) and LDL lipids (oxLDLlipids), serum antioxidant potential (TRAP), paraoxonase activity and malondialdehyde (MDA). Venous blood samples were taken before, immediately, 15 min and 90 min after exercise. Results During the treadmill run the concentration of oxHDLlipids was increased by 24 % ($p < 0.01$). Simultaneously, the ratio of oxHDLlipids to oxLDLlipids increased by 55 % and the oxLDLlipids levels decreased by 19 % ($p < 0.001$), while serum malondialdehyde and TRAP increased by 54 % ($p < 0.001$) and 29 % ($p < 0.01$), respectively. After the 90 minutes recovery the concentration of oxHDLlipids was decreased towards the pre-exercise level, but that of oxLDLlipids remained decreased below pre-exercise values ($p < 0.001$). The change in oxLDLlipids during run correlated positively with VO_{2max} ($r = 0.67$, $p < 0.001$) and negatively with the change in paraoxonase activity ($r = -0.47$, $p < 0.05$). Conclusions We conclude that acute exhaustive physical exercise increased the concentration of oxHDLlipids and decreased that of oxLDLlipids and the ratio of oxLDLlipids to oxHDLlipids, which suggests, that during physical exercise HDL has an active role in the removal of lipid peroxides.

THE REPEATABILITY OF THE ORAL FAT TOLERANCE TEST WITH AND WITHOUT PRIOR AEROBIC EXERCISE

O'DOHERTY, A.F.1, SATHYAPALAN, T.2, INGLE, L.1, CARROLL, S.1

University of Hull

Introduction The Oral Fat Tolerance Test (OFTT) is considered a repeatable measure used to assess triglyceride (TAG) responses within the postprandial state (Ryan et al., 2013), with higher TAG levels being observed in cardiovascular and metabolic disorders. Acute aerobic exercise intervention before OFTT reduces the postprandial TAG response (Maraki & Sidossis, 2013) but its effect on the repeatability of this measure is unknown. We aimed to investigate the repeatability of TAG to a specifically designed OFTT with and without prior standardised aerobic exercise. Methods On four separate days, healthy adult male participants underwent repeat OFTT and repeat OFTT with one hour of aerobic exercise (exercise intensity: 90% oxygen consumption at anaerobic threshold) performed immediately before meal ingestion. The OFTT meal composition included 75.4g total fat (47.5g saturated fat), 21.7g carbohydrate and 13.7g protein. Venous blood was sampled at baseline and hourly for 4 hours after OFTT meal ingestion and TAG area under the curve (AUC) was calculated using the trapezoidal method. Repeatability was assessed using non-parametric Bland Altman plots with predefined limits of agreement set at $\pm 10\%$ and $\pm 15\%$. Results Eleven males, median age 30 (IQR 17) years, body mass of 79.0 (IQR 14.6) kg, and body mass index (BMI) 24.6

(IQR 3.5) kg/m² were assessed. One participant was excluded for the OFTT condition due to breach of protocol. Bland Altman analysis of 4 hour TAG AUC revealed that 5 of 10 repeat measurements fell within $\pm 10\%$ and 9 of 10 repeat measurements fell within $\pm 15\%$ of the median TAG AUC for OFTT, a typical error of ± 0.86 mmol·4hour·l⁻¹. By comparison, only two of 11 repeat measurements fell within $\pm 10\%$ and two of 11 repeat measurements fell within $\pm 15\%$ of the median TAG AUC for OFTT with 1 hour prior aerobic exercise. Discussion The OFTT is a repeatable test in healthy men, however, moderate intensity aerobic exercise performed immediately before OFTT considerably increases the variability of TAG AUC. These findings have implications for interpretation of postprandial studies investigating the effects of exercise intervention performed immediately before OFTT. Future studies should investigate the repeatability of exercise intervention performed 8-24 hours before OFTT, a typical study design within this area of research. Maraki, M. I., & Sidossis, L. S. IMPACT OF 4-WEEK EXERCISE TRAINING ON THE ACUTE CHANGE IN VASCULAR FUNCTION TO EXERCISE

DAWSON, E.A.1, ERSKINE, R.1, CABLE, N.T.1,3,4, GREEN, D.J.1,3, THIJSEN, D.J.T.1,2

Liverpool John Moores University 2 Radboud University (Netherlands), 3 UWA (Australia), 4 Aspire Academy (Qatar)

Introduction: Exercise is a potent stimulus for acute changes in vascular function. The exact nature of this response is variable, with a decrease, increase or no change reported. In the present study, we explored whether the type of exercise and/or exercise training impact the nature of the response. Therefore, we aimed to determine 1) if acute, exercise-induced changes in vascular function are different between endurance and resistance exercise, and 2) whether this response is altered after 4-week of exercise training in healthy young men. **Methods:** Vascular function was assessed using flow-mediated dilation (FMD) both before and immediately after a 30-min exercise bout, consisting of endurance exercise ($n=16$, 20.9 ± 2.2 yr, 74.0 ± 7.6 kg, 178 ± 6 cm) or resistance exercise ($n=15$, 21.0 ± 2.4 yr, 76.1 ± 8.2 kg, 178 ± 5 cm). To explore the impact of exercise training, subjects were assigned to perform 4-weeks of Endurance Training (ET; 3 sessions per week) or leg Resistance Training (RT; 3 sessions per week). After training, vascular function was re-assessed before and after an acute bout of exercise (matched to the first exercise bout for relative exercise intensity). **Results:** First, we found a significant impact of the type of exercise on the exercise-induced change in FMD. Post-hoc analysis revealed that an acute bout of endurance exercise did not alter FMD ($6.3 \pm 2.1\%$ to $6.2 \pm 1.9\%$, $P>0.05$), whilst resistance exercise increased FMD ($7.2 \pm 2.3\%$ to $9.3 \pm 3.0\%$, $P=0.02$). Secondly, exercise training significantly altered the nature of the change in FMD to acute exercise ($P=0.022$). Post-hoc analysis showed that 4-week endurance training caused a decrease in FMD after exercise ($7.9 \pm 2.6\%$ to $5.3 \pm 2.1\%$; $P=0.001$), whilst 4-week resistance training abolished the acute, exercise-induced change in FMD ($7.6 \pm 3.1\%$ to $8.0 \pm 3.0\%$; $P>0.05$). **Conclusion:** Our data suggest that the mode of exercise alters the acute change in FMD following a single bout of exercise, with no change in FMD after endurance exercise and an increase in FMD after resistance exercise. Furthermore, 4-weeks exercise training altered the nature of the post-exercise change in FMD in both types of training, as training decreased FMD after endurance exercise and abolished the initial increase in FMD after resistance exercise. These data therefore strongly suggest that the mode of exercise as well as 4-week exercise training alters the nature of the change in FMD after an exercise bout in healthy young men.

12-WEEK RECREATIONAL SOCCER TRAINING IMPROVED HEALTH PROFILE OF TYPE 2 DIABETES PATIENTS MORE THAN RUNNING AND DIET ALONE – A BRAZILIAN STUDY

SOUZA, M.1, FUKUI, R.1, KRISTRUP, P.2, SILVA, M.E.R.1

University of Sao Paulo

Introduction Among Latin America countries, Brazil has the highest number of people with Type 2 Diabetes (T2D) estimated in 12.1% in São Paulo state (Borges et al., 2014). Lifestyle modification has been demonstrated to prevent outcomes, particularly coronary heart disease, and induce remission of early T2D. Therefore, we aimed to investigate the impact of recreational soccer combined with a caloric restricted diet on health profile of untrained Brazilian T2D patients vs. running training. **Methods** Sixty ($n=60$) untrained Brazilian T2D patients aged 47-74 years were randomized into a soccer+diet group (SDG; $n=19$), a running+diet group (RDG; $n=19$) and a diet group (DG; $n=22$). Training sessions were held for 40 min, 3 times per week for 12 weeks. Dual-energy X-ray, treadmill testing, and fasting blood samplings were performed before and post 12 weeks. **Results** Maximal oxygen uptake increased only in the training groups ($P<0.05$) while a decrease ($P<0.05$) was observed in DG after 12 weeks. Systolic blood pressure reduced ($P<0.05$) only in the SDG from 128.2 ± 3.2 to 124.2 ± 2.2 mmHg after 12 weeks, with no changes in diastolic blood pressure for any of the groups. HbA1c decreased ($P<0.05$) by ~10% in all groups after 12 weeks. In all groups, bone mineral density increased ($P<0.05$) by ~0.02 g/cm², fat mass decreased ($P<0.05$) by ~3 kg, and lean body mass was not altered (~64 kg ($P>0.05$)). For SDG and RDG, respectively, baseline triglycerides, total cholesterol and VLDL-cholesterol were reduced by 24.8% (37.3 ± 1.9 mg/dL), 12.5% (22.2 ± 0.2 mg/dL) and 24.3% (7.3 ± 1.8 mg/dL); 27.9% (50.6 ± 4.4 mg/dL), 10.4% (21.4 ± 0.5 mg/dL) and 28.0% (10.2 ± 0.8 mg/dL). LDL-cholesterol was lowered ($P<0.05$) only in the SDG by 15.4% (16.4 ± 1.3 mg/dL), while HDL-cholesterol was unaltered ($P>0.05$) in all groups after 12 weeks. Regarding between-group differences, SDG improved more ($p<0.05$) in baseline fasting lipids than RDG and DG during the 12-week intervention period. **Discussion** Soccer training lowered systolic blood pressure, which may reflect a better muscle capillarization and vascular structural adaptations (Krstrup et al., 2009). In addition, lower LDL-cholesterol levels suggests greater increased fat oxidation rate post-training (Pachalis et al., 2011) due to the multiple intense actions during soccer training stimulating musculoskeletal and cardiovascular adaptations better than running training. Recreational soccer training plus diet resulted in large benefits on health profile of T2D, and appear to better prevent cardiovascular issues than running plus diet and diet alone. OP-SH21 Organizational Aspects & Success

ORGANIZATIONAL FACTORS INFLUENCING THE INTERNATIONAL SPORTING SUCCESS IN HIGH-PERFORMANCE JUDO

MAZZEI, L., BÖHME, M.T., DE BOSSCHER, V.

School of Physical Education and Sport of University of São Paulo

Introduction Researchers and managers have a great interest in analysing the existing sports policies in different countries in the search of explanations for the international sporting success achieved by some countries and not by others. Recently, the studies in this issue have further advanced studying certain aspects of elite sport policies and key success factors of specific sports (Brouwers, Sotiriadou, & De Bosscher, 2015). In this study, the objective was to identify the organizational factors that influence the international sporting success in high-performance Judo. Methods A Sequential Exploratory Design (Creswell & Plano Clark, 2011) according was used, which involves an initial phase that collects and analyses qualitative data, followed by a second intermediate phase related to the development of a questionnaire and a third phase involves quantitative analysis. 33 international high-performance Judo stakeholders were interviewed in an initial phase. A questionnaire developed and validated by Content Validation of six experts was the second phase. And finally, in a third quantitative phase was performed an Exploratory Factor Analysis (EFA) on data obtained in a sample of 406 Brazilian judokas, divided into athletes, coaches, performance directors and experts. Results In the qualitative phase, 11 categories and 44 subcategories were identified, which were considered the dimensions and the organizational factors influencing the international sporting success in high performance Judo respectively. From these results, in the second phase a questionnaire was developed, validated and allowed the quantitative phase. In the quantitative phase, all the organizational factors were in the EFA results. The first six Factors had the highest coherence with the qualitative results, contributing with 50.97% of the total variance. Discussion The results found in the qualitative phase are similar to other studies that had the purpose of investigating elite sport policies and factors for the international sporting success. However, specific Judo characteristics and environment influence the development of Judo. Furthermore, the qualitative and quantitative phase allowed the development of the 'Judo Organizational Factors Influencing the International Sporting Success' model. Future research can deepen the understanding of the relationship among organizational factors or carrying out procedures involving other sports. Future research can deepen the understanding of the relationship among organizational factors or carrying out procedures involving other sports. PERFORMANCE MANAGEMENT: A SYSTEMATIC REVIEW OF PROCESSES IN ELITE SPORT AND OTHER HIGH PERFORMANCE DOMAINS

MOLAN, C.1, KELLY, S.1, ARNOLD, R.2, MATTHEWS, J.1

1: University College Dublin (Ireland), 2: University of Bath (UK)

Introduction The desire to achieve success within elite sport has seen various sports look beyond the application of sport sciences and coaching to management-led processes. Performance management has been identified as a process that impacts how athletes, coaches and support staff contribute to elite sport success. Due to the limited research in this area within elite sport and the potential transferability of processes from other settings, there is considerable merit in examining how performance is managed across alternative high performance domains, where individuals or teams must also work under pressure to deliver high standards of performance, e.g. military, surgical medicine and performing arts. The aim of this study was to conduct a systematic review of performance management within elite sport and other high performance domains. Methods Electronic database keyword searches and reference tracing were conducted to identify published, English language, peer reviewed articles with original empirical evidence. Further eligibility criteria related to the type of performance management process and performance domain were applied. Title, abstract, and full text screening was undertaken by two reviewers, and inter-rater reliability statistics were calculated. Following data extraction, thematic synthesis enabled the organisation of key performance management factors into 'descriptive themes'; and the development of higher level 'analytical themes'. Results A total of 17 studies from a possible 12,196 were included in the review. Five analytical themes (and 15 descriptive themes) representing factors associated with effective performance management in high performance domains emerged: collaboration, execute and review performance, leadership, manage the performance environment, and recruitment and retention of staff. Research design and sample characteristics for each study were also reported. Discussion This review details prominent features of performance management that are required to perform consistently at high levels in intensely pressurised environments. These identified factors range across person, operational and system levels and also highlight how factors from alternative high performance domains could be harnessed to enhance the performance management process within elite sport organisations or high performance units. Further research is needed to develop our understanding of both the theoretical components and the operationalisation of performance management within elite sport. Contact: conor.molan@ucdconnect.ie

RELATIONSHIP BETWEEN RISK TAKING WITH EMOTIONAL INTELLIGENCE IN SPORT ENTERPRISES

AYAZI, M.

Faculty member, Department of Physical Education, Roudehen branch, Islamic Azad University, Tehran, Iran

Introduction Cherniss (2000) have defined "Emotional intelligence" is the basis for personal qualities such as realistic self-confidence, personal integrity, knowledge of personal strengths and weaknesses, resilience in times of change or adversity, self-motivation, perseverance. As opportunities represent possible gain, pursuit of that gain must be tempered by the potential of loss through miscalculated efforts. Risk taking is not only the willingness to take a chance on an opportunity; it is the ability of the organization to use calculated actions to mitigate the risk inherent in opportunity pursuit (Mullins, 2005). Methods The research is regarded as an application one and the methods of data collection is descriptive and correlation, the population on this study included managers of sport enterprise in Iran. Sample size is based on formula for calculating the morgan and kerji table sample size 75 females and men completed the questionnaire risk taking (becherer,2008) and emotional intelligence(bar-on,2000).the data was analyzed based on multiple regression with the

significance level set at 0.05. Results Linear Regression analysis was performed in order to study the first research hypothesis. Risk taking and Emotional intelligence were the independent variables while sport enterprise was the dependent one. The analysis indicated that only risk taking was correlated ($R=0.47$) and could significantly predict ($F=37.15$, $p<0.001$), though moderately, a proportion of variance (44.2%) of the dependent variable . Discussion Emotional intelligence leads to marketing effectiveness in sport enterprise. Emotional intelligence and risk taking were affected to sport enterprise. Emotional intelligence domains deemed to be effectively risk taking in this exploratory study, there is evidence to suggest that it is contributing to overall marketing effectiveness of sport enterprise. In general, there is a strong relationship between the emotional intelligence domain of a sport enterprise and risk taking effectiveness. Therefore It is hardly deniable, that a substantial dose of cognitive intelligence is needed by a manager, but it is evident from the foregoing discourse that how well leaders manage and direct the feelings of sport enterprise, in order to attain the desired goals, largely depends on the managers level of emotional intelligence and risk taking. PS-PL03 Crossing borders through technology

COMPUTER VISION IN SPORTS

MOESLUND, T.

Aalborg University

Sports is said to be the social glue of society. It allows people to interact irrespective of their social status or age. With the rise of the mass media, a significant quantity of resources has been channeled into sports in order to improve understanding, performance and presentation. Manual creation of data describing details in sports events is tiresome and in many cases simply unrealistic. Technology is therefore becoming more and more crucial as the demand for improved understanding, performance and presentation increases. Moreover, since the nature of most sports means that monitoring by the use of sensors or other devices fixed to players or equipment is generally not possible, a rich set of opportunities exist for the application of camera-based computer vision techniques to help the competitors, trainers and audience. This talk will first present a brief overview over where computer vision is currently being used in sports as well as possible future applications of computer vision in sports. Hereafter a more in depth presentation of different computer vision researches in sports will be presented. These will focus on using thermal cameras (in order to ensure privacy) to automatically provide answers to questions like: How many people are currently using a particular sports facility? What are they playing? The level of oxygen consumption?

INNOVATIVE TECHNOLOGY IN SPORT: ETHICAL PERSPECTIVES

LOLAND, S.

The Norwegian School of Sport Sciences

Technological innovations of many kinds change sport. Firstly, a systematic review is given of various kinds of innovative sport technology. A categorization is proposed ranging from development of traditional sport equipment to innovations in information technology and biotechnology. Secondly, actual and possible implications for sport of these innovations are discussed from an ethical point of view. On the one hand, innovative technology can increase experiential values such as joy and mastery, reduce health risk, and enhance performance. On the other hand, new technology can change the nature of sport in problematic ways, increase health risk, and challenge athletes' status as responsible moral agents. Particular attention will be given to challenges posed by innovative biotechnologies.

COMPARING FACTORS DETERMINING THE ENJOYMENT OF PHYSICAL ACTIVITY IN 10-12 YEAR-OLD CHILDREN IN JAPAN AND SOUTH KOREA

IKEDA, T.1, HAN, N.2, CHOI, T.2, AOYAGI, O.3

1 Fukuoka Prefectural University, 2 Jeju National University, 3 Fukuoka University

Introduction Recently, Asian children have recorded poor results in relation to physical activity (PA) (Muller et al., 2013). Despite Japan and South Korea both being located in East Asia and having similar political and economic systems, it is still instructive to compare them in terms of issues relating to children's education and health. The purpose of this study was therefore to investigate and compare factors contributing to the enjoyment of PA in 10-12 year-old children in Japan and South Korea. Methods The research participants were 1,689 Japanese and Korean children aged from 10 to 12 years. Of these participants, 1,638 (96.98%) completed a questionnaire based on the "Scale on the Joy of Exercise" devised by Tokunaga & Hashimoto (1980). Factor analysis was applied in order to investigate the factors

determining PA enjoyment. Results Three factors pertaining to the enjoyment of PA were extracted: activity- and motor-characteristics (F1), self-improvement and human relations (F2), and watching and cheering (F3). The ANOVA for F1 showed a significant difference in relation to gender alone ($F[1, 1637] = 17.282, p < .001, B > G$). Similarly for F2, the effect of nationality was found to be significant ($F[1, 1637] = 17.627, p < .001, J > K$). By contrast, for F3, a significant interaction effect was detected ($F[1, 1637] = 8.618, p < .01$). The multiple comparison test combining nationality and gender therefore indicated a significant "nationality effect" in both of boys and girls ($t[824] = 2.890, p < .0125, JB > KB/t[810] = 7.639, p < .0125, JG > KG$). Discussion A tendency to enjoy PA was a common feature in boys in this age range irrespective of their nationality. On the other hand, cultural differences between Japan and South Korea were found with the exceptions of gender for (i) self-improvement and relationships with friends, and (ii) the watching or cheering of other activities. These results imply that it may be useful to provide PA while focusing on the amount of exercise and characteristics of the activities in order to improve the level of enjoyment among boys in both countries. For Japanese girls, it may be constructive to give them the chance to make friends through physical exercise or watching the activities of others. However, for Korean girls, as they did not exhibit enjoyment in relation to any factor, special consideration is required. These findings therefore revealed the nature and extent of some of the similarities and differences between Japanese and South Korean children in relation to PA. References Gao, Z. et al. (2014). THE DIFFERENCE BETWEEN THE MOVEMENT AND SELF-RECOGNITION OF CHILDREN IN THE STANDING LONG JUMP

YASUE, M., TATSUYA, A., TOMOHIRO, F., TAKESHI, U.

Hiroshima University

Introduction It is necessary for effective motor learning to recognize the ideal and actual movements correctly. However, few studies had revealed the degree of recognition for fundamental movements in children. The aim of this study was to investigate the level of the children for self-recognition in the standing long jump. In addition, we examined the relevance of the degree of self-recognition and the actual movement. Furthermore, we divided the self-recognition into two categories that were the recognition of the ideal movements and the recognition of their actual movements in this study. Methods As subjects, four elementary school boys and seven elementary school girls (fourth grade to sixth grade) were participated in this study. Subjects watched a video of the model for the standing long jump with its explanation, then performed as far as possible. Their movements were monitored and analyzed using three-dimensional motion analysis system (VENUS-3D, Tokyo). After the standing long jump, subjects evaluated their movements by using of visual analog scale. It was focused on the shoulder, knee, and landing angle in the standing long jump, and compared among the ideal, actual, and self-recognition of their movements. Results The results were summarized as follows; 1) children were able to correctly recognize the ideal movement in relation to the only landing angle. 2) Children were not able to correctly recognize the knee flexion angle at the takeoff phase and angle of shoulder joints at the air phase. 3) Children tended to have small images the ideal movement and perceive their own movements larger than actual. 4) There was no significant differences between images to the ideal movement and self-recognition of their movements. In other words, children could feel own movement in the same way as model. 5) There was no significant correlation between the degree of self-recognition and performance in present study. Discussion In conclusion, it might be difficult for children to recognize movements accurately regardless of their performance level. Therefore, there was a need for teaching to enhance not only the recognition of ideal movements, but also the recognition of own movements. Contact m156945@hiroshima-u.ac.jp

MIRROR-INDUCED VISUAL FEEDBACK IMPROVES INTER-MANUAL TRANSFER OF A SPORT SPECIFIC SKILL: COMPARISON BETWEEN DIFFERENT SKILL LEVELS

STEINBERG, F., PIXA, N.H., DOPPELMAYR, M.

Johannes Gutenberg-University Mainz

Introduction Mirror training therapy is a promising tool to facilitate the recovery process of motor skills after diseases such as stroke or hemiparesis. Recent studies have shown that the inter-manual transfer of fine motor skills is increased through mirror visual feedback compared to direct feedback conditions. This beneficial performance increase is thought to be effective not only in patients but also in healthy participants (review in Deconinck et al., 2014). This study tries to evaluate whether these augmented performance improvements by mirror-induced visual feedback could be used for learning a sport specific skill and whether effects are modulated by skill level. Methods 39 healthy and experienced Basketball and Handball players (18-38 yrs., 21 female) and 41 healthy novices with no Handball or Basketball experience (18-38 yrs., 21 female) participated in this study. They were equally assigned to a control group receiving direct feedback of the moving (right) hand and to a group who received mirror visual feedback. They were requested to perform a stationary basketball dribble task on a test setup typically used in the mirror training therapy, which was adapted to let participants dribble a basketball either with feedback through a mirror or direct feedback (adopted from Hamzei et al., 2012). The number of successful dribbling in a pre-test (left and right hand) was compared with the dribbling in a posttest (right and left hand) after completing four training days only with the right hand. Results ANOVAs with repeated measures revealed that experienced as well as novices improved dribbling performance of both hands from pre- to posttest measurements (all $p < 0.001; \eta^2 > 0.689$). Only for the experienced group a significant interaction showed that the left hand improvements of the mirror group was more pronounced than for the control group ($F[1,37] = 16.21; p < 0.001; \eta^2 = 0.305$). Discussion Inter-manual motor learning transfer from right to left hand can be improved by mirror visual feedback in a sport specific task. However, this effect cannot be generalized to motor learning per se since it appears to be modulated by individuals' skill level. References Deconinck, F. J., Smorenburg, A. THE INFLUENCE OF THROWING DEVELOPMENT ON LEARNING VOLLEYBALL OVERHAND SERVE

CHANG, C.Y., LIU, Y.T.

National Chengchi University, National Taiwan Normal University

Introduction The primary techniques of volleyball serve were are "tossing the ball" and "swinging the arm to hit the ball". The skill of overhand throwing is similar to the movement of "swinging the arm to hit the ball". It is possible that the development of throwing acts as an

influential factor in performing the volleyball overhand serve. The purpose of this study was to explore the relation between the volleyball overhand serve and the throwing development for the elite and novice volleyball players. Methods Ten female advanced-level college volleyball players and ten female college students without any volleyball overhand service experience participated in the study. The experts were tested with 10 trials of the overhand serves and 10 trials of distance throws. The novices had additional 10 trials of throwing test followed by practicing volleyball overhand serve for 270 trials over 3 weeks prior to the final tests of 10 trials of distance throw and 10 trials of the overhand serves. All the test performances were filmed with a high-speed camera (300fps). The task outcomes, ball velocity, and movement forms of the throws and serves were compared between groups; throwing variables from the 2 tests of the novice group were also compared. In addition, the Pearson product correlation was used to examine the relations among all the variables within the group. Results The performances of throwing and serving for the experts were significantly better than novices, and the throwing distance also improved after practicing the overhand serves for the novices. The throwing distance, ball velocity of throws, and throwing forms of experts and novices showed significant positive correlations with one another. The service performances also had significant positive correlation with the throwing movement forms for novices. There was no correlation, however, for experts. Discussion The performance of the volleyball overhand serve had tight relation with the development of distance throw ability. This tight link was demonstrated not only by the superior performances of both tasks from the advanced volleyball players but also the improvement of the distance throw from the novices after extended practice of the volleyball overhand serves. The mutual influences between the throwing and overhand serves continue before the stable patterns of both skills have occurred after prolonged practices. The overarm throws ability that is developed in childhood (Roberton, 1977) is important not only for the specific throwing performance found in baseball and softball but also for the performances of similar sport skills such as volleyball overhead serves. PE teachers and volleyball coaches may consider using the distance throw as an auxiliary exercise for volleyball beginners when learning overhand serve. Reference Roberton MA. (1977). J Human Mov Studies, 3, 49-59.

REPRESENTATIONAL MOMENTUM IN ADOLESCENT DANCERS

CHEN, Y.H.1,2, BELLERI, R.1, CESARI, P.1

1. University of Verona, Italy; 2. National Chengchi University

Representational momentum (RM) refers to the tendency that observers remember the stopping point of an event as being further forward in the direction of movement than it is in reality (Freyd & Finke, 1984). Previous studies reported that experts show a stronger RM effect than novices when viewing their domain-specific actions (Blättler et al., 2010; 2011). In this study, we investigated whether the RM effect could be also observed in adolescent ballet dancers when viewing a highly dynamic dance jump (i.e., grand jeté jump) that was divided into the ascending, flying and descending phases for showing different levels of movement momentum. Female adolescent dancers ($n = 22$; mean age = 14.9 years; with 9.8 years of classical ballet training) and age-matched non-dancers as controls ($n = 19$; mean age = 14.4 years) were recruited. In each trial, participants were first presented with three frozen-action photos of a dancer model performing a grand jeté jump. Then, they had to decide whether a fourth photo that showed the jump with different shift sizes (either moving forward or backward or no movement) was the same as the third photo or not. The overall pattern of results showed that memory for the stopping point of the jump was biased in the direction of movement, particularly for the descending and flying phases. The tendency found in the descending phase could be considered as a RM effect because the movement momentum in this phase was great due to gravity. Whereas the tendency found in the flying phase might be due to task difficulty because in this phase the dancer model was moving mainly forward in the air and the movement momentum was hardly to be detected. Moreover, adolescent dancers showed a marginally stronger RM effect than controls in the descending phase, suggesting that expertise can enhance the internal representation of the observed action with greater movement momentum implied.

WHY DOES MUSCLE RELAXATION DIFFICULT DURING SPORTS?

KATO, K., KANOSUE, K.

Waseda University

Introduction Muscle relaxation is an important aspect to make a fine control of the body in sports as well as daily life. It has been suggested that volitional muscle relaxation from contraction is accomplished by an active process in the brain, and not just the end of contraction (Toma et al., 1999). Recently, we have observed that muscle relaxation in one limb induced decrease in EMG level of contraction in the ipsilateral another limb (Kato et al., 2014; 2015). However, the mechanism of remote effect during muscle relaxation has not been well understood. The objective of this study was to clarify how the relaxation of one muscle influences on corticospinal excitability (Exp.1) and short interval intracortical inhibition (SICI) (Exp.2) in other remote muscles by using single- and paired-pulse transcranial magnetic stimulation (TMS). Then, we further investigated the inhibitory mechanism by adjusting test pulse of paired-pulse TMS (Exp.3). Method Subjects were asked to voluntarily relax the right foot with either dorsiflexion (tibialis anterior; TA relaxation) or plantarflexion (soleus; SOL relaxation) in response to an auditory stimulus. Single- (Exp.1) and paired- (Exp.2) pulse TMS was delivered to the hand area of the left primary motor cortex at different time intervals before and after the onset of TA or SOL relaxation. Motor evoked potentials (MEPs) were recorded from the right extensor carpi radialis (ECR) and flexor carpi radialis (FCR). Based on the results of Exp. 2, in Exp. 3 inhibitory mechanisms were carefully investigated by adjusting the MEP amplitude of the test-pulse. Result In Exp.1, MEP amplitudes of ECR and FCR caused by single-pulse TMS temporarily decreased after TA and SOL relaxation onset, respectively, as compared with those of the resting control. Furthermore, short-interval intracortical inhibition (SICI) of ECR evaluated with paired-pulse TMS temporarily increased after TA relaxation onset in Exp.2 and 3. Discussion Our findings indicate that muscle relaxation of the dorsiflexor induced reduction of corticospinal excitability of the ipsilateral hand muscles. This is most likely caused by an increase in intracortical inhibition. During multilimb movement in sports, simultaneous usage of each muscle with appropriate degree of contraction or relaxation is needed for good performance. Although coaches often just say "Relax more for only this muscle" to the player, we all know it's difficult to do. The present results suggest that when we try to relax in one limb, the desired muscle contraction in other limb is, unfortunately, also suppressed. References Toma K et al., Activities of the primary and supplementary motor areas increase in preparation and execution of voluntary muscle relaxation: An event-related fMRI study. A MIXED-METHODS EXAMINATION OF PHYSICAL ACTIVITY, SEDENTARY TIME, AND THEIR ASSOCIATION WITH FRAILTY AMONGST ETHNICALLY DIVERSE MIGRANT WOMEN 60+ YEARS

CASTANEDA-GAMEROS, D.1, REDWOOD, S.2, THOMPSON, J.L.1

1: University of Birmingham. Sport, Exercise and Rehabilitation Sciences

Introduction: Physical activity (PA) and sedentary time (ST) are recognised as key modifiable behaviours to improve older adults' health by preventing diseases, reducing disability and improving well-being. However, their association with frailty is less clear. In addition, little is known about factors influencing PA and ST in older women from diverse ethnic, socio-economic, and migration backgrounds. Therefore, the aims of the study were to: 1) examine associations between frailty and objectively measured ST and PA in ethnically diverse migrant women 60+ years living in the UK; and 2) explore key factors influencing PA and ST behaviours in this group. **Methods:** Sixty first generation migrant women (Mean age \pm SD= 70.8 \pm 8.1) wore a GT3X accelerometer for 7 days to measure PA and ST. Frailty was defined using a modified version of the frailty phenotype. Group differences were assessed using independent t-tests. Associations between PA, ST and frailty were examined via logistic regression. Semi-structured interviews were conducted in a subsample (n=36) and analysed using an inductive thematic approach. **Results:** On average, participants spent 69% of their waking time engaged in ST. Only 15% met the weekly recommendations for moderate-to-vigorous PA (MVPA). Frail participants had significantly higher ST (565.1 \pm 92.4 min/d vs. 528.2 \pm 85.6 min/d, p=0.04) and lower MVPA (4.5 \pm 4.9 min/d vs. 19.6 \pm 18.9 min/d, p=0.03) than non-frail participants; time spent in low PA was similar in frail vs non-frail participants (236.47 \pm 68.7 min/d vs. 189.3 \pm 94.6 min/d, p=0.11). Logistic regressions indicated that higher ST (OR: 1.02, 95% CI: 0.98-1.03) and lower MVPA (OR: 0.82, 95% CI: 0.68-0.98) were independently associated with frailty. Qualitative analyses indicated that maintaining independence and social support were the two key factors in promoting the uptake and maintenance of PA. Pain and risk of injury were the two most commonly reported barriers to achieving PA recommendations. **Conclusions:** Both frail and non-frail participants were highly sedentary with very few meeting MVPA recommendations. The associations between ST, MVPA and frailty suggest that increasing PA and decreasing ST may promote healthy ageing by decreasing the risk for frailty. Future PA strategies developed for this population should emphasise the importance of social support and maintaining independence in increasing the engagement of older ethnically diverse migrant women in PA. Recommendations should also provide detailed information on specific activities that are both safe and of sufficient intensity to optimise health and physical function.

AGE RELATED DIFFERENCES IN MUSCLE ACTIVATION AND EXPLOSIVE FORCE PRODUCTION IN OPEN AND CLOSED KINETIC CHAIN EXERCISES

PREVC, P., TOMAŽIN, K., STROJNIK, V.

University of Ljubljana, Faculty of sport

Introduction Decline in explosive strength and its functional significance in old age has been well acknowledged (Häkkinen and Häkkinen, 1991; Klass et al., 2008). The purpose of the study was to observe activation of the agonist - vastus lateralis (VL) - muscle and rate of force development in open (OKC) and closed (CKC) kinetic chain exercises in young (YP) and old (OP) participants. **Methods** Twenty YP (24 \pm 3 yr) and 15 OP (69 \pm 4 yr) subjects did explosive isometric unilateral knee extension - OKC and leg extension on leg press machine - CKC. EMG signal of VL in the first 100 ms after torque/force rise was expressed as relative EMG (normalized to maximal voluntary contraction, rEMG). Torque/force impulse in first 100 ms was analysed and expressed relative to maximal impulse (IMMAX). One-way ANOVA was used to test the differences between OP and YP, furthermore a two-way repeated measures ANOVA with one within (chain) and one between subjects factor (age group) was done. **Results** Old participants had compared to YP significantly lower rEMG in OKC (68% vs. 89%, p<0.01), but not in CKC (78% vs. 86%, p=0.353). A two way ANOVA revealed significant effect of age group \times chain interaction on rEMG of VL muscle (p<0.05). Age related differences regarding open and closed chain were confirmed also in mechanical parameters; there was significant effect of age group \times chain interaction on IMMAX (p<0.01), differences between OP and YP were significant only in OKC (~ 41 % lower in OP, p<0.01), meanwhile there were no differences in CKC (~ 9% lower in OP). **Discussion** Differences in VL activation and torque/force impulse between YP and OP were greater in the knee extension task than in the leg extension task. We concluded that age related loss of explosive strength was more affected in OKC compared to CKC, which was probably due to greater usage in daily activities. **References** Häkkinen K, Häkkinen A (1991). HEALTH BENEFITS OF CYCLE ERGOMETER TRAINING FOR OLDER ADULTS OVER 70: A REVIEW

BOUAZIZ, W.1,2, SCHMITT, E.1,2, GENY, B.2,3, KALTENBACH, G.1, VOGEL, T.1,2

1: CAPS /Strasbourg, France/, 2: DP /Strasbourg, France/, 3: FED /Strasbourg, France/

Introduction As the number of older adults continues to increase worldwide, more attention is being paid to geriatric health care needs, and successful ageing is becoming an important topic in the medical literature. A preventive approach to the care of older adults is thus a priority in our aging societies. The purpose of this study was to update evidence for the health benefits of cycle ergometer training (CET) for older adults over 70. **Methods** We searched online through eight electronic databases (PubMed Central, Medline, Scopus, Web of Science, SportDiscus, Embase, CINAHL Plus, and Cochrane library) up to September 2015 for original studies using the following keywords "exercise training, endurance training, or aerobic training and cycle ergometer, cycling or bicycle and health, health benefits and older adults, elderly, very old/elderly, aged, aging, oldest, old and over 70". Only studies that assess the health benefits of CET among older adults over 70 were included. **Results** Among the 4080 studies examined, twenty-five studies met the inclusion criteria. These studies reported that CET has a positive impact on cardiovascular function through an improvement in cardiorespiratory fitness, blood pressure values and endurance parameters. Specifically, it helps control metabolic outcomes through an improvement in body composition, metabolic and endocrine disorders. CET also improves functional reserve capacity mainly by increasing muscle strength, with conflicting results concerning the physical performance. Finally, one study suggests that CET may improve also the cognitive performance in older adults over 70. **Discussion** The main findings of this current review highlighted the effectiveness of CET as a major component of endur-

ance training program among older patients. The possible reasons of these positive findings can be explained by the suitable form of CET for promoting overall physical health among older adults over 70, and particularly because it is relatively easy and safe and causes no related injuries compared to walking on a treadmill. According to the current review, clinicians can now formulate actions to enable older adults over 70 to profit from the health benefits of CET. This will reinforce the current public health efforts to improve the health of this frail older population, and to help them to continue pursuing their daily activities independently. EFFECTS OF SQUARE-STEPPING EXERCISE WITH MUSIC ON COGNITIVE FUNCTION IN HEALTHY OLDER ADULTS

SHIMURA, Y.1, NAKAGAICHI, M.2, SHIGEMATSU, R.3, OKURA, T.4, KOMORI, Y.1, TANAKA, K.4

1: Osaka International University (Osaka, Japan), 2: Nagasaki University (Nagasaki, Japan), 3: Mie University (Mie, Japan), 4: University of Tsukuba (Ibaraki, Japan)

Introduction: Older adults generally have reduced functional fitness, including muscle strength, endurance and balance than young adults. Moreover, they have less cognitive function. Therefore, it is very important to improve not only physical fitness but also cognitive function for vitality aging in older adults. Some studies suggest that square-stepping exercise (SSE) could be an effective means to improve cognitive function (Abe et al., 2015). Furthermore, exercise with music program has been associated with enhanced cognitive function (Emery et al., 2003). The purpose of this study was to investigate the intervention effects of SSE with music on cognitive function in healthy older adults. **Methods:** Participants were twenty-four healthy older adults. Twelve participants performed SSE with music program for 90 min, 1 day a week, for 12 weeks (M-SSE group; 72.5 ± 6.3 years). We adopted familiar music for Japanese older adults in M-SSE group. On the other hand, the remaining participants performed normal SSE program without music for 90 min, 1 day a week, for 12 weeks (N-SSE group; 71.6 ± 3.9 years). SSE was performed using a thin-felt mat that was partitioned into 40 squares (Shigematsu et al., 2006). Cognitive function (Five-Cog. Test; Yatomi et al., 2005) was measured 2 times (first day session and 3 months after the initial session) in all the participants. **Results:** M-SSE group showed significant improvement in performance on the position judgment task (pre: 52.1 ± 14.6 , post: 56.8 ± 16.4 , $P < 0.01$) and animal name imagination task (pre: 49.9 ± 1.0 , post: 55.3 ± 10.4 , $P < 0.05$). On the other hand, N-SSE group showed significant improvement in performance on the word memory task (pre: 59.8 ± 8.2 , post: 68.5 ± 10.2 , $P < 0.01$), Clock drawing task (pre: 46.8 ± 9.0 , post: 52.1 ± 4.4 , $P < 0.05$), and animal name imagination task (pre: 53.8 ± 10.8 , post: 61.1 ± 10.2 , $P < 0.01$). **Discussion:** This study suggests that SSE with music has more beneficial effects on attentional capacity and verbal fluency than normal SSE. It could be a reason that the participants have to be conscious of both stepping to the rhythm and stepping into the correct position during SSE with music. However, it has smaller effects than normal SSE on episodic memory and visual-spatial ability. **References:** Abe et al. (2015) Jpn J Gerontol. 52, 162-169. Emery et al. THE EFFECTS OF RESISTANCE, AEROBIC AND COMBINED TRAINING AND DRETRAINING ON BLOOD APOLIPOPROTEINS, LIPOPROTEIN α AND HS C-REACTIVE PROTEIN PROFILE IN CORONARY ARTERY DISEASED PATIENTS

PANAYIOTOU, G.1, VOLAKLIS, A.K.2, TOKMAKIDIS, P.S.2, DOUDA, E.2, TOUBEKIS, G.A.3, SMILIOS, I.2, MAKRIS, A.1, JAMUR-TAS, A.4

1: European University Cyprus (Cyprus), 2: Democritus University of Thrace (Greece), 3: National and Kapodistrian University of Athens (Greece), 4: University of Thessaly (Greece)

Introduction Every year an increasing number of individuals are diagnosed suffering from coronary artery disease while this disease is the number one cause of death worldwide. For combating the risk factors of coronary artery disease many investigations recommended as important factors the exercise training and the avoidance of sedentary life style (Tully et al., 2005; Booth et al., 2012). Methods 60 males with coronary artery heart disease were randomly assigned into the resistance exercise group ($n=11$), the aerobic exercise group ($n=18$), the combine exercise group ($n=16$) and the control group ($n=15$). The three exercise groups carried out 8 months of resistance, aerobic or combine training consisting of 3 exercise sessions per week. Before the beginning of the study, after 4 and 8 months of training and after 1, 2 and 3 months of detraining blood apolipoproteins, lipoprotein (α) and hs C-reactive protein profile were determined. **Results** At the end of the training period, aerobic and combined training induced increases by 7.4% and 6.8% in apolipoprotein-A1 and decreases by -5.8% and -6.4% apolipoprotein-B, respectively. Resistance training did not cause any alterations in apolipoproteins. For hs C-reactive protein, a significant interaction between group \times time and a main effect of time was found. More specifically, after the training period, resistance, aerobic and combined exercise decreased hs C-reactive protein by -13.4%, -15.7% and -17.9%, respectively. During the detraining period, apolipoproteins, lipoprotein (α) and hs C-reactive protein were gradually returned to baseline values. **Discussion** The purpose of the present investigation was to compare the effects of three types of chronic exercise on blood apolipoproteins, lipoprotein (α) and hs C-reactive protein in aged patients suffering from cardiac artery disease. It was found that 8 months of aerobic or combined exercise caused significant elevations in apo-A1 and decreased apo-B levels whereas no changes were observed after resistance exercise. Lp(α) was not altered after exercise at any group. The biological role of apo-A1 is to protect the wall arteries while of apo-B is to promote arteriosclerosis, thus exercise modes that induced increases in apo-A1 and decreases in apo-B are considered to be very important for individuals suffering from heart diseases. hs-CRP levels were decreased after the three types of exercise. This observation is of importance since hs-CRP is a sensitive inflammatory marker that has been associated with CAD (Ridker et. al 2003). **References** Tully MA., Cupples ME., Chan WS., McGlade K., Young IS. DEVELOPMENT OF STEP WALKING EXERCISE PROGRAM USING NATURAL USER INTERFACE AND THE MICROSOFT KINECT TO PREVENT DEMENTIA: A PRELIMINARY STUDY

KANG, S.

Sangmyung University

Introduction Walking is a complex process involving motor skills, cognition, and perception, as well as a method to evaluate the onset of functional capacity decline (Makizako et al., 2015). Walking speed is known to be a reliable predictor of cognitive function and dementia, and difficulty walking while performing dual tasks is associated with cognitive impairment (Doi et al., 2014). **Methods** An exercise game aimed at dementia prevention in the elderly population will be developed, including the walking step exercise program contents, a mat

for lower limb movement detection, and a 3D camera. A natural user interface will inform users' movement using sound, vibration, and lights from the mat. The Microsoft KINECT TM will be used to develop a computer game exercise with several components: Active Walking (P1), Balance Walking (P2), Dual Task Walking (P3), and Visual Perception Walking (P4). Each program has three levels with five steps each. P1 is designed to promote caloric consumption via aerobic exercise. Lower limb muscular strength, balance, and posture control are emphasized for P2, while upper limb movements and walking combined for P3. Visual information for complex walking patterns is provided for P4. Results Feasibility and level of difficulty of walking exercise were screened and evaluated by professional instructors. They stated that this "Integrated interactive Exergame system" can be utilized to promote exercise and to address health problems in the elderly. Discussion Safety, motivation level, exercise frequency, and volume level necessary to prevent a decline in cognitive function need to be evaluated in a future intervention study. Also, this step walking exergame will enhance physical activity in the aging population. PHYSICAL FITNESS AND SELF PERCEPTION OF AGED POPULATION WITH DIFFERENT LIFE STYLE

REINALES, A.1, BEZERRA, P.2, MARTINS, J.1

1-University of Beira Interior 2-Instituto Politécnico de Viana do Castelo

Introduction Older adults should do at least 150 minutes of moderate-intensity aerobic physical activity (WHO,2011) Short-time training programs without any strength component can have moderate impact on functional capacity and self-perception of quality of life (Araújo & Araújo,2002). This study aims to clarify the relationship between the amount of weekly physical activity and physical fitness in older adults. Methods The sample consisted of 27 elderly voluntary patients (age 70.4 ± 3.7 years old), height 155 ± 59 cm, weight 68.9 ± 9.7 kg, BMI 28.5 ± 3.0) 92.6% women, 7.4% men. They were divided into 2 groups according to their weekly physical activity attendance: Group A trained one day a week and Group B two times a week. Physical fitness was assessed by Handgrip, 30-Second Chair, 6 Minute Walk, 8 Foot Up-and-Go, Back Scratch, Chair Sit-and- Reach tests; and two dimensions of the SF-36 questionnaire (Physical Functioning and Role Physical) were also assessed. Data has been analyzed using ANOVA One-Way to determine the differences between groups in the study variables. The statistical significance was set at $p < 0.05$. The study was done according to the Declaration of Helsinki. Results No significant differences were found between groups in physical fitness tests, but 8 Foot UP-and-Go test where Group B showed better scores than group A ($F(1,26)=6.2$; $p=.020$) The outcomes regarding to self-perception of health condition did not show any significant difference in the analyzed dimensions. Discussion The increase in training attendance seem not to have improved neither the physical fitness nor the self-perception of health. Findings report positive influence only on the agility test. The absence of significant differences between groups in the remaining variables may be influenced by the number of subjects; the type of exercises that were mainly focused on the cardio respiratory capacity, and not including muscle strength and flexibility. Further studies, including muscle strength intervention, and more robust samples are needed in order to maximize the impact of regular physical activity in elderly populations. References Araújo, D. ACTIGRAPHY-BASED SLEEP BEHAVIOR AND HIGH INTENSITY INTERVAL TRAINING : THE CHRONOTYPE EFFECT

GALASSO, L., VITALE, J.A., BONATO, M., LA TORRE, A., CARANDENTE, F.

University of Milan

INTRODUCTION Physical activity can improve sleep quality through numerous mechanisms by creating a state of general well-being. It is difficult to understand exactly how exercise impacts on sleep and vice versa: different volumes, intensities and types of physical activity could have some positive or negative effects on sleep and sleep loss or restriction could influence both physical and cognitive performances (Souissi et al., 2008). It is largely demonstrated that M-types go to bed and wake up earlier than E-types and that E-types use to sleep less during the working days but more during the weekends (Vitale et al., 2015). The aim of this study was to evaluate the effects of sleep behavior following the 4x4 min of high-intensity interval training (HIIT) proposed by Helgerud (Helgerud et al., 2001), performed by subjects at 08:00 pm, also taking into account the influence of the chronotype variable. METHODS 15 male subjects (mean age: 20 ± 2), soccer players, enrolled in the School of Exercise Science, University of Milan, at baseline filled in the Horne-Ostberg Morningness-Eveningness Questionnaire (MEQ) for the assessment of chronotype (Horne & Ostberg, 1976). An actigraph monitoring was performed for one week to detect nocturnal sleep PRE-HIIT, and POST-HIIT taking into account the following actigraphy-based sleep parameters: Actual Sleep % (AS), Sleep Efficiency % (SE), Immobile Time % (IT) and Movement Fragmentation Index % (MFI). We compared sleep behavior from PRE to POST conditions between chronotypes. RESULTS 9 soccer players resulted E-types while 6 resulted M-types. E-types and M-types did not present any significant differences for sleep behavior from PRE to POST condition, nevertheless M-types showed a trend to worsen their sleep in the POST condition with a decrease in SE and an increase in MFI. DISCUSSION Our results suggest that HIIT performed at 08:00 pm did not affect the sleep behavior in E-types while M-types, who are more active in the first part of the day, showed a strong trend to worse their sleep quality therefore it seems that they are disadvantaged when performing a training task in the evening. VOLTA DA UNICAMP: A ROAD RACE DROVE BY EDUCATIONAL ACTIVITIES

SALGADO, J.V.V., RUSSOMANNO, T.G., ANDRIES, O.J.

Faculdade de Educação Física - Universidade Estadual de Campinas

Introduction Road races have become the most popular sporting event in Brazil and all around the world, and this fast growing can be considered an important social phenomenon. The road race 'Volta da Unicamp' is an annual event in which the participant can choose between running 5 or 10 km or walking 5 km. The aim of this project was to integrate the concept of road race to the visions of the univer-

sity, integrating different areas of knowledge, contributing to the student's process of teaching and learning, producing knowledge and promoting healthy and - oriented physical activity Methods During the road race were done informative lectures; monitored training, route recognition and orientation about road races strategy. Training and health profile diagnosis of the participants were performed through optional survey at moment of the registration. Analysis of hydration was done before and after the race for a sample of participants; general health evaluation and guidance of the athletes; sensory analysis of isotonic drink before and after the race; measurement of the event impact in the environment through the emission of CO₂ and compensation by planting trees; and gathering, recycling all the garbage produced at the event. Results The road race was theme of papers in three scientific conferences and it was used as a laboratory to data acquisition to 4 PhD theses, to 3 final papers to undergraduate students and to 3 scientific initiation projects. Beyond the immediate results of evaluations, in order to guidance and remedy the most frequent questions from participants were made free lectures about: sports nutrition, training, health and hydration, special populations, biochemical markers, performance and technology etc. It was still created a permanent official website to the event with specific information writing by professionals. Discussion The 'Volta da Unicamp' promotes and encourages physical activity, produces and disseminates knowledge, contributes to sports professionals by creating a basis of study and formation to students and, above all, offers to athletes and general public information's that may help them to know their own body, creates a new modality to the health and performance perspective and promotes social and civic action. EXPRESSION OF ANGIOGENESIS- AND INFLAMMATION-RELATED FACTORS AFTER EXERCISE-INDUCED MUSCLE DAMAGE IN HUMANS

TRYFONOS, A.I., PHILIPPOU, A.I., MARIDAKI, M.2, KOUTSILIERIS, M.1

National and Kapodistrian University of Athens

Introduction: Multiple molecular and cellular processes are rapidly activated following skeletal muscle damage to restore normal muscle structure and function. The remodelling processes may involve revascularization [1] and an inflammatory response, which can activate angiogenic pathways in the damaged tissue before its resolution and the completion of muscle repair or regeneration [2]. Nevertheless, less is known about the expression profile of angiogenesis and inflammation-related factors following eccentric exercise-induced muscle damage [3]. The aim of this study was to examine the expression responses of genes associated with angiogenesis and inflammation in human skeletal muscle after eccentric exercise. **Methods:** Ten healthy men (25 ± 5 yr, 180 ± 5 cm, 77 ± 8 kg) performed 50 maximal eccentric muscle actions using the knee extensor muscles on an isokinetic dynamometer. Muscle biopsy samples were collected from the vastus lateralis before and 6h, 48h and 120h post-exercise. Real Time-PCR was used to examine changes in the mRNA expression of the inflammation and angiogenesis-related factors: VEGF, VEGFR-2, HIF-1α, Ang-2, Ang-1, Tie-2, TNF-α, IL-6, IL-8 and MMP-9. ANOVA was used for statistics. **Results:** Muscle damage resulted in increased mRNA levels of some of the factors examined but with a differential time-expression profile. Specifically, TNF-α expression increased 6h and 48h post exercise ($p < 0.05$), while IL-8 expression increased and remained elevated throughout the experimental period ($p < 0.01$). HIF-1α exhibited an early increase only at 6h after the competition of the exercise ($p < 0.05$). Both VEGFR-2 and Tie-2 increased only at 48 h post-exercise ($p < 0.05$). Ang-2 revealed an increase at 6h and 48h post exercise ($p < 0.05$), while IL-6, VEGF, MMP-9 and Ang-1 mRNA expression did not exhibit statistically significant changes throughout the experimental period ($p > 0.05$). **Discussion:** The post-exercise increased expression of angiogenesis and inflammation related factors may indicate the activation of these remodelling processes after muscle damaging exercise. The different time course of the transcriptional upregulation of those factors may imply their specific biological roles during the regeneration and adaptation processes following muscle damage. More studies are needed to further characterize the inflammatory and vascular remodelling responses of skeletal muscle to eccentric exercise in humans. **References:** 1.Jarvinen et al. Am. J. ENDURANCE EXERCISE TRAINING REGULATES MITOCHONDRIAL BIOGENESIS IN SKELETAL MUSCLE OF DIABETIC MICE

YEO, H.S.1, KIM, H.J.1

1: Korea national sport university (Seoul, Korea)

Introduction It is well established that mitochondrial biogenesis is an important factor for metabolic function. However, decreased mitochondrial biogenesis has been reported in skeletal muscle of diabetes (Ritov et al., 2005). Regular endurance exercise has significant benefits on overall health, including the prevention of obesity, cardiovascular disease, and diabetes (Gaziano et al., 2007). Therefore this study examined the role of endurance exercise training on mitochondrial biogenesis in type 2 diabetic mice. **Methods** Twelve db/db mice were divided into exercise training group ($n=6$) and control group ($n=6$). Mice in exercise training group ran on a rodent treadmill for 1 hour at 12m/min for 12 weeks (5d/w). Soleus (type I) and extensor digitorum longus (type II) muscles were obtained to compare the change of mitochondrial biogenesis response. AMPK, PGC-1α, NRF-1, mtTFA protein expressions were analyzed by western blotting. Results PGC-1α(116%), NRF-1(127%) and mtTFA(39%) protein expression in type I muscle were significantly higher than those in type II muscle ($p < .01$). Exercise training significantly increased the expression of phospho/total AMPK(51%, $p < .001$), PGC-1α(65%, $p = .008$), mtTFA(39%, $p = .027$) in type I muscle. However, only mtTFA(27%, $p = .048$) was significantly increased by exercise training in type II muscle. **Discussion** This study demonstrated that 12 week endurance training significantly increases mitochondrial biogenesis markers in diabetic mice. The higher expression of PGC-1α and down-regulated proteins (NRF-1, mtTFA) in type I than type II muscle of diabetic mice seems to be due to different mitochondrial content according to muscle fiber types. Furthermore, the exercise training contributed to increase phospho/total AMPK, PGC-1α expression only in type I muscle, whereas mtTFA protein was increased in both type I and type II muscles by the training. Taken together, these results suggest that long-term endurance training positively effects on mitochondrial biogenesis in skeletal muscles of diabetic mice and the effects would be differently associated with muscle fiber types. **References** Gaziano TA, Galea G, Reddy KS. MONITORING OF A FOOTBALL TEAM DURING A COMPETITION SEASON BY MEASURING SERUM MYOSIN ISOFORMS

CUSSÓ, R.1, CARMONA, G.2, CADEFAU, J.A.1,2, SOLANAS, J.L.4, REVUELTA, G.3, MAESTRO, A.3, GUERRERO, M.

1:University of Barcelona. 2:INEF; 3: RSCG. 4: Ambit.

Introduction We developed an ELISA methodology sandwich type to improve the medical diagnosis of the professional sports men muscle damage. The new technic was applied to obtain basal values of a reference population and to monitor a team players during a football season. Methods 49 reference volunteer and 27 male professional football players from the Sporting of Gijon Club participated in this study. In the case of players, blood was obtained at the pre-season and at different time-points along the season. In ELISA test monoclonal anti myosin fast and slow antibodies tapisson a polystyrene plate. The calibration curve was performed with purified pork myosin. To close the sandwich ELISA, the polyclonal rabbit antibody was added. Plates were incubated with an anti-anti rabbit antibody linked to peroxidase and TMB substrate for the luminescent reaction of the peroxidase. The absorbance was read at 450 nM wavelength. Results The calibration curve shows a very good linearity. The intra-assay coefficient of variation was assayed using three different samples low, medium and high values. CV is below 11% for Fast myosin and below 6% for Slow myosin. Linearity for Fast myosin was 80% and for the Slow myosin 90%. Comparing the results of the football team with reference population we observe that our players move below the normal average respect to Fast myosin and above the normal average respect to Slow myosin. In the competitive pre-season there is not increase in serum but at the beginning of season both types of fiber are damaged but not in the same magnitude, as the ratio indicated, due to the tactic and training conducted by the team. Discussion The new ELISA assay has greater speed, sensitivity and reproducibility that the Western Blot and shorten the result time from 48 to 4 hours, allows for processing 26 samples at the same time and it is more economic. Values for Fast myosin in the reference population shows no differences between sex and age. Significant differences were found of Slow myosin from older group (45-66) compared to younger (20-44). It may be caused by their lifestyle, which must be more sedentary at maturity, or loss of muscle into mature persons. Moreover, tracking myosin isoforms during a season of racing in a soccer team offers new insight into the state of the fast and slow fibers relating it to the possible significance of sarcomere damage that can occur during different phases of training and competition. PROTEOMIC PROFILE OF CALCANEAL TENDON IN AGING AND RESISTANCE TRAININGBARIN, F., DURIGAN, J., OLIVEIRA, K., MIGLIOLI, L., ALMEIDA, J., CARVALHO, M., DE ARAUJO, H., FRANCO, O., MARQUETI, R.
Universidade de Brasília (UnB)

INTRODUCTION The calcaneal tendon (CT) is the most commonly injured tendon in the human body (Maffulli 1999). Moreover, with advancing age, the amount of damage increases further (Chen, Yao et al. 2006). In this context, resistance training (RT) could be used to minimize such damages (Kjaer 2004). The aim of the present study was to obtain the identification, detailed protein cataloging and biochemical characterization based on the effects of the aging process and the RT in CT of rats. METHODS Twenty-four Rattus norvegicus albinos, ages 4 and 24 months, were used and further divided into four groups: young sedentary (YS), young trained (YT), old sedentary (OS) and old trained (OT). RT climbing protocol was performed on alternating days, three times per week for 12 weeks. Subsequently, the CTs were removed and analyzed by liquid chromatography tandem-mass spectrometry (LC-MS/MS). RESULTS The analysis by LC-MS/MS showed 142 distinct proteins, however, only 29 proteins met the inclusion criteria and were analyzed. Aging causes a reduction in the abundance of seven proteins related to extracellular matrix (ECM) organization and other biological regulations. However, RT promoted the positive regulation of seven proteins in YT and two in OT group, results in an adjustment of the ECM organization and the maintenance of healthy tendons. DISCUSSION This study contributes to a better understanding of beneficial effects of RT on the proteomic profile of the calcaneal tendon during aging. Our results demonstrated a down regulation of important proteins for tendon functionality and homeostasis during aging, as collagen alpha-2(II), collagen alpha-1(II), cartilage oligomeric matrix protein and serotransferrin, which might explain the clinically large number of lesions along with the decline of the biomechanical properties during senility. Moreover, changes in proteins related to ECM organization, biological regulation, stability of the ciliary architecture and metabolic/development/cellular processes functions, demonstrated the importance of RT as a strategy to reduce the deleterious effects inherent to biological aging. PREVENTIVE EFFECTS OF PHYSICAL TRAINING ON OXIDATIVE STRESS PARAMETERS AND NEUROTROPHIC AND INFLAMMATORY MEDIATORS DURING SARCOPENIA PROCESS IN ELDERLY MENPINHO, R.A., SBARDELOTTO, M.L., PEDROSO, G.S., TAVARES, F., FARIA, M., BRESCIANINI, S.M.S., EFTTING, O.S., THIRUPATHI, A., NESI, R.T., SILVEIRA, P.C.L.
Universidade do Extremo Sul Catarinense

INTRODUCTION Regular exercise can decrease the deleterious effects of the aging and limit the development and progression of chronic disease in elderly people. The aim of this study was to investigate the effects of different physical training programs on oxidative stress parameters, inflammatory and neurotrophic mediators in serum of elderly men. METHODS Fifty-five volunteers healthy men (60 to 80 years) were divided into four groups: control (Ctr, n=14), aerobic training in dry land (ATdl, n=12); combined training in dry land (CTdl, n=12); and combined training in water (CTw, n=17). The training protocols were performed for a total period of 8-wk, three times per week, 60 minutes per workout. Ten milliliter of blood were drawn 72 hours before (baseline) and 48 hours after the last training session. The serum was aliquoted and stored at -70 °C until biochemical assays of BDNF, IGF-1, MDA, carbonyl groups, total thiols, catalase, GPx, TRxR, GSH, IL-1 β , IL-6, IL-8 and IL-10. RESULTS An elevated level of BDNF was observed in ATdl group while IGF-1 level was increased in CTdl group. All training models were reduced oxidative damage in lipid and increased the activities of both TRxR and GPx as well as GSH level. However, the CTw group seems to be more effective in the antioxidant system. In addition, IL-6 and IL-8 levels were decreased significantly, but IL-6 was more susceptible to different types of physical training. DISCUSSION Changes in levels of neurotrophic and growth factors (Kalinkovich and Livshits, 2015), oxidative stress parameters and inflammatory mediators (Meng and Yu, 2010) have been observed during aging, and it can be linked with sarcopenia. In this sense, the physical exercise has been appointed as one of the

possible strategies to regulate the cellular redox state in the elderly subjects (de Gonzalo-Calvo et al., 2013). However, the type, intensity, frequency and duration of exercise are not yet fully established and seem to be decisive for this protective effect. Our results showed that the mechanisms of systemic adaptation induced by different models of training in dry land and water were distinct, where each type of exercise activates differently neurotrophic and growth factors as well as the regulation of cellular oxidative stress and inflammatory parameters. Taken together, the results show that the effects of training in elderly men are varied and exercise type-dependent manner. REFERENCE Kalinkovich A, Livshits G. Ageing Res Rev. 2015;22:58-71. EFFECT OF AEROBIC EXERCISE TRAINING ON NADPH OXIDASE ACTIVITY IN MUSCLE MICROVASCULAR ENDOTHELIAL FUNCTION IN AGED MEN

JEON, Y.N., YEO, H.S., RA, S.G., LIM, C.H., YANG, H.J., JANG, H.Y., KIM, C.K.

Korea National Sport University

Introduction Elevated oxidative stress is a prominent feature of vascular diseases, for which obese individuals are at increased risk (Thomas et al., 2003). NADPH oxidase has been shown to be a significant source of oxidative stress derived from vascular tissue (Griendling et al., 2000), and may be particularly relevant to the obese population. The present study was performed to investigate the exercise training effect on NADPH oxidase activity on microvascular endothelial function of skeletal muscle in control and obese aged men. Methods Five control and six obese aged men (>65 yrs) were participated in the study. All subjects performed an aerobic exercise training for 12 weeks (70% HRmax). Microdialysis experiments were conducted in the vastus lateralis muscle of all subjects. Samples were analyzed for H₂O₂ and nutritive blood flow. Results Significant difference in NADPH oxidase activity existed between lean and obese individuals, whereas no significant difference found in dialysate H₂O₂ concentration between groups before and after aerobic training ($P>.05$). However, it was higher in old obese men than old control by SOD containing APO perfusion ($P=.036$). Nutritive blood flow perfused perfused by ACh containing APO was significantly higher (decrease in o/i ratio) than only ACh perfusion in old obese group ($P<.05$). Discussion These findings confirmed that ROS mainly produced by NADPH oxidase as well as microvascular endothelial function would be improved by inhibiting NADPH oxidase in obese aged men. Additionally, ROS and nutritive blood flow did not altered in the aged men following aerobic exercise training. References Griendling KK, Sorescu D, UshCio-Fukai M. (2000). Circ Res, 86, 494-501. GENOME-WIDE ASSOCIATION STUDY OF ELITE RUSSIAN ENDURANCE ATHLETES

KHABIBOVA, S.

First Moscow State Medical University, Moscow, Russia

It is well recognized that humans vary in their ability to achieve success in endurance sports and their predisposition is based on genetic factors. The aim of the study was to identify single nucleotide polymorphisms (SNPs) associated with elite endurance performance (maximal oxygen consumption rate, VO_{2max}) in Russian endurance athletes using a genome-wide association study (GWAS) approach. VO_{2max} was measured in 71 elite endurance Russian athletes (41 males and 30 females). HumanOmni^{IL}-Quad BeadChips (Illumina Inc, USA) were used for genotyping of 1,140,419 SNPs. We found that 568 SNPs were associated with VO_{2max} in the combined cohort of endurance athletes (with $P<0.001$ adjusted for sex). Of those, two SNPs, namely SLC16A10 rs9400467 ($P=0.0002653$) and SLC38A1 rs10785611 ($P=0.00013$) are located in or near the genes expressions of which in the human skeletal muscle were previously reported to be linked with VO_{2max} (Su et al. 2015). These genes are involved in the regulation of energy metabolism in skeletal muscles (SLC16A10) and glutamine uptake (SLC38A1). Interestingly, the rs9400467 polymorphism is also associated ($P= 6,5*10^{-14}$) with tyrosine levels of human blood samples (Shin et al. 2014) and tyrosine ingestion improves aerobic performance. Our results suggest that at least SLC16A10 rs9400467 and SLC38A1 rs10785611 polymorphisms may predict human physical performance. References: Shin SY. et al. HYDRATION STATUS AND WATER INTAKE OF CYPRIOU ADOLESCENT STUDENT-ATHLETES LIVING IN A WARM ENVIRONMENT

APHAMIS, G., ANDREOU, E., STAVRINOUE, P., ALA EDIN, D., BAZALO, I., GIANNAKI, C.D.

University of Nicosia

Introduction Dehydration can decrease exercise capacity, self-rating of alertness and ability to concentrate (Shirreffs et al., 2004), which can affect school work. As chronic dehydration was observed in young athletes living in a cool environment (Phillips et al., 2014), the aim of this study was to assess the hydration status and water intake of Cypriot adolescent student-athletes living in a warm environment, during school hours. Methods 141 student-athletes (15–17y; boys n=102) participated in this study. All data were collected on arrival at school (7.30am) and at 1.30pm (temperature $\geq 28^{\circ}\text{C}$). Hydration was assessed via urine specific gravity (SG): Euhydration SG ≤ 1.020 , slight dehydration SG 1.021–1.029, serious dehydration SG ≥ 1.030 . Participants completed a subjective feelings questionnaire on thirst, fatigue, concentration and alertness (Shirreffs et al., 2004), and recorded all food and fluid intake (from waking until leaving school) for water intake estimation (DietPlan6 software). Results On arrival at school, 13 students were euhydrated (group 1), 67 students were slightly dehydrated (group 2), and 50 students were seriously dehydrated (group 3). Hydration status of the participants did not change over time. Group 3 had less water intake before coming to school (209 ± 108 ml) than the other groups (group 1: 234 ± 114 ml; group 2: 274 ± 149 ml; $P = 0.000$). Total day water intake was similar between groups (group 1: 670 ± 388 ml; group 2: 875 ± 489 ml; group 3: 751 ± 477 ml; $P = 0.126$). Group 3 felt less alert than the other students ($P = 0.029$) in the morning. Alertness decreased further for group 3 by the

end of the school day ($P = 0.009$). Thirst was similar between groups. Increased SG correlated with fatigue ($P = 0.006$), which in turn correlated with decreased concentration ($P = 0.000$) and alertness ($P = 0.000$). Discussion 90% of the participants were dehydrated for the entire school day. Seriously dehydrated students did not feel thirstier and had similar water intake with their better hydrated peers. Dehydration was related with increased sense of fatigue and indirectly with decreased concentration and alertness. As student athletes are expected to perform well both academically and in competitive sport, dehydration during school hours should be prevented and managed. EFFECTS OF COLOSTRUM SERUM ADMINISTRATION ON SEROTONIN SYNTHESIS IN THE BRAIN DURING EXHAUSTIVE EXERCISE IN RATS

SEO, J.H.1, LEE, K.J.1, OAK, J.S.2, YOO, I.H.2, KANG, S.J.3

1.Baekseok University, 2.Dankook University, 3.SangMyung University

INTRODUCTION It is well known that over-expression of serotonin (5-hydroxytryptamine, 5-HT) in the brain induced by exhaustive exercise disturbs exercise performance. Tryptophan hydroxylase (TPH) is the rate-limiting enzyme for serotonin biosynthesis. This study was conducted to determine the effects of colostrum serum on serotonin synthesis in the brain during exhaustive exercise in rats. **METHODS** In this study, animals were randomly divided into five groups: control group, exercise group, 50 mg/kg colostrum treatment and exercise group, 100 mg/kg colostrum treatment and exercise group and 200 mg/kg colostrum treatment and exercise group ($n = 10$ in each group). The rats in the exercise groups performed treadmill running once a day for 7 days. On the 7th day of the experiment the time to exhaustion during treadmill running was determined for the exercise groups. **RESULTS** In the present results, 5-HT-positive cell, TPH-positive cell, 5-HTT, 5-HT1A expression in the dorsal raphe nucleus were significantly increased by exhaustive treadmill running. Treatment with colostrum led to a significant increase in the time to exhaustion in response to exhaustive running on a treadmill with the significant decrease in 5-HT synthesis, TPH expression, 5-HTT, 5-HT1A expression in the DRN of rats. **DISCUSSION** The present study demonstrated that colostrum serum increased endurance exercise performance through inhibition on serotonin production in the brain.

INTAKE OF MACRO-AND MICRONUTRIENTS AMONG HUNGARIAN SOCCER PLAYERS

DOBAK, Z., BIRO, M., NYAKAS, C.

1. University of Physical Education, 2.Eszterhazy Karoly University of Applied Sciences, Eger, Hungary

INTRODUCTION In sport nutrition one of the general concepts is that the varied natural diet spontaneously consumed may cover the needs. However the nutritional requirement of different sport types, the actual changes in body composition, the nutritional defects especially in micronutrients may require to use of specified nutrition. In competitive sport, hydration and supplements have also a distinguished role for maximal performance. **OBJECTIVE** The aim was to examine professional Hungarian soccer players' macro- and micronutrients intake, eating habits, body composition in general and according to the different training cycles (training-, rest- and match days). Based on that personal dietary advises were also aimed to formulate. **INVESTIGATION AND METHODS** Twenty seven elite athletes aged between 18-30 years were included from a single soccer team. The participation was anonym and voluntary. Dietary analysis software (NutriComp®) recorded the athletes' three-day dietary diary in relation to their exercise cycles (training, rest and competition days). We performed body composition measurement with InBody device 230®. The data analysis was performed using SPSS software package including paired t-test. **RESULTS** On the training day the average energy intake was 38.5 kcal/kg/day, at rest day 36.2 kcal/kg/day, and at match day it amounted to 40.3 kcal/kg/day. The evaluation of averaged three-day dietary diary revealed that energy intake remained significantly ($p<0.05$) below the desired value (adjusted to the present quantified sporting activities it was 50 kcal/kg/day). The vitamin D, iron, calcium intake was below the recommended RDA values defined for the adult population (calcium 741 mg/day, iron 13.7 mg/day, vitamin D 3.5 mg/day). On average, soccer players consumed variable kinds of supplements daily which did not include vitamin D or calcium products. On training day one-fifth of the soccer player energy intake came from protein, and the rest came from fat and carbohydrates in about the same ratio (42% carbohydrates, 37% fat, 20% protein intake, 1% other). There was no significant difference in carbohydrates consumption between training and match days. High fat diet was typical among the Hungarian professional soccer players in each training cycle period. On match day the most attention was payed to increase protein intake on expense of fat intake. **SUMMARY** Appropriate energy intake is only possible with a well-balanced macronutrient consumption meeting the enhanced energy requirement. In our survey a negative energy balance characterized each training cycle. Defective food habits and incorrect diet throughout the training cycle may degrade performance. The micronutrient dis-balance especially attracts attention and call for the importance of individual and targeted intervention regarding nutrition supplements. In addition, defining lifestyle factors disturbing or supporting nutrition would be also helpful for explanation.

A PALEOLITHIC HIKING INTERVENTION IMPROVES ACUTE BUT NOT CHRONIC CLINICAL MARKERS OF HEALTH IN ATHLETIC MALE ADULTS

KRUSCHE, T., PLATEN, P.

Ruhr-Universität Bochum

Department of Sports Medicine and Sports Nutrition, Faculty of Sport Science, Ruhr-Universität Bochum, Germany **Introduction** Imitation of Paleolithic lifestyle (PL) is associated with health-improving effects due to its relation to the human genome [1,2]. However, previous studies mainly describe the benefit of a Paleolithic diet (PD) or movement pattern (PM) for overweight or diabetic people with a higher cardiovascular risk. Aim of the study was to investigate the health-improving potential of a PL intervention for healthy athletic male adults. **Methods** A group of 12 healthy athletic young adults (age=22±2 y; BMI=23.4±2.0 kg/m²; VO2max=57.9±4.1 mL/min/kg) were exposed to the rural area of Lapland reproducing PM and PD for 10 days (d1-d10: daily hiking distance: 13.0±2.5 km, 1 day rest). Testing occurred before, during and after (d-6, d6, d+1) the intervention followed by a follow-up 3 months after the end of the intervention (d+9). Serum glucose (GLU), total cholesterol (CHO), high density lipoprotein cholesterol (HDL) and triglyceride (TG) were analysed. Also body mass (BM), fat mass (FM) and systolic blood pressure (SBP) were measured. **Results** We found a significant acute decrease of BM, FM, SBP, CHO, GLU and TG ($p<.05$) (BM: d-6=76.0±2.1, d6=74.0±1.9, d+1=73.1±1.9 kg; FM: d-6=12.5±0.4, d+1=11.1±0.4 %; SBP: d-6=124±11, d+1=113±8 mmHg; CHO: d-6=3.8±0.2, d6=3.4±0.2, d+1=3.6±0.2 mmol/L; GLU: d-6=5.1±0.1, d6=2.8±0.7, d+1=4.7±0.1 mmol/L; TG: d-6=0.8±0.1, d6=0.6±0.0, d+1=0.6±0.0 mmol/L, respectively). HDL increased on d+1 but remained unchanged during and after the intervention com-

pared to d-6 ($p>0.05$) (d-6=1.3±0.1, d6=1.2±0.1, d+1=1.5±0.1, d+91=1.4±0.1 mmol/L, respectively). BM increased and GLU decreased on d+91 compared to d-6 ($p<0.05$) (d+91: BM= 77.8±2.1 kg; GLU=3.7±0.2; mmol/L, respectively). FM, SBP, CHO and TG remained unchanged 3 months after the end of the intervention ($p>0.05$) (d+91: FM=12.7±0.5 %; SBP=123±10 mmHg; CHO=3.7±0.2 mmol/L; TG=0.8±0.1 mmol/L, respectively). Conclusion In conclusion, a 10-day PL intervention has an acute small beneficial effect on health related parameters like FM, SBP, GLU, TG in healthy physically active male adults. The intervention did not result in any effects on mean value of HDL. Furthermore the intervention does not enhance clinical markers of health 3 months after the end of the intervention. However, increase of BM 3 months after the intervention is not associated with increased FM. Compared to results of past studies we speculate about a reinforcing mechanism by the combination of PM and PD without evidence about the primary predictor [1]. Further research is needed in a randomized controlled setting. References [1] Frassetto et al. (2009). Eur J Clin Nutr, 63, 947-55. [2] O'Keefe et al. (2004). Mayo Clin Proc, 79, 101-8. MEAL FREQUENCY DOES NOT AFFECT BODY COMPOSITION CHANGE DURING WEIGHT GAIN PERIOD IN ATHLETES

HARA, A., TORII, S., TAGUCHI, M.

WASEDA University

Introduction Positive energy balance is important factor for weight gain in athletes. However, when the volume of one meal is large, the body increase their burden of digestion and absorption. Although it is recommended to increase the meal frequency in the position stand (La Bounty et al., 2011), the study has not been done on positive energy balance. The effect of meal frequency on body composition change during weight gain period for athletes is unknown. Therefore, the aim of this study is to examine the effect of meal frequency on body composition change during weight gain period. Methods Eight rowers (20.5±1.1years, body height: 169.8±2.9cm, body weight: 68.3±4.8kg) were participated in this study. The study was a randomized crossover design with two 8-wk dietary intervention. During the intervention, subjects overall consumed the same amount of energy and nutrients per day which makes athletes in positive energy balance with either regular meal frequency (3 meals/d; RFr) or high meal frequency (6 meals/d; HFr). A 5-wk washout period was placed between the trials. Body composition was measured by DXA and fasting blood samples were collected at pre- and post-intervention of each trial. The feeling of fullness was assessed by 100-mm visual analogue scales (VAS) before eating every meals. Results Training volumes of all the subjects during both intervention periods were similar. In the RFr trial, body weight (BW), skeletal muscle (SM) and adipose tissue (AT) increased by 2.92±1.91kg, 1.04±0.62kg and 1.65±1.30kg, respectively. In the HFr trial, BW, SM and AT increased by 3.14±1.42kg, 1.28±0.39 and 1.69±1.15kg, respectively. There were no significant differences in the increases of each measurements between trials. Subjective feeling of fullness vary in individuals. Insulin, HOMA-IR, cortisol, testosterone levels were not significantly different between trials. Discussion It was found that meal frequency does not affect body composition change during weight gain period, because the amount of energy and nutrients intake was absolutely identical. We hypothesized that body weight and fat mass are gained by RFr meal, as a reason for that, large amount of energy intake per meal induce increasing quantities of insulin secretion. However, there was no difference in insulin concentration in this study. Consequently, when the additional energy is equal, meal frequency may not effect on change in body composition in athletes. This is the first study to investigate the effect of meal frequency when athletes are under positive energy balance for weight gain. References La Bounty, P. M., Campbell, B. I., et al. (2011). J Int Soc Sports Nutr, 8:4 Contact mtaguchi@waseda.jp

THE INFLUENCE OF BUCHINGER'S FASTING ON ISOMETRIC RESISTANCE PERFORMANCE OF SPORTS STUDENTS

STALLMANN, C.1, OERTZEN-HAGEMANN, V.1, LIMMER, M.2, PLATEN, P.1

1 Ruhr-Universität Bochum, Department of Sports Medicine and Sports Nutrition, Germany 2 Deutsche Sporthochschule Köln, Institute of Outdoor Sports and Environmental Science, Germany

Buchinger fasting (BF) is associated with beneficial cardiovascular, metabolic, and psychological adaptations. Early fasting is characterized by a high rate of gluconeogenesis with the use of amino acids. Prolonged protein catabolism possibly causes a loss of muscle mass, making BF for athletes unfavourable. The aim of this study was to analyse if the increased protein degradation affects the resistance performance, hence if fasting should be avoided by athletes. 18 sports students (female: n=8, male: n=10, age: 24.5±1.6 y, height: 175.7±6.7 cm, body mass: 74.9±9.8 kg) underwent a BF with one relief day, five fasting days, and three build-up days. Subjects were tested before (Pre), while (W, on 5th fasting day), and after (Post, on 3rd build-up day) BF. While BF they did moderate physical activity as recommended by Buchinger without systematically training. Body composition was measured by bioelectrical impedance analysis (BIA) and Body Fat Caliper (BFC). Isometric manual strength was tested with a manual force measuring device and the isometric strength of leg extension with a force gauge on a force chair. Both were tested regarding to maximal strength and strength endurance. For the statistical analysis the best out of three maximal contractions was considered for maximal strength, the mean over ten maximal contractions of 6 sec with 15 sec break for strength endurance. Body weight was reduced (Pre: 74.9±9.8 kg; Post: 71.4±10.7 kg, p=0.000) as well as the body fat mass (BIA, Pre: 13.0±3.3 kg; Post: 11.5±2.4 kg, p=0.007). The muscle mass showed no difference between before and after BF (BFC, Pre: 27.3±8.0; Post: 26.1±6.4 kg). BF had no influence on the maximal manual strength (Pre: 50.0±9.9 kg; W: 47.4±10.8 kg; Post: 47.0±10.0 kg), and the maximal strength of leg extension (Pre: 58.4±13.9 kg; W: 56.9±14.6 kg; Post: 58.1±13.7 kg). The strength endurance of manual strength (Pre: 38.9±7.6 kg; W: 37.7±8.6 kg; Post: 38.1±7.2 kg), and leg extension strength (Pre: 51.9±12.4 kg; W: 52.7±13.2 kg; Post: 53.6±13.0 kg) remained also unaffected. Short-term fasting had no effect on the isometric maximal strength and strength endurance of sports students. The loss of body mass along with no reduction in muscle mass is not relevant for isometric strength performance. According to that, athletes could fast at pre-season preparations without expecting a loss of isometric strength. For further studies in this area a survey of long-term effects (e.g. retesting after two and four weeks) of fasting on resistance performance would be recommendable. In case of positive effects periodical fasting might be beneficial for athletes.

PARABEN ANALYSIS ON SPORT AND ENERGY DRINKS BY LC-MS-IT-TOF

ACAR CEVIK, U., LEVENT, S., ÖZKAY, Y., ÖZTÜRK, Y.

Anadolu University

Introduction Parabens have been employed for about a century as preservatives in foodstuff, cosmetics and pharmaceuticals, beverage and personal care products. In general, after they enter human body, PBs are partially hydrolyzed by esterases to p-hydroxy-benzoic acid or hydroxylated to produce glycine/glucuronide/sulfate conjugates. These conjugates possess increased water solubility relative to the free species, which facilitates their excretion. In vitro studies indicate that PBs induce the growth of MCF-7 human breast cancer cells

and influence the expression of estrogen dependent genes. In this respect and although parabens were generally considered harmless to human beings for a long time, several concerns have been raised over the past twenty years about parabens safety with emphasis given on their endocrine disrupting potential (Myridakis et al., 2015; Papadopoulos et al., 2016; Patel et al., 2016). Sport and energy drinks are often used in the various areas of competitions by sportsman. Although there is description about ingredient of these drinks there is no data about preservative compounds such as parabens. Thus in this study some commercially available drinks are analysed whether they include parabens or not. Methods The sport drinks were analysed in a Shimadzu LC-MS IT-TOF system (Shimadzu, Tokyo, Japan) instrument. Mobile phase was used as solvent A, acetonitrile (95%); solvent B, water (5%) at a flow rate of 0.15 ml/min and a sample injection volume of 2 µl. Relative mass of the observed peaks in chromatograms were checked in the MS spectrums and the mass values that were in agreement with the calculated Mass of any paraben were determined. Results Eight different samples were analysed in the present study. In some of them some parabens were detected. However, none of the determined parabens were out of suggested limits. Discussion LC-MS IT-TOF is very sensitive and rarely used system in analyses of the compound in very large interest area. In the present study, by using this system a new method, which can be used for detection of parabens was developed and applied for sport and energy drinks. Some interesting data were obtained. CHANGES IN NEURAL ACTIVITY DUE TO POSTURE POSITION

ÖZCAN-ÇAKIR, C.E.1, ATIŞ, E.S.1, ÇOTUK, H.B.1, GÖKSEL-DURU, D.2, DURU, A.D.1

1: Marmara University, 2:İstanbul Arel University (İstanbul, Türkiye)

Introduction Posture position is one of the factors that effects human's mental activity (Rice et. al., 2013). In recent studies, neuronal synchronization was investigated during resting state using the elite sportsmen, amateur sportsmen and healthy control subjects (Del Percio et. al., 2011). This study aimed to analyze the electrophysiological differences that are observed between different positions during tasks that are involving working memory activities among the elite sportsmen and healthy controls with electroencephalogram. Methods Subjects (n=3) were asked to rest while sitting, standing up and lying positions (on a hang up bed in a supine position). 16 channel EEG electrodes have been placed on frontal, parietal, occipital, central and temporal areas. Backwards subtraction from a three digit number by seven was used as a paradigm to increase the mental workload. Applying this paradigm requires increased working memory. For each condition, EEG data has been recorded for 3 minutes. After this preprocessing step, EEG data has been epoched using 1 sec windows and the Fourier spectrum has been obtained for each corresponding window. Finally frequency outputs were averaged over epochs. Results In line with previous studies, it was observed that the parietal and occipital alpha band powers were decreased when the subjects open their eyes. During the eyes closed mental activity period, alpha band power was found to be lower than the eyes closed resting and higher than the eyes open resting period. When the subjects were in the standing upright position, similar results were obtained as in the sitting position tasks. Discussion According to previous studies, it was reported that in elite sportsmen, parietal and occipital alpha and delta band powers were found to increase more than the alpha and delta values of the control subjects (Babiloni et. al., 2010). Moreover, in elite athletes cortical activity was found to be greater than the controls while they were standing up on a force/balance platform (Del Percio et. al., 2009). Our results are also in agreement with the literature. Our research was limited with the number of subjects that participated in the experiments. Nevertheless, number of the subject are going to be increased. References Babiloni C, Marzano N, Lacarbona F, Infarinato F, Aschieri P, Buffo P, Cibelli G, Soricelli A, Eusebi F. (2010). EFFECTS OF PHYSICAL TRAINING ON ERYTHROCYTE TRACE ELEMENTS .

MAYNAR MARÍÑO, M.

University of Extremadura

INTRODUCTION One of the least studied physiological aspects of sports nutrition are the trace elements and their actions in athletes. Physical activity can change the concentration of minerals available in blood (plasma and serum), as well in urine. Therefore, the objectives of this work are to determine trace mineral concentrations in erythrocyte of subjects with different levels of physical training compared with a sedentary control group. METHOD So we've had a total of 76 subjects living in Cáceres (Spain) and separated into three groups: 22 belonging to the group of highly trained, 24 moderately trained group and 30 to the sedentary group that did not practice physical activity. We take, to all of them, blood samples at nine hours of fasting and after erythrocyte was separated with centrifugation. The samples, after being appropriately treated, were analyzed by ICP-MS. RESULTS The results of our study show, in erythrocytes, lower concentrations of Cu, Fe and Zn ($p<0.001$) in athletes compared to moderate training group and control group. An inverse correlation between degree of training and erythrocyte concentration of Cu, Fe, Se and Zn was found ($p<0.001$). DISCUSSION These low values of Fe are probably related to deficiencies in iron intake as indicated by some studies (Latunde-Dada, 2012). The decrease in Cu erythrocyte, sometimes referred in athletes, appears to be related to a change in the intake of Cu but could reflect a redistribution in tissues by physical activity (Vitoux y cols., 1999). The study of Carvalho et al. (2012), with results similar of our study and conducted in swimmers, indicate a possible nutritional deficiency of this mineral. Therefore we can conclude that physical training produces changes in erythrocyte concentrations of trace elements Cu, Fe, Se and Zn. SKIN-GAS ACETONE CONCENTRATIONS ON SURFACE OF ACTIVE MUSCLES FOLLOWING SUBMAXIMAL EXERCISE

KATO, H.I., TAMURA, K.I., MATSUURA, K.I., TAKAI, S.I., UTSU, Y.I., YOSHII, Y.I., OHKUWA, T.I., TSUDA, T.I., ITOH, H.I.

Nagoya Institute of Technology

Introduction Ketone bodies (3-hydroxybutyrate, acetoacetate and acetone) are generated in the liver, mainly from the oxidation of fatty acids, and exported to other tissues for use as energy source (Mitchell et al. 1995). Acetone is mainly produced by decarboxylation of acetoacetate. Therefore, it is known that exercise increases acetone levels in plasma (Balasse et al. 1989), expired air and skin-gas (Yamai et al. 2009). Although a few studies (Mori et al. 2008, Yamai et al. 2009) have reported increased human skin-gas acetone concentrations according to exercise intensity, no one has confirmed changes in skin-gas acetone directly from the surface of active muscles during submaximal exercise. Therefore, the purpose of this study was to measure skin-gas acetone concentrations directly from surface of active muscles following submaximal exercise. Methods Eleven healthy male students performed constant-load (60%HRmax) cycle exercise for 30 min. The skin-gas samples were obtained from left hand and left quadriceps muscle by covering with a polyethylene bag in which pure nitrogen gas (150mL) was introduced for 30 sec, and collected in a sampling bag at rest, 5, 10, 15, 20, 30 min during exercise, and 5, 10, 20 min recovery of the exercise. Acetone concentration was analyzed by gas chromatography. Results Skin-gas acetone concentrations significantly increased during the exercise compared to the resting values ($p<0.01$), then immediately returned to resting values both in hand and quadriceps muscle samples. Significantly higher resting skin-gas concentrations are observed in hand compared to quadriceps muscle samples, however, higher increasing rates were found in quadriceps muscle samples (5-6 times) than in hand (2 times) compared to resting values. Discussion We succeeded to measure skin-gas acetone concentrations directly from surface of active muscles following the exercise. Increased skin-gas acetone concentrations both in hand and active quadriceps muscles after the exercise have suggested that 60%HRmax cycle exercise in this study induced the production of ketone bodies in the liver, from the oxidation of fatty acids (Mitchell et al. 1995), and some of increased ketone bodies eliminated as skin-gas acetone. Differences in increasing rates between hand and quadriceps muscles may due to the differences in blood flow rates in each tissues (Rowell et al. 1986). References Mitchell GA et al. EFFECT OF UNDERWATER ACTIVITYT ON SKELETAL MUSCLE METABOLISM AND NUTRITIVE BLOOD FLOW IN SCUBA DRIVERS

RA, S.G.1, JEON, Y.N.2, YEO, H.S.2, LIM, C.H.2, JANG, W.H.2, KIM, C.K.2, YOON, J.S.1

1:CBU(Chonju, Korea), 2:KNSU(Seoul, Korea)

Introduction This study was performed to investigate the mechanism for microvascular response (vasoconstriction) by α -adrenaline after a single bout of diving of SCUBA divers who have been undergone long-term intermittent cold exposure. To purpose of the study, nutritive blood flow, metabolism and reactive oxygen species (H₂O₂) were analyzed by locally perfusing the α -adrenergic blockade (phentolamine) in vastus lateralis of quadricep muscles. Methods Seven divers (age 35-45 years) who have been diving over 50 times per year were participated in this study. An acute bout of diving was performed at 20m below the East sea (13-14°C) for 30 min after wearing dry suit and SCUBA gear. Dialysate samples were obtained through three microdialysis probes inserted into right vastus lateralis muscle at pre and post diving and recovery (60 min). Results The skin temperature of vastus lateralis was significantly decreased after 20 minutes compared with those before diving ($p=0.35$), and it was increased during elevation to surface between 25-30 minutes ($p=0.15$). There was no interaction in the nutritive blood flow ($p>.05$) between treatment (phentolamine perfused probe vs. control probe) and period (pre and post diving, recovery 40 minutes). No interactions were observed between treatment and period($p>.05$) in glucose, pyruvate, lactate, and glycerol of vastus lateralis muscle. H₂O₂ was not changed in pre diving, post diving and the recovery for 40 minutes ($p>.05$), however it was increased at 60 minutes of recovery compared with 40 minutes of recovery ($p=.034$). Discussion Taken together, these results suggest that α -adrenergic activity by low water temperature do not affect the microvaculature in skeletal muscle of scuba divers have been undergone long-term intermittent cold exposure. The concentration of the metabolites such as glucose, glycerol, lactate, pyruvate might be related to energy metabolism by diving activities in cold water, but not by α -adrenergic activity. MYOGLOBIN REGULATES MITOCHONDRIAL RESPIRATION THROUGH ITS INTERACTION WITH COMPLEX IV

MASUDA, K., TATSUYA Y., TAKAKURA, H., HASHIMOTO, T., ISHIZAWA, R., FURUCHI, Y., KATO, Y., IWANAKA, N., JUE, T.

Kanazawa University

Purpose Mitochondria play a principal role for metabolism, and their respiratory capacity regulate energy expenditure. A key enzyme regulating the respiratory capacity is cytochrome c oxidase complex IV. Any deficiency in complex IV would reduce VO₂ and are linked to several diseases, such as mitochondrial myopathy. In muscle, mitochondrial respiration tends to be very sensitive to complex IV activity. Recently, we showed that the muscle-specific protein myoglobin (Mb) interacts with complex IV. Here, we demonstrate that the interaction facilitates the mitochondrial respiratory capacity in skeletal muscles. Methods The experiments in the present study were composed of two parts: one utilized Mb overexpressing myotubes, and the other used genetic modification to overexpress or suppress Mb expression. Myotubes were used to investigate the significance of the Mb up-regulation during differentiating period. Myoblasts enabled us to analyze the transient effect of Mb gene modification without effects of endogenous myoglobin. Mitochondrial oxygen consumption using Oxygraph-2k were measured to evaluate phenotype in mitochondrial respiration by Mb gene modification. Immunoprecipitation and immunoblotting in cell fractionations were performed to test the localization of the Mb protein and to investigate its interaction with given proteins in the mitochondria. Results Although mitochondrial DNA copy numbers were not altered in Mb-overexpressing myotubes, O₂ consumption was greater in these myotubes than in mock cells. This improved respiratory capacity could arise from the activation of enzymatic activity of respiratory complexes. The experiments show that mitochondrial respiration was up-regulated in myoblasts transiently overexpressing Mb. Only complex IV activity was activated in Mb-overexpressing myoblasts. Complex IV activity was decreased in the myoblasts that Mb expression was suppressed by Mb-siRNA transfection. Conclusion We conclude that Mb specifically regulates the

activity of complex IV in skeletal muscles, and that Mb modulates directly skeletal muscle mitochondrial respiration and oxidative capacity.

CIRCULATING IRISIN LEVEL AS A PREDICTIVE BIOMARKER FOR SARCOPENIA

KONG, I., CHANG, J., KIM, T., NGUYEN, T., KIM, H., YEH, B.

Yonsei University Wonju College of Medicine

Introduction Myokines are in high on the list of candidate biomarkers of sarcopenia due to its muscle-specificity and endocrine effects. Irisin is one of the recently identified myokines, however, its role of pathological sarcopenia still remains unclear. The objective of the present study is to investigate the validity and accuracy of circulating irisin level as a potential biomarker for sarcopenia. Methods We evaluated anthropometrics, body composition, sarcopenia-related parameters and measured serum irisin level in 715 community-dwelling Koreans. Sarcopenia was determined based on a clinical diagnosis of muscle atrophy and weakness. Receiver operating characteristic (ROC) was performed in order to validate the performance of circulating irisin as a biomarker to discriminate between normal and sarcopenia. Results Mean circulating irisin levels were significantly decreased in sarcopenia groups regardless of gender (all $p < 0.05$) and a negative correlation between serum irisin concentration and incident sarcopenia was revealed by nominal logistic regression ($p < 0.001$). In logistic regression models, the association persisted after adjustment for characteristic of individuals ($p < 0.01$). Serum irisin concentrations of $<1.0 \mu\text{g/ml}$ for men and $<1.2 \mu\text{g/ml}$ for women had the optimal predictive values for sarcopenia, with the area under the ROC curves of 0.873 and 0.685, respectively. In fully adjusted model, the discriminatory potentials improved to 0.942 ($p < 0.01$) for men and 0.804 ($p < 0.01$) for women, respectively. Conclusion Decreased circulating irisin level sensitively reflects muscle weakness concomitant with muscle atrophy. Therefore, irisin could be a potential biomarker to predict sarcopenia and provide new avenues for monitoring age-related muscle changes. Contact In Deok Kong, MD, PhD: kong@yonsei.ac.kr

EFFECTS OF VOLUNTARY EXERCISE AND CALORIC RESTRICTION ON HEPATIC FAT ACCUMULATION IN WBN/KOB-LEPRA RATS.

SHIROYA, Y., MINATO, K.

Wayo Women's University

Introduction: Physical exercise and caloric restriction are commonly recommended for prevention and amelioration of obesity and life-style-related diseases, including diabetes and fatty liver. The WBN/Kob-Lepra (fa/fa) rat is a model of chronic pancreatitis and non-insulin-dependent diabetes with obesity, that has been developed by introducing the mutant leptin receptor fatty gene (Lep^{fa}) derived from the Zucker fatty rat into the original WBN/Kob (lean) rat genome. The aim of the present study was to investigate the effects of voluntary exercise and/or caloric restriction on the hepatic fat accumulation and its relationship to insulin resistance in genetically obese WBN/Kob-Lepra rats. Methods : Male WBN/Kob-Lepra (fa/fa) rats at 6 weeks of age were randomly assigned to obese (OB; n=10), obese-caloric restriction (CR; n=8), or voluntary exercise plus caloric restriction (CR+EX; n=9) groups. WBN/Kob (+/fa) lean rats served as a control (C; n=6) group. The C and OB rats had free access to food. The CR and CR+EX rats had food intake restricted to 69% and 70% of the OB group level, respectively. The CR+EX rats were exercised voluntarily on the wheel ergometer with a load of 30% on their body weight every day. Mean running distance was $1711 \pm 458\text{m/day}$. After 6 weeks, all rats were prepared for the experiment. The liver was excised and weighed. Hepatic tissues were prepared for transmission electron microscopy. Results : The body weights, food intake and epididymal fat weights of the OB rats were significantly greater than the C, CR and CR+EX rats. Electron micrographs of the hepatocytes in both the OB and CR rats revealed lipid droplets accumulation. Voluntary exercise combined with caloric restriction attenuated weight gain, reduced visceral fat weights, increased the soleus muscle weight and significantly reduced the value of HOMA-IR, the serum glucose, triglycerides and free-fatty acids concentrations compared with the OB rats. Furthermore, CR+EX rats showed marked reduction of lipid droplets in the hepatocytes. However, caloric restriction alone elevated the HOMA-IR as OB rats and tended to increase serum free-fatty acid levels compared with the OB rats. Discussion : These findings suggest that voluntary exercise combined with caloric restriction improved obesity and insulin resistance in this model of chronic pancreatitis and non-insulin-dependent diabetes with obesity, whereas caloric restriction alone could not. The improvements in insulin resistance by voluntary exercise, may contribute to the amelioration of hepatic fat accumulation as well as lipid metabolism in WBN/Kob-Lepra (fa/fa) rats.

EVALUATION OF EXERCISE BENEFITS: TYPE 2 DIABETES DEVELOPMENT IN FRUCTOSE FED RATS

DUPAS, J., GOANVEC, C., FERAY, A., GUERRERO, F., MANSOURATI, J.

Université de Bretagne Occidentale

Introduction Type 2 diabetes (DT2) is a major risk factor of atherosclerosis. As hypertension or dyslipidemia, DT2 can occur in patients with metabolic syndrome and may result in endothelial dysfunction. Physical activity is one of the preventive treatments of endothelial dysfunction. The aims of this study were thus to develop a new animal model of induced DT2 and to investigate the impact of exercise on the DT2 development. Methods Male Wistar rats were randomly divided in 4 groups, sedentary (Sed; n=8), exercise (Ex; n=8); sedentary fructose (SedFF; n=8) and exercise fructose (ExFF; n=10) with a fructose enriched drink (20% w/v) for 12 weeks. Exercise rats (Ex, ExFF) were trained on a treadmill at moderate intensity (60-70% maximal aerobic speed) for 6 weeks (0° incline, 1h/day, 5 days/week). Rats were weighed, their drink and food consumption were measured weekly. Fasting glycaemia and systolic pressure were monitored. Glucose tolerance was evaluated using an oral glucose tolerance test; insulinemia was measured concomitantly. Endothelial function was studied on isolated aorta rings. Antioxidant enzymes activities (Catalase (CAT), Super oxide dismutase (SOD) and Glutathion Peroxidase (GPx)) were measured on a spectrophotometer in both left ventricle and gastrocnemius muscle. Results After 6 weeks of fructose, supplemented rats had a higher energy intake ($p < 0.001$) but were not overweight. These rats also presented an increased fasting glycaemia ($p < 0.001$) and a reduced glucose ($p < 0.01$) and insulin ($p < 0.05$) tolerance. Systolic blood pressure (137 ± 3 vs. $111 \pm 2\text{mmHg}$, $p < 0.001$) and heart weight were also increased ($p < 0.05$). After 12 weeks of fructose supplementation, SedFF rats had an increased weight ($p < 0.001$) and presented insulin resistance (Homeostatic model assessment of insulin resistance (HOMA-IR): SedFF 2.51 ± 0.5 , cut-off value for insulin resistance: 1.85). In FF rats, exercise helped to reduce weight ($p < 0.001$), fasting glycaemia ($p < 0.01$), heart weight ($p < 0.01$) and insulin resistance (HOMA-IR $p < 0.001$). Fructose diet progressively induced an increased in antioxidant enzymes in both studied muscle. On the other hand, exercise reduced antioxidant enzymes activities level independently of the diabetic status. This reduction is supposed to be beneficial. Surprisingly, even though fructose supplementation had no effect on aorta endothelial function, an improvement of this function was observed with moderate exercise in both diabetic and control rats ($p < 0.01$). Conclusion In this new model of Wistar rats with induced DT2, moderate

exercise improved some DT2 markers like fasting glycaemia and insulin resistance and as beneficial impact on antioxidant enzyme activities levels. However exercise improves endothelial function independently of diabetic status. Contact Julie.dupas@univ-brest.fr

EFFECT OF BEETROOT JUICE SUPPLEMENTATION ON MITOCHONDRIAL FITNESS IN HEALTHY ELDERLY MEN.

CALABRIA, E., DAL SACCO, L., SCHENA, F., CAPELLI, C., TAM, E.

University of Verona

INTRODUCTION Several studies report relevant benefits of dietary NO₃- in athletes. They may also be potentially positive for aging people with exercise intolerance. Aging is associated with functionally impaired mitochondria and increased oxidative stress, but the benefits of dietary NO₃- in the elderly remain largely unknown [1]. Mitochondrial activity in human blood cells (PBMCs) has been described in various disease states, linked to physical fitness [2], and considered a potential systemic mitochondrial marker. Hence, we decided to investigate the influence of beetroot juice supplementation on mitochondrial respiration in PBMCs of healthy elderly people. **METHODS** 5 males (68.8±5 yy; 77.3±10 kg; 172.2±6.3 cm; VO₂peak 39.2±4.2 mL/kg/min) participated in a randomized, double blind, cross-over study. Baseline measurements (VO₂peak, blood sampling) were carried out before the treatment and after 6 days of concentrated beetroot juice supplementation (or placebo). Mitochondrial respiration was assessed in freshly purified human PBMCs with a OROBOROS O-2k. **ROUTINE** respiration (R), Complex I-linked LEAK, OXPHOS capacity (CI), CI&II-linked OXPHOS and ETS capacity were determined in a single SUIT protocol. **RESULTS** Concentration of leukocytes did not change before and after the treatment. Tukey's multiple comparison test showed that NO₃- supplementation significantly increases ($p<0.05$) flux control ratios associated to basal metabolism (ROUTINE) and CI oxidative activity (5 and 6% respectively). Data relative to O₂ specific flux supported by CI&CI and the ETS state were significantly increased from 43±15 to 58±21 ($p<0.05$), while RCR was significantly reduced ($p<0.05$). A significant relationship between age, VO₂peak and respiratory ratios associated to complex I and ETS was found at baseline. **DISCUSSION** The preliminary results obtained in 5 subjects (on-going study) suggest that PBMCs are suitable cells to investigate the mitochondrial adaptations to nitrate supplementation in healthy, elderly subjects. There is a growing interest in the use of NO₃- supplementation also for therapeutic aims (COPD, hypertension, heart failure and insulin resistance). Recent studies investigated the effects of dietary NO₃- on skeletal muscle, leading to variable and controversial results affected also by O₂ availability [1,3]. The evidence that beetroot juice affects the pattern of mitochondrial bioenergetics in PBMCs opens the possibility to easily monitor adaptations in longitudinal studies and to further understand the mechanistic details of NO₃- response. 1 Affourtit C et al., Frontiers in Phys. doi: 10.3389/fphys.2015.00211 2 Tyrrell DJ et al., (2015) Exp Gerontol. doi: 10.1016/j.exger.2015.07.015. 3 Whitfield J et al., (2016) J Physiol. EVALUATING THE EFFECTIVENESS OF A PILATES BASED EXERCISE PROGRAMME FOR THE REDUCTION OF PERCEIVED FUNCTIONAL DISABILITY AND PAIN ASSOCIATED WITH NON-SPECIFIC CHRONIC LOW BACK PAIN.

KONSTANTAKI, M., LLEWELLYN, H.

Leeds Beckett University, Buckinghamshire New University

Non-specific low back pain (LBP) has become a major health problem and is, by definition, a symptom of unknown cause. Approximately one-third of the adult population is affected by LBP and the related costs have now reached epidemic proportions. Health care resources in the current economic climate are limited and more cost effective methods for the treatment and management of non-specific LBP need to be established. Pilates based exercise is becoming increasingly incorporated in to spinal rehabilitation, yet there is limited evidence on the efficacy of the technique. The aim of this study was to evaluate the effectiveness of a 6-week Pilates based exercise programme for the reduction of perceived functional disability and pain associated with non-specific chronic low back pain. Subjects (n=13) with chronic non-specific LBP (>12-weeks) were recruited to a wait-list controlled trial. All subjects were assigned to a 6-week control period (WLC) and a subsequent one hour Pilates based exercise intervention (PI), twice per week, for 6-weeks. Outcome measures for perceived functional disability and pain were assessed pre/post control and intervention periods with the Oswestry functional disability questionnaire (ODQ) and visual analogue scale (VAS) respectively. Results from a related samples Wilcoxon signed rank test revealed a significant ($p<0.01$) improvement in ODQ scores after the 6-week Pilates intervention. A paired samples t-test revealed no significant difference in VAS scores ($t=1.21$; $df=11$; $p>0.05$) post intervention for the PI group. The findings of this research concluded that a 6-week Pilates based exercise programme was effective in reducing perceived functional disability but not pain associated with non-specific chronic LBP. These results should be viewed cautiously due to the study design, limited sample size and short duration of the intervention. Future research should consider a randomised wait-list controlled trial of greater duration and sample size to ascertain the long term effectiveness of Pilates based exercise for chronic non-specific LBP.

SENSORIMOTOR TRAINING VS. REACTIVE BALANCE TRAINING: SPECIFIC STIMULI INDUCE SPECIFIC NEUROMUSCULAR AND FUNCTIONAL ADAPTATIONS

FREYLER, K., KRAUSE, A., RITZMANN, R., GOLLHOFER, A.

University of Freiburg

Introduction Balance training is widely applied in different settings of rehabilitative medicine (Silva et al. 2015) and as a training method for fall and injury prevention (Pan & Bai 2014). Typically, two types of balance modality can be classified according to their biomechanical constraints, and thus result in different strategies of compensating for dislocated masses: sensorimotor training (SMT) referring to a static ledger pivoting around the ankle joint vs. reactive balance training (RBT) challenging equilibrium via externally applied perturbations of the support surface. Possible differences in task-specific functional outcomes between the two modalities have not been profoundly studied. The objective of the study was to investigate the specificity of neuromuscular adaptations in response to SMT and RBT within a test-intervention paradigm. Methods Thirty-eight subjects were assigned to either SMT or RBT. Before and after four weeks of intervention training, postural sway and electromyographic activities of shank and thigh muscles were recorded and co-contraction indices (CCI) were

calculated. We argue that specificity of training interventions could be transferred into corresponding test settings containing properties similar to those of SMT and of RBT, respectively. Results i) Postural sway was reduced in both intervention groups in all test paradigms; magnitude of changes and effect sizes differed dependent on the paradigm: when training and paradigm coincided most, effects were augmented ($P<0.05$). ii) These specificities were accompanied by segmental modulations in the amount of CCI, with a greater reduction within the CCI of thigh muscles after RBT compared to the shank muscles after SMT ($P<0.05$). Discussion The results clearly indicate the relationship between test and intervention specificity in balance performance. When intervention and test paradigm coincided, effects were augmented; thereby neuromuscular segmental distinctions occurred to a larger extent in the proximal body segment in the RBT-group and in the distal segment in the SMT-group. Based on the current findings, RBT could serve as a further expansion to include the proximal segment into training. Considering fall or injury mechanisms, it is supposed that when the available torque at the ankle joint is not sufficient, regaining stability requires resorting to more proximal strategies (Bobrova et al. 2009). Hence, the strategy to precisely control the upper body segment oscillations contributes to determine the risk of falling (Bobrova et al. 2009). References Silva P et al. (2015). EFFECTS OF AEROBIC WARM-UP ON FLEXIBILITY AND ISOMETRIC STRENGTH AFTER STATIC STRETCHING

TAKEUCHI, K.1,2, NAKAMURA, M.3, TSUKUDA, F.1, HOJO, T.3, TAKEMURA, M.2

1. Biwako Seikei sport college, 2. Tsukuba University, 3. Doshisha University

Introductions Many previous studies have proposed that static stretching before competitive sports should be avoided (Behm et al., 2011) because performance decreases immediately after static stretching. Warm-up programs before sports practice comprises aerobic warm-up following static stretching. However, the effects of aerobic warm-up after static stretching are unclear. If aerobic warm-up recovers the decrease in performance after static stretching, it may be possible to use static stretching beneficially, because it prevents muscle-tendon related injuries (Amako et al., 2003). **Purpose** The aim of this study was to elucidate the effects of aerobic warm-up after static stretching on flexibility and isometric strength in the ankle joint. **Methods** Fourteen healthy male subjects (age: 23.9 ± 2.2 years) performed in two separate randomized groups: (1) control group and (2) warm-up group. Subjects enrolled in the control group performed 10-min rest after 5-min static stretching. Subjects enrolled in the warm-up group performed 10-min aerobic warm-up using a cycling ergometer (60 W, 60 bpm) after the static stretching. Muscle tendon unit (MTU) stiffness from 15 to 25 degrees of ankle dorsiflexion, ankle dorsiflexion range of motion (ROM), passive torque at ROM maximum, and peak torque during isometric contraction of ankle plantar flexion were measured using an isokinetic dynamometer. **Results** In the control group, ROM (26.8 ± 7.5 – 28.9 ± 7.6 degrees, $p < 0.05$), MTU stiffness (0.69 ± 0.19 – 0.54 ± 0.12 Nm/degree, $p < 0.05$), and peak torque during isometric contraction (111.6 ± 32.7 – 90.6 ± 33.3 Nm, $p < 0.05$) were significantly different; however, passive torque at ROM maximum did not change significantly (25.6 ± 7.3 – 27.6 ± 7.5 Nm, $p = 0.52$). In the warm-up group, ROM (25.0 ± 5.9 – 29.3 ± 6.5 degrees, $p < 0.05$), passive torque at ROM maximum (24.4 ± 7.4 – 28.7 ± 7.4 Nm, $p < 0.05$), and MTU stiffness (0.68 ± 0.18 – 0.53 ± 0.18 Nm/degree, $p < 0.05$) were significantly different; however, peak torque during isometric contraction (112.8 ± 33.6 – 118.5 ± 36.6 Nm, $p = 0.18$) did not change significantly. **Conclusions** The results indicated that aerobic warm-up recovers the negative effects of static stretching in relation to decrease of isometric strength. **References** Behm DG, Chaouachi A. INTRA-RATER RELIABILITIES OF ANKLE DORSIFLEXION STRENGTH EVALUATION USING THE ORIGINAL COSTUMED DEVICE IN WEIGHT BEARING POSITION

YOSHIDA, M., YOSHIDA, M., YAMAMOTO, K., TAKEDA, T.

Hokusho University

Introduction Since malalignment of the lower limb results in the risk of the lower limbs injuries, it is important to evaluate the posture during basic physiological activities, such as squat and jump landing. Deficits of ROM or dorsiflexion strength in ankle joint are risk factors of knee and ankle injuries. Therefore, it is essential to evaluate the joint movement on sagittal plane because all lower extremity joints are needed to have flexibility in weight bearing position for absorbing the landing force during dynamic performances. Limitation of ankle dorsiflexion ROM and deficit of ankle dorsiflexion strength interfere with dynamic performance. Some researchers measure ankle dorsiflexion strength using a handheld dynamometer (HHD). However, most researches had assessed the ankle dorsiflexion strength with the subjects in a supine position. We consider that it is more valid to measure it in weight bearing position than in non-weight bearing position. Furthermore, HHD is easy to use, and is portable, but it is not certain if HHD has reliability for measuring isometric ankle dorsiflexion strength. The purpose of this study was to confirm the intra-rater reliabilities of dorsiflexion strength assessment using HHD in the subjects with weight bearing position. **Methods** 18 subjects with no injury of lower extremity participated in this study. Although HHD is useful to assess strength of the muscles, if not for stabilizing firmly, it could not actually measure the strength. Therefor, we used the costumed device holding HHD to measure ankle dorsiflexion strength. The subjects were seated on a chair in 90 degrees of the knees flexion and placed their foot under the device to which HHD was fixed. The examiner adjusted the device to keep the subjects with 0 degree dorsiflexion of ankle joint. HHD was placed above the dorsal side of the metatarsal bone. The subjects were asked to press HHD as much as possible strongly by dorsiflexion. The subjects exerted maximal dorsiflexion force for 5s and their maximal isometric force were recorded. The test procedure was repeated 3 times on each side. All tests were performed by one examiner (physiotherapist). **Intra-class correlation coefficient (ICC)** was used to confirm the inter-rater reliabilities. **Results** Mean dorsiflexion strength was 20.4 ± 5.1 kgf (right side 20.7 ± 5.7 kgf / left side 20.1 ± 4.4 kgf). Intra-rater reliabilities of dorsiflexion strength testing were excellent $ICC=0.82$, $95\%CI$ 0.72 to 0.90). Evaluation of the ankle dorsiflexion strength with HHD has excellent intra-rater reliability. **Discussion** The measurement of isometric ankle dorsiflexion strength using HHD seems to be a reliable method. While a therapist measure ankle dorsiflexion strength using HHD, it is difficult to stabilize HHD. However, using our measurement technique, it could be measured easily and excellent reliability with weight bearing position. **References** Moraux, A. (2013). PHYSICAL ACTIVITY LEVEL IN INPATIENTS WITH CHRONIC MUSCULOSKELETAL PAIN DURING MULTIDISCIPLINARY REHABILITATION

TERRIER, P.

Clinique Romande de Réadaptation SUVACare (CRR)

Introduction Severe orthopedic trauma often leads to chronic disabilities and pain that induce reduced daily physical activity and deconditioning. To enhance recovery, intense multidisciplinary rehabilitation is advised. In addition to specific interventions aimed at treating pain and disabilities, an important therapeutic goal of multidisciplinary rehabilitation is to increase the physical activity level (PAL). To assess the efficacy of physical activity promotion, the main objective of the present study was to measure PAL of inpatients in rehabilitation stay as compared to PAL at home. Furthermore, we sought to determine whether change in PAL was mediated by a modification of walking behavior. Methods The study included 124 patients with chronic musculoskeletal pain after an orthopedic trauma. They stayed in the CRR for 4 to 6 weeks. Each weekend, the patients went back to home for 2 days (days off). During the second week of the stay, from Thursday to the next Wednesday, the participants wore an accelerometer. As a proxy for PAL, we computed the proportion of waking time spent in moderate intensity activities (e.g. walking), expressed as percentage. In addition, each walking bouts were specifically detected in the acceleration signals, and the proportion of long duration walks (>1 min.) as compared to total walking time was assessed. We separately analyzed the week days (at the clinic) and the weekend days (at home). Moreover, in a subset of 32 subjects, we analyzed PAL at home during one week before the hospitalization. Results In the subset of 32 patients, we observed no significant PAL differences between the weekend during the stay and the week before hospitalization: the proportion of time spent in moderate intensity activities was similar (8.7% vs. 8.9%). On the other hand, in the full set (N=124), a substantial difference existed between the weekend (days off at home) and the week (at the clinic): 8.6% vs. 12.3%, i.e. +43% increase. We observed a parallel change in walking behavior between the days off and the week: the proportion of long duration walks increased from 25% to 46% (+86%). Discussion We found that it is very possible to take advantage of the days off spent home during the hospitalization to assess the habitual PAL. We determined that the rehabilitation cares induced a substantial increase in PAL (+43%). In addition, the patients undertook more long walks, the proportion of which almost doubled during the rehabilitation week. We conclude that multidisciplinary rehabilitation is effective to increase the patients' participation in walking activities, which enhance PAL. Contact Philippe.Terrier@crr-suva.ch

LOW INTENSITY ISOMETRIC HANDGRIP EXERCISE HAS NO TRANSIENT EFFECT ON BLOOD PRESSURE IN CORONARY ARTERY DISEASE PATIENTS

GOESSLER, K., BUYS, R., CORNELISSEN, V.A.

KU Leuven

Objective: Hypertension is highly prevalent among patients with coronary artery disease (CAD). Exercise-based cardiac rehabilitation is known to reduce blood pressure (BP). However, less is known about the transient effect of a single bout of exercise. Isometric handgrip exercise has been proposed as a non-pharmacological tool to lower BP, but its potential has not yet been evaluated in CAD patients. Therefore we aimed to investigate the acute effect of low intensity isometric handgrip exercise on BP measured shortly after exercise in the office and during the subsequent 24 hrs during daily life activities in CAD patients. Methods: Twenty one male CAD patients (median age 68; range 55-70) participating in a phase III cardiac rehabilitation program were included. All patients completed two experimental sessions in random order: one control session and one low intensity isometric handgrip session. BP was measured by means of a 24h ambulatory BP monitor pre-intervention, for one hour in the office and subsequently for 24 hrs during their daily practice. Physical activity was assessed by means of a SenseWear device. Results: Baseline BP averaged $136.1 \pm 11.1 / 78.3 \pm 6.8$ mmHg and was similar at both test occasions ($p > 0.05$). Following the experimental sessions, we observed a time-effect for office BP and HR ($p < 0.001$) which was not different on both days (p -interaction > 0.05 for all). During normal daily activities, no significant differences between both test days was found in 24h, daytime and nighttime BP and HR ($p > 0.05$ for all). No adverse events occurred. Conclusions: Low intensity isometric handgrip exercise is safe in stable CAD patients but does not induce a transient reduction in BP during daily life activities. Further research investigating the longer-term effects of isometric handgrip training is still warranted.

THE BENEFITS OF PRESCRIBING LOW INTENSITY RESISTANCE EXERCISE DURING HEMODIALYSIS ON PHYSICAL FITNESS AND SERUM LIPID PROFILE IN END STAGE RENAL DISEASE PATIENTS

YASUKAWA, S.

NTT Medical Center Tokyo

Objective The purpose of this study was to determine the effects of prescribing low intensity resistance exercise during hemodialysis (HD) on physical fitness and serum lipid profile in end stage renal disease patients. Subjects Seventeen Japanese patients participated in this study (male; 12, female; 5, age; 70.9 ± 10.7 years old, dialysis history; 6.1 ± 5.3 years). All the participants were diagnosed as stage 5 chronic kidney disease and received HD three times per week at NTT Medical Center Tokyo. Methods Ethical approval was provided after the subjects performed written informed consents. Physical therapists prescribed the patients our original tube exercise program for upper major muscle (3 types; pectoralis major, back muscles and hand grip), lower major muscle (6 types; quadriceps femoris, hamstrings, gluteus maximus, gluteus medius, adductor muscles, triceps surae) and trunk (abdominis) by using the Thera band®. The participants were asked to perform 3 sets of 10 repetitions while they were treated with a HD session of 30 min through 24-week intervention period. Exercise intensity was set at 11-13 in Borg's scale. Muscle strength (quadriceps femoris (QF), pectoralis major (PM) and 30-second sit to stand test), 6 minutes walk test, 10 meters walk test and Time up and go test were evaluated at baseline, 4 week, 8 week, 12 week and 24 week of this trial. Serum total cholesterol (T-cho) and triglyceride (TG) level were measured every 4 weeks from 8 weeks before the start of intervention to 24 weeks. The study periods were divided into 3 segments: the first third, pre-intervention (PRE); the second third of the study period (ST); and the last third (LT). Averages of serum T-cho and TG level of each segment were compared. Results No musculoskeletal and/or cardiovascular complications, which were induced by the exercise program, were recognized. Significantly improved muscle strength was observed; as follows QF (73.7 ± 25.2 Nm to 83.2 ± 27.2 Nm, $p < 0.05$) and PM (26.7 ± 11.3 Nm to 31.6 ± 11.3 Nm, $p < 0.05$) after 24 week. The baseline 30-second sit to stand test of 16.5 ± 5.0 significantly increased up to 19.7 ± 6.1 ($p < 0.05$) after 12 week and 20.6 ± 6.6 times ($p < 0.05$) after 24 week. With respect to serum lipid profile, reduction of TG was observed in PRE vs. LT (111.5 ± 46.6 mg/dl to 95.2 ± 33.7 mg/dl, $p = 0.06$), while T-cho did not changed. Conclusion The low intensity resistance exercise during hemodialysis for patients with end stage renal disease could improve muscle strength (QF, GP and 30-seconds sit to stand test) in safe, and it might slightly impact on serum triglycerides level.

HYDRATION STATUS, NEUROMUSCULAR RESPONSES, AND COMPETITIVE STATE ANXIETY IN PROFESSIONAL TENNIS PLAYER DURING OFFICIAL COMPETITION

LOPEZ-SAMANES, A.1, ORTEGA, J.F.1, PÉREZ-LÓPEZ, A.2, PALLARÉS, J.G.3, MORA-RODRÍGUEZ, R.1

1: UCLM (Toledo Spain), 2: UAH (Alcalá, Spain), 3: UMU (Murcia, Spain).

Introduction: Tennis is a racquet sport with thousands of followers around the world. During non-official competition, physiological and psychological variables have been studied. Data from the hydration status (Hornery et al., 2007) indicates that tennis players compete hypohydrated but does not sustain important dehydration during a match. Likewise, neuromuscular fatigue has not been evidenced after a tennis match (Ojala & Hakkinen, 2013). In addition, before a match, competitive state anxiety (CSA) showed changes in somatic and cognitive anxiety (Filaire et al., 2009). On the other hand, during official competition (ATP/WTA, Challenger and Futures), professional players are awarded with prize money/points for the ATP ranking, which could be associated with higher physiological demands and increased competitive anxiety. The aim of this study is to describe hydration status, neuromuscular responses, and CSA in professional tennis player during an official competition.

Methods: During the qualifying draw from a \$10000 ITF Future tournament, 9 professional male tennis players (3 with ATP ranking between 1400-1800 and 6 between 50-180 in the national ranking) were assessed using, a battery of physiological and psychological measurements. Before the match, hydration status was assessed by urinary specific gravity (USG), and fluid balance was assessed by pre and post-match body weight changes. Before, and after match, neuromuscular fatigue was assessed by counter movement jump (CMJ) and competitive state anxiety was measured using a validated questionnaire (CSAI-2R).

Results: USG before the match was 1.026 ± 0.002 . After the match participants lost $1.2 \pm 0.2\%$ of their body weight. CMJ decreased a $4.85 \pm 1.4\%$ after match no reaching statistical significance ($p=0.203$). Before match, CSA scores for somatic and cognitive anxiety indicated medium to lower values. **Discussion:** As it was described in non-official matches, professional tennis players began official matches in a hypohydrated status. However the beverages ingestion during the match avoided significant dehydration and there were no evidence of neuromuscular fatigue. Our findings suggest that in spite of the special considerations that an official tennis match represents, CSA profile is lower in comparison to a non-official competition. EXTERNAL LOAD ASSESSMENT DURING SMALL SIDED GAMES IN SOCCER: INFLUENCE OF PITCH SIZE AND GOAL-KEEPER PRESENCE

MODENA, R.1,2, TOGNI, A.2, FORNASIERO, A.1,2, SAVOLDELLI, A.1,2, PELLEGRINI, B.1,2, SCHENA, F.1,2

1 CeRISM, University of Verona

Introduction Several studies aimed to analyze the time motion characteristics using speed thresholds and the physiological responses (1) in soccer small sided games (SSGs). Recently the global position systems technology (GPS) allows to quantify the players acceleration (3). In this study we quantified external load during SSGs with different pitch sizes and with or without goalkeeper (GK) by using acceleration data as novel methodology. Methods 12 amateur soccer players took part in the study during in-season period. A total of 91 drills were monitored in 4 conditions: 2 SSGs in a 30x20 m field with (S-GK) and without GK (S) and 2 SSGs in a 40x30 m field with (L-GK) and without GK (L). Every 4-players SSGs lasted 4 x 4 minutes with 3 minutes of recovery and during these each player wore a GPS device (Viper, Statsport, UK). Differences between SSGs format were assessed for total distance covered (TD) and distance covered in six different speed zones (D): walk, jogging, medium, high and very high speed and sprinting. Also we considered the total number of accelerations (ACC) and decelerations (DEC) phases and those performed in different intensity zones. Every difference were assessed using one-way ANOVA with Bonferroni adjusted 95% confidence intervals. Results The results are shown as mean difference [95% CI's]. The total distance covered (TD) was higher in L-GK and L ($470.8 [462 - 478.6]$ m and $467.3 [455.3 - 479.2]$ m respectively) than in S-GK and S ($372.6 [364 - 381.3]$ m and $410.5 [402.8 - 418.1]$ m respectively) ($p < 0.001$). TD is also higher in S than in S-GK ($p < 0.001$). The number of both ACC and DEC was higher in L-GK ($51.8 [50.6 - 53.0]$ and $48.1 [47.0 - 49.3]$ respectively) than other SSGs ($p < 0.001$) while in L there was the lowest number of ACC and DEC ($47.2 [45.9 - 48.5]$ and $45.4 [44.1 - 46.7]$ respectively) ($p < 0.001$). No significant differences between L and S-GK were found. Furthermore, we found several differences among SSGs format in acceleration activities distribution. Discussion In agreement with previous study higher TD were measured in larger pitch size, however the GK influences TD only in small pitch. The differences found in accelerations profile can help coaches to propose the correct muscular load and acceleration patterns using SSGs with different rules. References 1. A COMPARISON OF U18 SCHOOL AND ACADEMY RUGBY UNION MATCH PLAY

READ, D., JONES, B., TILL, K.

Leeds Beckett University

Introduction Understanding the physical demands of rugby union can assist coaches in the preparation of players. Match demands in senior players for domestic competitions (Cahill et al., 2013) and international games (Quarrie et al., 2013) are well established. However, despite adolescent rugby union players playing concurrently at various standards, there is no study that has attempted to compare them. Therefore, the purpose of this study was to compare the physical demands of U18 school vs. academy rugby union match play. Methods A full season of games from the academy (6 games) were analysed and matched by six games from the school standard. Each player wore a microtechnology unit which contained a global positioning system and tri-axial accelerometer in addition to a heart rate monitor. The players were split into forwards and backs with only players who participated in the entire game included in the subsequent analysis (Forwards; school [n=25], academy [n=21] and Backs; school [n=25], academy [n=24]). All data were analysed using magnitude based inferences. Institutional ethical approval was granted. Results Forwards: Total distance was almost certainly greater in academy forwards

(5461 ± 360 vs. 4881 ± 388 m). Distance walking was unclear between the two groups, but jogging, striding and sprinting was almost certainly, very likely and likely greater in academy forwards in comparison to school forwards. PlayerLoadTM slow was possibly greater for academy forwards whilst heart rate mean and maximum was likely lower for academy forwards. Backs: Total distance was very likely greater in academy backs (5597 ± 383 vs. 5260 ± 441 m). Distance walking and sprinting was unclear. Distance jogging was almost certainly greater in the academy backs and striding was possibly greater. PlayerLoadTM slow was possibly greater in academy backs whilst heart rate mean and maximum was unclear between the two groups. Discussion This study shows that academy rugby union provides forwards and backs with a greater physical demand than school players of the same position. The increase in PlayerLoadTM slow suggests an increase in static exertions for academy players. Future research should look to explore the interaction between physical and technical performances between different standards of adolescent rugby union. ANALYSIS OF PERFORMANCE IN DIFFERENT AGILITY TESTS IN YOUNG SOCCER PLAYERS

PERRI, E., MASSARI, M., TRECROCI, A., IAIA, F.M., ALBERTI, G.

università degli studi di milano

Introduction: Agility, described as the ability to perform quick runs with directional changes, is an important component of soccer performance (Sheppard J.M. et al. 2006). Agility is a complex capacity (Young W.B. et al. 2002) and further information are needed to better elucidate its reproducibility and the different skills affecting performance during sprint/agility tests. Therefore, the aim of the present study was to: i) determine the reliability of three different sprint/agility tests; ii) examine any existing relationships among the tests and iii) analyse their physical characteristics. Methods: Ten young soccer players from the same professional team (16.9 ± 0.3 years; 178.7 ± 4.8 cm; 68.8 ± 5.6 kg) were involved in the study. The participants carried out two testing sessions separated by one week. Each testing day included three trials of following three tests: 1) 20-m straight sprint 2) Sprint with 90° turns and 3) Sprint with 90° turns dribbling with the ball (Sporis G. et al. 2010). Performance was measured using photoelectric cells (Optojump, Microgate, BZ, Italy), and GPS (Qstarz 15 Hr, Italy). Only the best trial was considered and the following parameters analysed: time, maximal speed (MS), mean power (MP), mean power in change of direction (CODMP). Results: A significant difference in performance time between Sprint and Agility with ball in test-retest was 3.2 ± 0.1 vs 3.1 ± 0.1 s ($p < 0.01$), 9.1 ± 0.4 vs 8.9 ± 0.5 ($p < 0.01$), respectively. The coefficients of variation between the test-retest were: 1.8 ± 1.3 , $2.8 \pm 1.9\%$ and $2.3 \pm 1.0\%$ for Sprint, Agility and Agility with ball, respectively. No correlation in performance time were observe between 20-m Sprint and Agility ($r = 0.11$ $p > 0.05$), Sprint and Agility with ball ($r = 0.33$ $p > 0.05$) as well as Agility and Agility with ball ($r = 0.16$ $p > 0.05$). No differences ($p > 0.05$) were noted in CODMP between Agility and Agility with ball (25.9 ± 1.7 vs 24.2 ± 2.0 $\text{W} \cdot \text{kg}^{-1}$) ($p > 0.05$). Significant differences ($F = 966.5$ $p < 0.001$) in MP were shown between 20 m sprint vs agility ($p < 0.001$), 20-m sprint vs agility with ball ($p < 0.001$) and agility vs agility with ball ($p < 0.001$). Discussion: A variation was observed in performance time between the test-retest indicating high sensitivity and the need of a familiarization period when performing sprint/agility tests. The pronounced differences in MP together with the absence of relationships found among the three different tests suggest that different abilities upregulate performance during sprint, agility and agility with ball. DO TRAINING EXPOSURES PREPARE ADOLESCENT RUGBY UNION PLAYERS FOR MATCH-PLAY?

PHIBBS, P., JONES, B., TILL, K.

Leeds Beckett University

Introduction The aim of the study was to assess the differences in external training loads and movement demands between training and match-play in adolescent rugby union (RU) players. For mean training and match demands to be similar, athletes would have to be exposed to the equivalent loading of multiple matches within their training week, which may be impractical. An alternative analysis of comparing maximum demands instead of mean demands between conditions may offer a more appropriate comparison. Methods Sixty-one adolescent RU players (mean \pm SD; age 17.0 ± 0.7 years) were recruited from four teams representing school and regional academy. Players were categorized into four independent groups based on playing standard and position; school forwards (SF; n=15), school backs (SB; n=15), academy forwards (AF; n=16) and academy backs (AB; n=15). Global positioning system and tri-axial accelerometer data were obtained from 61 match files during 6 matches, and 152 training files during 15 training sessions. Maximum data from individual training sessions that elicited the highest value for each variable were used in the comparison to match-play. This approach was used to account for variance in specific training objectives for respective sessions (e.g. collision or running focus), as mean data may dilute the magnitude of exposure for specific loads within the training week. Differences between training and match-play measures were analysed using paired t-tests, Cohen's d effect sizes with 90% confidence interval. Results Within the SF group, training was significantly greater than matches for total and relative high speed running (HSR [$\geq 61\%$ maximum velocity (Vmax)] and HSR-min-1), total and relative very high speed running (VHSR [$> 90\%$ Vmax] and VHSR-min-1), and relative peak velocity (%Vmax). Contrastingly, in the SB group, training were significantly less than match play for total distance (TD), %Vmax, VHSR and VHSR-min-1. Within the AF group, match-play was significantly greater than training for relative low speed activity (LSA-min-1 [$< 61\%$ Vmax]). Finally, within the AB group, training was significantly greater than match-play for relative PlayerLoadTM (PL-min-1) and HSR-min-1. Discussion Players from a higher representative standard (i.e. academy) were exposed to external loads and movement demands during their training week comparative to the demands of match-play. However, within schools, due to positional differences during match-play, training sessions may under-prepare backs and over-prepare forwards. Coaches should ensure that training sessions reflect the standard- and position-specific demands of match-play to adequately prepare players for competition.

EFFECT OF INTENSIFIED STEP AEROBICS TRAINING ON NEURAL AND MUSCULAR FUNCTION OF THE PLANTAR FLEXORS IN PATIENTS WITH OSTEOPOROSIS

BEHRENS, M., MAU-MOELLER, A., WEIPPERT, M., HUSMANN, F., HERLYN, P., BRUHN, S., MITTLMEIER, T., SCHOOBER, H.C., ZSCHORLICH, V., FISCHER, D.C.

University of Rostock

Introduction Muscle strength is a major factor in balance control, gait performance and the occurrence of falls in elderly people[1]. This aspect is especially important for osteoporotic patients who have an increased risk for fall-related fractures. This study investigated the effect of intensified step aerobics training on maximum voluntary contraction strength, neural activation and muscular function of the plantar flexors in older osteoporotic patients. Methods Twenty-seven patients (mean age 75 yrs) were randomized into control ($n = 14$) and intervention groups ($n = 13$). The intervention group received a supervised intensified step aerobics training (twice weekly, 1 h per session) over 6 months. Neuromuscular function was investigated before, and after 3 and 6 months of training using electrical stimulation of the posterior tibial nerve. Isometric explosive and maximum voluntary contraction strength, normalized muscle activity of triceps surae and tibialis anterior, electrically evoked spinal reflex responses of the soleus muscle (H-reflex at rest, V-wave) and peak twitch torque of the plantar flexors were analyzed. The statistical approach comprised an analysis of covariance (ANCOVA) with baseline measurement and sex entered as covariates. Results After 3 and 6 months of training, maximum voluntary contraction strength in the intervention group was significantly higher by 7.7 Nm (9.1%; 95%CI: 3.3-12.2 Nm, $P = 0.002$) and 12.4 Nm (14.8%; 95%CI: 6.4-18.5 Nm, $P = 0.001$) compared to controls. These changes were due to neural and muscular adaptations indicated by an increased V-wave and a heightened peak twitch torque at rest. Furthermore, after 6 months of training, isometric explosive voluntary strength in the time interval 0-50 ms was significantly higher for the intervention group. Discussion Our data indicate that the training regimen can be recommended to improve neural and muscular function of the plantar flexors in older osteoporotic patients. High moments have to be generated by the muscles of the lower limbs to ascend and descend the step board[2]. This might have stimulated neural and muscular adaptations comparable to those induced by strength training. [1]Wolfson L, Judge J, Whipple R, King M. (1995). J Gerontol A Biol Sci Med Sci, 50, 64-67. [2]Andriacchi TP, Andersson GB, Fermier RW, et al. (1980). J Bone Jt Surg, 62-A, 749-757.

RELATIONSHIP BETWEEN ONE-LEG STANDING ABILITY AND RATE OF FORCE DEVELOPMENT IN COMMUNITY-DWELLING ELDERLY PEOPLE

TAKEHIRO, K.1, TOME, I.1, YOSHIHIRO, F.2, MASASHI, T.1, SEIGO, M.3, YUYA, W.4, MISAKA, K.4, NORIAKI, I.1

1:Kyoto University, 2:Kobe Gakuin University, 3:Yamato University, 4:Kyoto Gakuen University

Introduction The rate of force development (RFD), which is defined as explosive muscle strength, increases with maximum voluntary contraction (MVC). However, previous studies reported that early-phase RFD in the time interval of up to 40 ms from onset of contraction, which may be primarily influenced by neuromuscular adaptations, has not been associated with MVC (Gruber, 2004; Andersen, 2006). In addition, while lower limb muscle strength is known to contribute to performance during standing in elderly people, few studies have examined the relationship between standing ability and early-phase RFD. The purpose of this study was to investigate the influences of RFD on standing ability in elderly women. Methods The subjects comprised 125 community-dwelling elderly women (mean age, 73.5 years). One-leg standing time (OLST) with eyes open, which was used to represent standing ability, was measured for a maximum of 180 s. Isometric strength of knee extension (MVC) at 90° flexion position was measured by using a dynamometer. RFD was defined as the slope of the force-time curve from the onset of contraction (from 2.5% of MVC). The subjects were asked to exert force as fast as they could. Early- and late-phase RFD, which were defined as time intervals of 0-30 and 0-200 ms respectively, were calculated from the mean RFD. Peak RFD was also calculated as RFDmax. Stepwise regression analysis was performed with OLST as dependent variables, and age, MVC, RFDmax, and early- and late-phase RFD as independent variables. Results The OLST was 67.2 ± 63.6 s. The MVC was 257.4 ± 64.1 N. The RFDs were as follows: maximum, 2.19 ± 1.02 N/ms; early phase, 1.38 ± 0.99 N/ms; and late phase, 1.02 ± 0.35 N/ms. Stepwise regression analysis revealed that age (standardised coefficient = -0.356) and early RFD (standardised coefficient = 0.281) were significant and independent determinants of OLST. MVC, RFDmax, and late RFD were not identified as significant determinants of OLST. Discussion This study showed that only early-phase RFD was associated with OLST. Our results suggest that early-phase RFD (<30 ms) may be more important for one-leg standing ability than MVC or maximum RFD in elderly people. References Markus Gruber, Albert Gollhofer. COMPARISONS OF WALKING-BASED TRAINING TECHNIQUES IN COPD

POMIDORI, L., FELISATTI, M., TERRANOVA, M., POZZATO, E., CONTOLI, M.

University of Ferrara

Background Low exercise capacity is a negative prognostic factor in COPD. Exercise training improves exercise capacity. Walking-based endurance training programmes are very effective in improving exercise capacity and quality of life in COPD. Exercise-induced dyspnea is a major limiting factor for endurance training in COPD. Downhill walking has been recently proposed as a brand new low metabolic-cost training program in COPD patients. Aim: we performed an exploratory study to evaluate and compare the respiratory patterns and the magnitude of dyspnea during different modalities of walking-based training programs in COPD. Methods 10 moderate-to-severe COPD patients were included in the analysis. In a random orders patients were submitted for 3 consecutive days to walking-based training sessions on treadmill set-ups at different inclination (+1% or -10%) or free walking on the ground. The session lasted 6 minutes at a controlled walking speed of 80% of the mean speed recorded during baseline 6MWT. All patients were equipped with Spiropalm® which allowed measurement of the ventilatory pattern and continuous monitoring of heart rate and oxygen saturation. Results Compared to the other two walking-based training modalities, the walking session on treadmill set-ups at negative inclination (-10%) induced a significant

reduction of minute ventilation during the session ($p<0.05$) and at the end of the session a reduction of dyspnea ($p<0.05$). Conclusion Walking-based training session at negative inclination can represent an effective modality for exercise training in COPD. Studies evaluating long-term effects of this technique on relevant clinical outcomes in COPD patients are needed. CONTACTS luca.pomidori@unife.it

ASSESSING BALANCE PERFORMANCE: INTRASESSION RELIABILITY OF A WOBBLE BOARD

FUSCO, A.1, GIANCOTTI, G.F.1, VARALDA, C.2, DI MICCO, G.1, CAPELLI, G.1, CAPRANICA, L.3, CORTIS, C.1

1 University of Cassino and Lazio Meridionale; 2 Italian Weightlifting Federation FIPF, Rome, Italy; 3 University of Rome "Foro Italico"

Introduction Wobble Boards (WB) are often used in different clinical settings to improve neuromuscular function and reduce injury risk (Williams and Bentman, 2014). Although their effectiveness is well known, nowadays only few devices are able to quantify WB balance performances and relatively few studies investigated their reliability (Hamer et al, 1992). Therefore, the purpose of this study was to determine the intrasession reliability of a computerized WB. Methods After signing an informed consent, 28 (15 females, 13 males) college (major: sport sciences) students (age: 25.5 ± 3.3 years; weight: 64.0 ± 12.7 kg; height: 167.4 ± 10.3 cm) were involved in the study. Balance performance was assessed on a computerized WB (diameter=40cm) as the time spent in the target zone (TZ, diameter=6.3cm) displayed on a screen. Participants were asked to stand barefoot on the WB with a comfortable double leg stance, keeping their hands on their hip. The WB Balance test was administered during 2 testing sessions (Familiarization session-FS and Test session-TS), organized with a 1-week interval in between. Each session consisted of a 3-min free practice followed by three 30-s trials (1-min sitting recovery in between) of two conditions: 1) with Visual Biofeedback (VBF), showing real time performance; and 2) without Visual Biofeedback (NVBF), looking at a black wall. Consistency of the WB scores across the three trials was determined using intra-class correlation coefficients. Results For VBF, both FS and TS showed $ICC=0.68$ (FS: 95% CI: 0.50-0.82; TS: 95% CI: 0.49-0.82). For NVBF, FS showed $ICC=0.41$ (95% CI: 0.18-0.64), whereas the relative picture for TS was $ICC=0.40$ (95% CI: 0.17-0.63). Discussion Findings confirm that WB could be a useful, portable, and relatively affordable equipment for the evaluation of balance performances in different clinical settings, especially when a visual feedback is provided. However, the level of expertise of the studied sample limits the generalizability of the present results, thus different population needs further investigation. ANALYSIS OF TWO SPECIFIC JUMPS IN FEMALE BALLET DANCERS

MANNACIO, E., CONDELLO, G., RIPANI, M., CICCARELLI, A., TESSITORE, A.

University of Rome Foro Italico

Do not insert authors here Introduction Classical ballet differs from many sports for its expressiveness and range of motion. It requires high specific skill abilities, rather than a dramatic change of physiological demands (Twicchett et al., 2009; Wyon et al., 2011). Although jumping is an integral part of the majority of ballets, for some specific jumps the dancers attempt to control technique and elegance of their executions rather than perform maximal efforts. Thus, this study aimed to investigate the dancer's ability to maintain stable jumping performances, following the ballet technique. Methods Two groups of female ballet dancers [Expert (EXP), n=12, age 18 ± 3 yrs and Novice (NOV), n=10, age 12 ± 2 yrs] performed two trials of two specific vertical jump protocols: 1) Changement (CHA), composed by 5 consecutive jumps starting from plié in fifth position, and 2) Echappé (ECH), composed by two cycles of 'echappé' for a total of four jumps (each cycle included a first jump from plié in fifth position to plié in second position and a second jump vice versa). Height (H), Jumping Point Gap (JPG) and Used Area (UA) were measured by means of the Optojump Next system (Microgate, Italy). Differences were assessed through ANOVA for repeated measures ($p \leq 0.05$). Results In CHA test, no differences were found for H and UA, whilst differences were seen for JPG ($p=0.003$) between the five consecutive jumps [1st: 2.4 ± 2.2 ; 2nd: 4.2 ± 3.6 ; 3rd: 4.4 ± 3.7 ; 4th: 5.1 ± 4.9 ; 4.8 ±3.8 cm]. Moreover an approach to significance ($p=0.52$) and a difference ($p=0.42$) between groups were found for H (EXP: 12.3 ± 2.3 and NOV: 14.6 ± 3.3 cm) and JPG (EXP: 3.6 ± 3 and NOV: 4.9 ± 4.5 cm), respectively. The ECH test revealed main differences between jumps for H ($p<0.001$), JPG ($p=0.003$) and UA ($p<0.001$), while differences between groups emerged for UA ($p=0.001$). Post-hoc analysis maintained differences ($p<0.05$) between each jump from the fifth position (with a larger occupied area) to the second one (with a smaller area) and vice versa for H and UA. Discussion The findings of this study showed as in CHA dancers carried out a control on the jump height in order to maintain their aplomb, trying to limit the medio-lateral displacement (which, however, was significant). In fact, it could be speculated that the higher the jumping height, the higher the JPG value. Moreover, the medio-lateral displacements are also influenced by the dancers' experience. In fact, the NOV group showed both higher H and JPG values compared to the EXP one. Furthermore, the dancers' technical skill is also demonstrated by their ability to perform similar jumps in each of the two echappé cycles (with larger and smaller area, respectively). RE-TEST RELIABILITY OF BALANCE TESTS IN PRESCHOOL CHILDREN

FREUDENTHALER, T.1,2, SCHMEISSL, A.1, MUELLER, E.1, RING-DIMITROU, S.1,2

1 Paris Lodron-University Salzburg 2 SALTO (Salzburg Together against Obesity)

Introduction From the first human step to the final step balance is essential to mobility. It is considered to be a fundamental part of motor competence amongst pre-schoolers. However, information about the test-retest reliability of single balance tests remains scarce. Lack of data is apparent on single balance items. Therefore we aimed to study test-retest reliability of commonly used balance tests utilized in German speaking countries. Methods We selected three dynamic tests and two static tests, as part of German Motoric Test Batteries (Boes et al., 2004; Zimmer & Volkamer, 1987), a static test as proposed by Ortega et al. (2014; standing on one leg, SOL) and a new dynamic test proposed by SALTO. 16 kindergarten children (all 5 year old) characterized as means (SD) 115.3 cm (7.0), 21.9 kg (5.1), 50% girls performed the following tests: walking forward and backwards on a 2 m long/10 cm broad carpet area (MOT4-6), walking forward on a 3m long/3 cm broad/5 cm high balance beam (SALTO), standing on one leg on a T-beam (KMS 3-6) and on the plain floor (SOL). The retest was performed seven days later. Non-parametric tests were performed with SPSS 23: test-retest reliability with spearman correlation (r_s , p), item discrimination power with item-total correlation (r_{it-i}) and item difficulty as quotient of reached to max possible points multiplied with 100 (P_i). Results The analyses revealed the following statistics for dynamic balance with MOT 4-6 walking forward $r_s=.62$, $p=.011$, $P_i=90.63$, $r_{it-i}=.28$, walking backwards $r_s=.40$, $p=.128$, $P_i=32.8$, $r_{it-i}=.61$, SALTO $r_s=.71$, $p=.002$, $P_i=33.2$, $r_{it-i}=.68$. Respectively for static items KMS were $r_s=.54$, $p=.031$, $P_i=27.7$, $r_{it-i}=.28$ and SOL were $r_s=.84$, $p<.001$, $P_i=53.7$, $r_{it-i}=.60$. Discussion In conclusion MOT 4-6 exhibited low to moderate and SALTO moderate to high retest-reliability for dynamic balance items. KMS 3-6 re-

vealed low and SOL high retest reliability for static balance. Regarding a screening and monitoring of balance in 4 to 6 year old children we recommend SOL for static and SALTO for dynamic balance testing. A STUDY OF SPRINT-ASSISTED TRAINING FOR PARA-SWIMMERS

TANAKA, T., YOSHIMURA, Y., YASUKAWA, M., OISHI, K.

Chuo University

Introduction: Because the outcomes of swimming races are decided by only fractions of a second, many different training methods have been developed to improve performance. One such training method is sprint-assisted training, commonly used by coaches and competitive swimmers to improve the swimmer's ability to apply force over a greater distance. However, the most appropriate assist velocity for challenged individuals in para-swimming is unknown. Purpose: To investigate the effects of change in assist velocity for challenged persons in para-swimming. Methods: This study evaluated one female Japanese competitive para-swimmer. The subject has a functional mobility para-swimming classification of "S6" for butterfly. This study used a pulling assist system with a velocity meter (Maglischo, 2003), which includes a wire line to pull the subject. The system precisely recorded intracyclic velocity variations during 25 m of maximum effort, with assist mean velocities of 0.0 m/sec (baseline), 1.1 m/sec (Assisted Speed [AS] 1) and 1.2 m/sec (AS 2), respectively. Results: In stroke phase, minimum velocity was 0.53 ± 0.07 m/sec and maximum velocity was 1.42 ± 0.05 m/sec at baseline. Minimum velocity at AS 1 and AS 2 was 0.81 ± 0.04 m/sec (vs. baseline, t-test, $p < .001$) and 0.87 ± 0.07 m/sec (vs. baseline, t-test, $p < .001$), respectively; maximum velocity at AS 1 and AS 2 was 1.38 ± 0.09 m/sec (vs. baseline, t-test, $p = 0.142$) and 1.57 ± 0.03 m/sec (vs. baseline, t-test, $p < .001$), respectively. Thus, the minimum velocity (vs. baseline) became larger at AS 1 and AS 2. The maximum velocity (vs baseline) was similar at AS 1, and grew larger at AS 2. Assist velocity AS 1 influenced minimum velocity, and AS 2 influenced both minimum and maximum velocity. Conclusions: Identifying the assist velocity that influences minimum speed is the first step in determining the most appropriate assist velocity. This finding may help to develop optimum assist conditions for training competitive para-swimmers. References: Maglischo, E. W. (2003). Swimming Fastest. Human Kinetics.

VISUAL PERCEPTION AND DECISION MAKING IN DYNAMIC ENVIRONMENTS. AN EXPERIMENTAL STUDY IN VOLLEYBALL

VELENTZAS, K., SCHAPER, T.

Bielefeld Universität

A spiked volleyball with a velocity of 16.9 ± 2.4 m/sec requires approximately 412ms to hurtle into the defense zone (Melrose, Spaniol, Bohling, & Bonnette, 2007). Taking into account the temporal structure and technical/tactical demand of floor defense, perceptual skills are crucial and affect athletes' performance (Neumaier, 1983; Vickers, 2007). The present study aims to provide evidences about the relationship between perceptual strategies and decision making in volleyball and to scrutinize differences in gaze control between athletes of different levels. Method For this purpose, female volleyball players participate in our study [novices-NV ($N = 15$), intermediate-IV ($N = 13$), German U19 national team ($N = 13$)]. 48 spike actions recorded from the defender perspective (position 5) were presented in a random order. Reaction time is measured by keyboard entries (Presentation®) and gaze behavior was evaluated by a SMI® eye-tracker. Participants were asked to "read" and enter spikes' direction (five possible choices) on the keyboard as fast as possible. Reaction-time was calculated in relation to the hitting moment. Results The analysis of the decisions' accuracy shows no significant differences between groups ($X^2(df = 2, n = 41) = 4.21$). However, reaction time decreases significantly on increasing expertise $F(2, 41) = 15.88, p < .001$, Tukey-HSD Post-Hoc [MN_{NV} = 478ms; MN_I = 206ms; MU_{U19} = -30ms]. Eye tracking data reveal significant shorter fixations for higher expertise $F(2, 41) = 4.428, p = .018$, [MN_{NV} = 237ms : MN_I = 203ms]; [MN_{U19} = 237ms : MU_{U19} = 184ms] but no differences regarding the number of the fixations. Discussion The results of the present study match previous studies partly only. Differences in gaze strategies can't be ascertained. However we found differences regarding the fixations' duration and the reaction time. The results indicate that experts are able collect and actualize information more efficiently by using almost the same gaze strategies as the novices. TEMPORAL FEATURES OF DIFFERENT MOTOR IMAGERY TASKS FOR YOUNG AND OLDER ADULTS IN LOCOMOTION.

IASEVOLI, L.I., FUSCO, A.I., GALLOTA, M.C.I., PAOLUCCI, S.I., IOSA, M.I., BALDARI, C.I., GUIDETTI, L.I.

Università degli Studi del Foro Italico

Introduction Motor Imagery (MI) is a cognitive process related to the ability to mentally simulate an action without physically execute it. Some author have proposed a new form of MI defined dynamic motor imagery (dMI) that refers to the mental representations of the action performed simultaneously with external movements. The main aim of this study was asses the influence of ageing in dMI and classic motor imagery (sMI) considering different types of walking as forward (FW), lateral (LW) and backward (BW). Methods 30 individuals (15 young, 27.1 ± 3.8 years old; 15 elderly, 65.9 ± 9.6 years old) were asked to imagine moving (sMI) towards a target positioned at the distance of 10 meters for the three locomotion condition. The same participants were also asked to imagine the same locomotor condi-

tions accompanied by a stepping in place (dMI). After that, individuals really moved (real locomotion, RL) towards the target. The duration of required tasks were recorded by means of a chronograph digital timer stopwatch. A 2x3x3 ANOVA with age (young and elderly) as between tasks (sMI, dMI, RL) and condition (FW, BW, LW) as between factor. Results The main effect of age was close to statistical significance ($p=0.055$), as performances of elderly were slightly slower than young adults. Both task and condition factor, as well as to their interaction ($p<0.01$) significantly affected performances. The time spent in FW for sMI was slower compared dMI in young ($p=0.0051$) and elderly ($p=0.0037$) despite both resulted not significantly different from RL. Also the performances in LW for sMI resulted significantly lower than dMI performances ($p<0.001$) and RL ($p<0.001$) while RL and dMI performances were not significantly different ($p=0.140$) as well as for FW ($p=0.099$) and BW ($p=0.438$). The same pattern was found in BW. Discussion Our results showed that age affected only marginally the requested performances. The temporal similarity between sMI and RL are preserved in young and older people for simple and FW. In FW, BW and LW our results confirmed a better time accuracy of dMI, significantly closer to RL, compared sMI. Hence, when the mental perception of timing is added the spatial updating of information, given by the stepping in place, could furnish feedbacks to obtain similar times, both in young and older adults. The changes determined by aging in the biomechanics of walking patterns seem not to be reflected in the mental processing of usual movement. References Guillot, A., et al. 2005. Introduction Coping strategies can be understood as volitional actions, both cognitive and behavioral damage to deal with situations of threat or challenge, the evidence in the sporting context. In this sense, the objective was to verify the behavior of coping levels of 8 styles at different times. Methods Attended by 23 synchronized swimmers (SS) in infant classes (S = 13) and youth (S = 10) aged between 9 and 15 years (12.13 ± 1.98), participants from 2 SS tournaments, known as time 1 (T1) and time (T2). An educational intervention was given by a judge on the important assessment items to athletes 24 hours before to T2. This judge did not act in any of these two moments. So the T1 and T2 differed with the implementation of this intervention. The coping levels were tested through the inventory of Coping for athletes in competition situation in T1 and T2. This inventory consists of two dimensions Coping Orientation (CO) and Guidance to Removal (GR), which include eight sub-dimensions, 4 EO (Revaluation, Direct Action, Social-Support, Self-Controll and 4 OA (Aggressive Action, Denial, Distraction, Action Inhibition). Normality ensuring the distribution and reliability ($0.89 < \alpha < 0.88$) of the data (0.88 0.05), one Student t test for paired samples was used to compare possible significant differences in T1 and T2. Results The results found in 10 tested pairs (-2.40

DEVELOPMENTAL DIFFERENCES IN ACHIEVING PSYCHOSOCIAL DEVELOPMENTAL TASKS AND PSYCHOLOGICAL COMPETITIVE ABILITY AMONG MALE JAPANESE ATHLETES

TAKENOUCHI, T.1, OOHATA, M.2

1: Nagoya University (Nagoya, Japan), 2: Kawabeyasuragi Clinic (Gifu, Japan)

Introduction Psychological competitive ability (PCA) refers to a trait that enables athletes to compete to the best of their ability (Tokunaga, 2001), which is a necessary trait for exceling in sports. Takenouchi and Oohata (2015) demonstrated that the achievement of psychosocial developmental tasks (PDTs) was related to PCA of athletes. However, developmental differences in the relationship between the achievement of PDTs and PCA have not been clarified. Therefore, these developmental differences were investigated in male Japanese athletes. Methods Male athletes responded to a questionnaire assessing five PDTs: trust, industry, identity, intimacy, and psychological weaning, which were selected based on developmental theories, such as by Erikson (1959). Moreover, athletes' PCA was evaluated using the Diagnostic Inventory of PCA for Athletes (Tokunaga & Hashimoto, 2000) that assesses five factors: volition for competition, mental stability and concentration, confidence, strategic ability, and cooperation. Junior high school (n = 119), high school (n = 102), and college athletes (n = 169) provided valid data. Results Multiple regression analyses indicated that trust, industry, intimacy, and psychological weaning significantly predicted the total PCA score in junior high school athletes, industry in high school athletes, and industry, identity, and intimacy in college athletes. The results of college athletes have been previously published (Takenouchi & Oohata, 2015). Discussion Industry was related to PCA in all developmental stages, suggesting that it was critical for improving PCA. Trust and psychological weaning are considered to be PDTs that start to engage in relatively early developmental stages, and therefore they were related to PCA in junior high school athletes. Identity is assumed to be well developed during late adolescence and therefore it was related to PCA in college athletes. Intimacy, which includes intimacy with the same and opposite sexes, is assumed to be a PDT at relatively early and late developmental stages, respectively. Therefore, intimacy was considered to be related to PCA in junior high school athletes and PCA in college athletes. These results suggest that PCA of athletes develop as they sequentially achieve PDTs related to each developmental stage. References Erikson, E. H. (1959). *Identity and the life cycle*. MENTAL TOUGHNESS AND SELF-AFFIRMATIONS FOLLOWING PERCEIVED THREAT

MEGGS, J., LAZARUS, L.

Sheffield Hallam University

Mental toughness is arguably a prerequisite for sporting success and is a collection of cognitive, affective and behavioural components that allow an individual to remain in pursuit of their goals, despite threats or adversity. Self-affirmation theory provides a cognitive framework for understanding individual differences in response to perceived threats. The current study sought to apply SAT to understanding how mentally tough people respond to. A cross-sectional design including 82 sports people was used to examine individual differences in responses to a perceived social threat. Participants were asked to think of a perceived threat either in within sport (loss of a sporting title) or elsewhere in their lives (rejected by a social circle) and were asked to write a short essay about the experience. Next, participants

were given an opportunity to engage in direct self-affirmation (write about why social relationships/experiences are important to them), indirect self-affirmation (write about why another core value was important to them) or to disengage (indicating defensive processing). Overall, those high in global mental toughness tended to engage in direct self-affirmation significantly more than those with lower levels of mental toughness. Other findings included that those who had the highest level of commitment were those who engaged fully in the social threat exercise and engaged in direct self-affirmation. Whereas, those people who did not engage with the social threat (they chose not to reflect/respond to this manipulation) but then also engaged in indirect self-affirmation, had the highest levels of emotional and life control. In conclusion, it appears that mental toughness is a multidimensional construct and different cognitive processes underlie each individual characteristic of mental toughness. Self-affirmation theory can shed some light on these cognitive differences.

MO-PM28 Training Effects

THE EFFECTS OF MUSCLE ACTION, REPETITION DURATION AND LOADING STRATEGIES OF A WHOLE-BODY, PROGRESSIVE RESISTANCE TRAINING PROGRAMME ON MUSCULAR PERFORMANCE AND BODY COMPOSITION IN TRAINED PERSONS

FISHER, J., CARLSON, L., STEELE, J.

Southampton Solent University

Introduction Previous research has shown higher surface electromyography (sEMG) amplitude and motor unit (MU) activation (measured by intramuscular spike-amplitude-frequency (ISAF) histograms) for concentric (CONC) compared to eccentric (ECC) muscle actions where loading strategies are equated (Moritani, et al., 1987). As such, ECC training has been of interest as a result of the capacity to use increased loading strategies or reduce metabolic cost (Vogt and Hoppeler, 2014). However, research has produced equivocal results with regard to eccentric (ECC) only compared to traditional resistance training (RT). When considered in relation to load- and repetition duration-accentuated (ECC) training strategies (Hortobágyi, et al., 2001; and Dias, et al., 2015, respectively), as well as the use of isolated, isokinetic and isointertrial RT methods there is a relative dearth of literature considering multi-joint, multi-exercise RT interventions. **Methods** The present study considered fifty-nine male and female participants, with > 6 months RT experience, randomly divided in to 3 gender counterbalanced groups; ECC only (ECC, n=20), repetition duration-accentuated ECC (ECC-A, n=20), and traditional (CON, n=19) performing full body, effort matched RT programmes 2 d.wk⁻¹ for 10 weeks. Outcomes were muscular performance including absolute muscular endurance and predicted 1-repetition maximum (RM), in addition to body composition. Results No significant between groups differences were identified for change in muscular performance measures for leg press or pull down exercises, or for body composition changes. Analyses revealed a significantly greater improvement for CON compared to ECC groups ($p < 0.05$) for change in absolute muscular endurance for the pull-down exercise. Effect sizes for muscular performance changes were moderate to large for all groups and exercises (0.75-2.00). **Discussion** The present study supports previous research that ECC only RT produces similar improvements in muscular performance to traditional training where intensity of effort is controlled. For strength coaches and athletes with limited time resources and engaging in sport-specific skill training, the present study supports that a time efficient manner of uncomplicated RT appears an efficacious approach to improving muscular performance. CARDIORESPIRATORY EFFECTS OF ONE-LEGGED HIGH-INTENSITY INTERVAL TRAINING IN NORMOXIA AND HYPOXIA

MENZ, V., SEMSCH, M., MOSBACH, F., BURTSCHER, M.

University of Innsbruck

Introduction Although there is no consensus about an optimal training method to enhance VO_{2max}, nevertheless training of small muscle groups and repeated exposure to hypoxia seem to be promising approaches (Esposito et al., 2011; Burtscher et al., 2004). Therefore, this study was aimed at gaining innovative insights into the effects of small muscle group training in normoxia and hypoxia. **Methods** Thirteen healthy participants were randomly assigned to the hypoxic (HG, N=7) or normoxic (NG, N=6) training group. Both groups completed nine high-intensity interval training sessions in 3 wks. The NG performed the training in normoxia (FiO₂: 0.21; ~ 600 m) and the HG in hypoxia (FiO₂: 0.126; ~ 4500 ml). Each session consisted of 4 x 4 min one-legged cycling at 90% of maximal heart rate separated by 4 min recovery periods. Before and after the intervention period, VO_{2max} and peak power output were assessed in a laboratory cycling test. Results Peak power output significantly improved within both groups ($9.6 \pm 4.8\%$ and $12.6 \pm 8.9\%$ for HG and NG, respectively) with no significant interaction ($p=0.277$). However, VO_{2max} only significantly increased after training in hypoxia from 45.4 ± 10.1 to 50.0 ± 9.8 ml/min/kg ($10.8 \pm 6.0\%$; $p=0.002$) with no significant interaction ($p=0.146$). The maximal O₂-pulse improved within the HG and demonstrated a significant interaction ($p=0.040$). **Discussion** Nine sessions of one-legged cycling training significantly improved VO_{2max} and peak power output. The results of the present study showed that local muscle group training performed in hypoxia did not improve exercise tolerance to a greater extent than normoxic training. However, training under hypoxic conditions may generate greater effects on VO_{2max} than a similar training in normoxia. The sample size may have been too low and the training period too short to detect differences between HG and NG. EFFECTS OF A STAIR DESCENDING EXERCISE ON DELAYED ONSET MUSCLE SORENESS OF THE LOWER LIMBS AND ASSOCIATED MUSCLE DAMAGE

TAMARI, Y.I., WADA, T.I., YOSHIDA, N.I., ONODERA, S.2

1 Graduate School, Kawasaki University of Medical Welfare, 2 Kawasaki University of Medical Welfare

Introduction: Effects of cadence during stair descending exercises on the lower limbs are different in the first and second halves of the stance phase (Tanabe et al., 2015). Knee joint extension muscles in the first half of the stance phase are stretched as cadence increases; therefore, the burden on the lower extremities increases. However, the burden on the knee extension muscle decreases with cadence in the second half of the stance phase. The aim of this study was to clarify the effect of cadence at different times during a stair descending exercise on the DOMS in the lower limbs. **Methods:** The subjects were 8 healthy Japanese male adults (age: 21±1 years, height: 173.7±4.7 cm, weight: 69.3±9.3 kg, BMI: 23.0±2.7, mean±SD). Each subject signed an informed consent form. The subjects performed a stair descending exercise comprising 207 steps and 10 round trips. They used an elevator to return to the beginning of the movement. Cadence exercise conditions were 90 steps/min (90-condition), 110 steps/min (110-condition), and 130 steps/min (130-condition). The condition order was random. The subjects had a 15% body weight load. Measurements included maximal isometric strength, thigh circumference (muscle damage indices), and muscle soreness. Muscle soreness was determined based on the visual analog scale. Measurements were taken before exercise, immediately after exercise, and on post-exercise days 1–4. **Results and Discussion:** There was a significant negative correlation between the peak DOMS score and isometric maximum strength changes immediately after exercise and 4 days later in the 110-condition ($p < 0.05$). There was also a significant positive correlation between the peak DOMS score and thigh circumference changes immediately after exercise and 4 days later in the 110-condition ($p < 0.05$). There were no significant changes in the peak DOMS and muscle damage indices in the 90- and 130-conditions. This suggests that DOMS and muscle damage indices do not always match. DOMS was rapidly expressed and slowly subsided in the 90- and 130-conditions. Muscle soreness immediately after and 12 h after exercise was significantly higher in the 90- and 130-conditions in comparison with the 110-condition. These results suggest that DOMS was suppressed during the stair descending exercise with a cadence of 110 steps/min. **Conclusion:** This study revealed that the stair descending exercise burden on the lower limbs is reduced when the cadence is 110 steps/min. BODY HEIGHT AFFECTS INCREASE IN ARTERIAL STIFFNESS FOLLOWING ACUTE RESISTANCE EXERCISE

TAGAWA, K., RA, S.G., SAWANO, Y., YAMAMOTO, K., YOSHIKAWA, T., MAEDA, S.

University of Tsukuba

Introduction The increase in arterial stiffness is an independent risk factor for future cardiovascular disease (Safar and London. 2000). Resistance training is recommended to increase muscle strength and mass (American College of Sports Medicine. 2009). However, it has been reported that resistance exercise increases arterial stiffness (Devan et al. 2005). Recently, it has been reported that lower body height is related to a higher risk in cardiovascular morbidity and mortality compared with tall individuals in the meta-analysis (Paajanen et al. 2010). The purpose of this study was to investigate whether body height affects change in arterial stiffness following acute resistance exercise. We hypothesized that lower body height emphasizes increase in arterial stiffness following acute resistance exercise. **Methods** Nine healthy men (age, 24.9 ± 1.5 years) performed five sets to exhaustion at intensity of 80% of one repetition maximum for unilateral biceps curl. Blood pressure (SBP, MBP and DBP), heart rate (HR) and carotid-femoral pulse wave velocity (cfPWV; index of aortic arterial stiffness) were assessed before exercise, immediately after exercise, and 30 min after exercise. **Results** There were no changes in blood pressures and HR during experiment. The cfPWV significantly increased only 30 min after exercise ($p < 0.001$). Body height was associated with the change in cfPWV following 30 min of resistance exercise ($r = -0.67$, $p < 0.05$). Moreover, the multivariate stepwise linear regression analysis revealed that body height independently related to the change in cfPWV following 30 min of resistance exercise ($\beta = -0.67$, $p < 0.05$). **Discussion** Previous study reported that lower body height is related to a higher risk of cardiovascular morbidity and mortality compared with tall individuals (Paajanen et al. 2010). This study showed that body height affects the change in arterial stiffness following acute resistance exercise. We firstly suggest that high body height suppresses the increase in aortic arterial stiffness following resistance exercise. **Conclusion** The present study suggests that high body height suppresses the increase in aortic arterial stiffness following acute resistance exercise. EFFECT OF NANO-PLATINUM HARMONIZED FIBRES ON RECOVERY AFTER TRAINING

ZINKE, F., BAKENECKER, P., HAHN, D.

Ruhr-University Bochum

Introduction There is a wide but also controversial range of recovery strategies so that none of them is generally accepted. Quite differently to the common strategies the clothing manufacturer VENEX implemented nano-platinum harmonized technology (PHT) fibers containing DPV567-F into their clothes called recovery wear. DPV567 demonstrated T-cell proliferation (Ghoneum et al. 2014) and is assumed to increase parasympathetic activity when wearing PHT containing clothes. Thus, the purpose of the study was to investigate the effect of recovery wear on performance parameters, Creatinkinase activity (CK) and subjective pain intensity (PI), regeneration-condition (RC) and sleep quality perception (SQ). **Method** In a cross-over design 14 strength trained males performed two training sessions including 200 maximal jumps in the morning and ten sets of squats with the 10 repetition maximum in the afternoon. Performance testing (CMJ, Drop Jump (DJ), maximum voluntary contraction (MVC) of the knee extensors), CK, PI, RC and SQ were done before the first training, after first training, before second training, after second training and 24, 48 and 72 hours after first training. The participants had to wear either recovery wear (R) or a placebo product (P) during one hour after first training and during the 3 nights after the training day. A 6 week washout phase was in between the two testing blocks. **Results** Since this is an ongoing study the preliminary results are based on 10 subjects that completed both testing blocks yet. Compared to baseline before the training sessions all performance parameters (CMJ, DJ, MVC) showed a significant decrease after both training sessions (MVC decrease $22\pm13\%$ (R) and $33\pm10\%$ (P); $p<0.05$), but no difference was observed between groups (R vs. P), neither for fatigue nor for recovery. However, we found significantly reduced subjective pain intensity in the R-Group 5 ± 1 (24h) and 6 ± 2 (48h) compared to the P-Group 7 ± 1 (24h) and 7 ± 2 48 hours after training (scale 1-10). Similarly, compared to P-Group 3 ± 2 (24h), 3 ± 2 (48h) and 5 ± 2 (72h), subjective RC was significantly improved in the R-Group 4 ± 2 (24h), 5 ± 2 (48h) and 7 ± 1 72 hours after training. Finally, the R-Group 8 ± 1 reported better SQ in the third night after training in comparison to P-Group

(7±2). Discussion Due to lacking differences between groups concerning the performance testing it is assumed that there is no immediate effect of the PHT wear on recovery from training induced fatigue. On the other hand subjective ratings demonstrated an effect towards recovery wear and especially SQ showed a difference in the third night after training. This might indicate that the PHT recovery wear needs some time to have a meaningful effect on performance. References Ghoneum M, Pan D., Katano H. (2014). JSM Nanot & Nanom, 2(2), 1031. DOES THE HEALTH PROMOTION PROGRAM SKIPPING HEARTS HAS A LONG-TERM EFFECT ON SPEED AND SPEED-STRENGTH IN CHILDHOOD AND ADOLESCENCE?

ENGL, T., THOMANDL, L., MEYER, M., POSTLER, T., HOFMANN, H., OBERHOFFER, R., SCHULZ, T.

Institute of Preventive Pediatrics

Motor skills of children decreased in the last years as a result of physical inactivity. Therefore, intervention approaches with the objective of improving good basic motor skills are getting more and more important. One of these approaches is the health promotion project "Skipping Hearts", which was evaluated in 2012/13 (N=1493) and showed short-term positive effects on basic motor skills (Oberhoffer et al., 2015). Although many intervention programs are published only a few long-term studies can be found. Thus, the aim of this survey was to find out whether there is a long-term effect in speed and speed-strength. 191 children (Age t3 in years: CG: 12,1±0,1; SH-B: 12,1±0,1; SH-CH: 12,1±0,1 / height t3: CG: 153,5±1,3 cm; SH-B: 155,0±0,8 cm; SH-CH: 155,0±1,2 cm / weight t3: CG: 43,0±1,8 kg; SH-B: 43,4±0,8 kg; SH-CH: 44,3±1,3 kg) of the skipping hearts population were included in a third measurement (t1 initial examination; t2 after 4 month; t3 after 3 y). 97 children received a 90 minutes Basic Workshop (SH-B), 55 the Champion Program (SH-CH) with additional 10 units (à 45 minutes), respectively. The remaining 39 children served as a control group (CG). The 20-meter sprint (time in sec), countermovement jump (cm); height in cm), standing long jump (distance in cm) and tapping (number of foot contacts in 4 seconds) were used as examination parameters. Statistical analysis was performed with a two-way repeated measures ANOVA. Every group improved after 3 years in 20-meter sprint (t1/t3 : CG 4,10±0,05 sec / 3,68±0,04 sec; SH-B 4,01±0,03 sec / 3,61±0,21 sec; SH-CH: 4,12±0,05 sec / 3,76±0,05 sec, cmj (t1/t3: CG: 21,72±0,51 cm / 26,64±0,80 cm; SH-B: 21,95±0,41 cm / 25,71±0,47 cm; SH-CH: 19,81±0,61 cm / 25,28±0,71 cm), standing long jump (t1/t3: CG: 123,34±2,58 cm / 162,18±3,20 cm; SH-B: 126,56±1,91 cm / 157,58±2,02 cm; SH-CH: 117,44±3,15 cm / 148,87±4,00 cm) and tapping (t1/t3 CG: 20,73±0,71 / 28,87±0,57; SH-B: 21,94±0,53 / 28,51±0,54; SH-CH: 21,94±0,53 / 28,51±0,54). The statistical analysis showed significant differences between the groups concerning standing long jump and tapping. The health promotion project "Skipping Hearts" seems to have only short-term effects on motor skills like speed-strength in childhood and adolescence. The missing long-term effect can be explained physiologically. Clearly, the amount of training in the defined time period does not result in physiological improvements in the body unless a change in behavior patterns can be achieved. Therefore, in the long run intervention programs should focus more on the change of behavior patterns. Oberhoffer R, Schulz T, Postler T. (2015). Dtsch Z Sportmed., 66, 175. CHANGES IN RELATIVE EXERCISE INTENSITY DURING A TWO HOURS ENDURANCE RACE USING A TANDEM-BICYCLE FOR EXERCISE

ONODERA, S.1, HAYASHI, S.2, WADA, T.3, YOSHIDA, N.3, TAMARI, Y.3, MURATA, M.3, YAMAGUCHI, H.4, YOSHIOKA, A.5, KATAYAMA, K.6, OGITA, F.7

1Kawasaki University of Medical Welfare, 2Fukuyama Heisei University, 3Graduate School, Kawasaki University of Medical Welfare, 4Kibi International University, 5Okayama University, 6Nagoya University,

Background: It was reported that the exercise intensity of the front saddle of a tandem bicycle was greater than the rear saddle. We verified this theory by evaluating a 2-h endurance tandem race. The purpose of this study was to compare the relative exercise intensity of the front and rear saddles. Methods: Two healthy male subjects (front saddle: age, 23 years; height, 173 cm; body weight, 80 kg; and peak oxygen uptake, 43.9 ml/kg/min and rear saddle: height, 161 cm; body weight, 72 kg; and peak oxygen uptake, 45.1 ml/kg/min) volunteered for this study. They performed ten laps around a 3.7-km track. In the race, the rated perceived exertion (RPE), heart rate, blood pressure, and rectal temperature were measured every three laps. Urinary catecholamine (adrenalin, noradrenalin, and dopamine; creatinine correction) was measured before and after the race. The relative exercise intensity was calculated as the average heart rate of one lap. The ambient air temperature was 5°C and humidity was 57%. Results and Discussion: The mean speed of one lap was 21.9 km/h. In the front and rear saddles, the mean heart rate was 152 ± 2 bpm and 139 ± 7bpm, relative oxygen uptake (%VO₂peak) was 77.6 ± 5.8% and 72.6 ± 5.8%, RPE was 14.0 and 13.3, blood pressure was 154/74 ± 14/5 mm Hg and 150/70 ± 5/1 mm Hg, and rectal temperature was 38.4 ± 0.3°C and 38.1 ± 0.2°C, respectively. Urinary adrenalin, noradrenalin, and dopamine in the front saddle before the race were 13.9, 97.7, and 330.0 ng/mg Cr. After the race, these levels were 27.2, 169.3, and 355.2 ng/mg Cr. In the rear saddle before the race, levels were 15.9, 152.8, and 797.2 ng/mg Cr. After the race, they were 24.2, 168.3, and 632.9 ng/mg Cr. In the front saddle, the mean values of all measured variables were successively higher compared to the rear saddle during the tandem race. The difference between the front and rear saddle was about 6% of relative exercise intensity, and these differences were because of the handle, brake, and gear operations and wind pressure. Conclusion: The relative exercise intensity of the front saddle was higher than that of the rear saddle during the 2-h tandem race. [The Ministry of Education, Culture, Sports, Science and Technology, Grant-in-Aid for Scientific Research (15K01509)]

IS HIGH-INTENSITY INTERVAL TRAINING ASSOCIATED WITH HIGHER DROPOUT?

RELIĆ, D.

University of Heidelberg, Medical Faculty Mannheim

INTRODUCTION: Regular exercise is known to prevent cardiovascular disease and a wide range of other health problems, yet a large proportion of adults in European countries are insufficiently active with 25-50% of individuals dropping out of an exercise program within the first six months [2]. Given that lack of time is the most common barrier to exercise, time-efficient exercise interventions are needed. High-intensity interval training (HIT) is a useful strategy and has been demonstrated to improve fitness and health parameters with substantially lower time effort compared with traditional continuous aerobic training. However, HIT may be inappropriate for sedentary individuals given its strenuous character [1,3]. Due to a lack of data on dropout in HIT-studies, this study assessed HIT-intervention trials with sedentary individuals that reported dropout. METHODS: Electronic databases (MEDLINE, PubMed, Google Scholar) were searched for research articles published from 2000-2015. Inclusion criteria were sedentary/untrained individuals or subjects with or without known

cardiovascular disease/risk factors, aged >18 yrs, trial duration ≥3 weeks, information on dropouts/completers and a detailed description of the HIT-protocol. Dropout was defined as the proportion who completed the study. Associations were assessed by Spearman correlation coefficients. RESULTS: 52 studies (mean duration: 9.5±4.5 weeks) with 898 subjects (mean age: 43±17 yrs) were included in the analysis. Mean dropout rate was 9.3%. Dropout was associated with longer session time ($p=0.36$, $P<0.05$), exercise volume/week ($p=0.33$, $P<0.05$), total exercise volume/study ($p=0.50$, $P<0.001$) and study duration ($p=0.45$, $P<0.001$). Dropout was greater in studies using treadmill/running protocols (12.7%) compared to cycle-protocols (6.1%, $P<0.05$). Participant age and exercise intensity were not associated with dropout. CONCLUSION: Dropout in HIT appears to be lower compared to traditional exercise programs. Given the association between HIT-volume and dropout rate, future studies should identify the minimally effective dose of HIT needed to improve health status. Such efforts would be important to increase sustainability and public health impact. REFERENCES: 1)Biddle SJ, Batterham AM (2015). VALIDITY OF THE FITBIT CHARGE HR AND GARMIN FORERUNNER 225

CLAES, J., AVILA, A., BUYS, R., COOL, H., SEGERS, A., CORNELISSEN, V.

KU Leuven

Introduction The amount of multi-component sports and physical activity watches available on the consumer market is rising dramatically due to an increasing awareness of the benefits of physical activity (PA) for health. As the modalities of PA determine the effect on all-cause mortality, an adequate measurement of PA is needed to guide PA behavior. Therefore we aimed to evaluate and compare the validity of two different commercially available PA devices: Fitbit Charge HR and Garmin Forerunner 225. Methods Eighteen healthy adults (n=13 females) aged 18-40 years performed a predefined treadmill protocol twice. First, a familiarization session to determine the walking speeds needed to achieve moderate and high exercise intensities. Second, a 50 minute session consisting of 5' sitting, 5' standing, 10' walking at 4 km/h, 10' walking at an intensity of 4-6 METs and 10' walking at an intensity of ≥7 METs. Each walking bout was separated by a standardized rest period. During the session, participants wore a Jaeger Oxycon Mobile for breath-by-breath analysis to allow calculation of EE by indirect calorimetry (= criterion method) and a Fitbit Charge HR and Garmin Forerunner 225 on the left arm. Participants were videotaped to allow for manual counting of the steps taken during the session. Paired t-tests, Wilcoxon signed ranks tests and Bland-Altman assessment for agreement were done to compare the devices with the gold standard. Results The Fitbit HR showed no significant differences in comparison with indirect calorimetry or video analysis (207.7±25.0 kcal vs 206.4±34.6 kcal; $p=0.768$ and 3357±184 steps VS 3336±158 steps; $p=0.44$). Bias was 1.31 kcal (limits: -90.7, 93.3) and 20 steps (limits: -198, 239). There was no statistically significant difference for EE between the Garmin and the criterion method (248.5±84.01 kcal vs 206.4±34.6 kcal; $p=0.064$) whereas the estimated number of steps from the Garmin was significantly lower (2750±489 steps vs 3337±158 steps; $p<0.001$). Bland-Altman assessment resulted in a bias of 42.1 kcal (limits: -118.4, 202.6) and -587 steps (limits: -1477, 303). Discussion To our knowledge, this is the first study to evaluate the validity of these wrist worn PA devices. Our results concur with previous studies that examined the validity of other Fitbit devices and also reported accurate estimation of EE and step counts. 1.2. The Garmin Forerunner 225 seems less valid to measure accurately EE and steps. References 1. Takacs J, et al. (2014). (5):496-500. 2. Diaz KM, et al. (2015). *Int J Cardiol*. 185:138-40. DIVING AND METABOREFLEXES

TOCCO, F., MAGNANI, S., PINNA, V., SAINAS, G., PALAZZOLO, G., CORONA, F., DI GIACOMO, A., MANNONI, M., VANNI, S., GHIANI, G., CRISAFULLI, A.

Cagliari University

Introduction Diving reflex (DR) is characterized by bradycardia and vasoconstriction of selected vascular beds. The result is a reduced cardiac output (CO) with a maintained blood pressure. Conversely during exercise the peripheral accumulation of metabolic end-products caused a stimulation of group III and IV nerve-endings in involved muscles, known as muscle metaboreflex (MM), which is able to improve myocardial performance (Crisafulli et al., 2003). The aim of study was to assess hemodynamic changes during simultaneous activation of MM and DR in a laboratory setting. Methods A group of trained divers underwent the following protocol randomly assigned: A)Post-exercise muscle ischemia session (PEMI): 3 min of resting followed by 3 min of arm cranking exercise at 30% of Wmax, followed immediately by 3 min of PEMI on the same arm induced by inflating a tourniquet to 200 mmHg. 3 minutes of recovery was further allowed after the cuff was deflated, for a total of 6 minutes of exercise recovery. B) Control exercise recovery session (CER): the same rest-exercise protocol used for A followed by 6 min of recovery without inflation. C) DR session: the same rest-exercise protocol used for A followed by 1 min of breath-hold (BH) with face immersion in cold water. D) PEMI-DR session: the same protocol used for A with 60 seconds of BH with face immersion in cold water during the first minute of PEMI. SV, heart rate (HR) and CO were collected by means of impedance method. Mean blood pressure (MBP) and systemic vascular resistance (SVR) were also calculated. Differences among conditions were studied by means of the analysis of variance (ANOVA) for repeated measures. Results At the end of apnoea HR was decreased in condition C and D respect to A (-38.8% and -33.7% vs. +8.7%; $p<0.05$). Since SV increased at the same time point (C=+57.6% and D=+41.1% vs. A=+12.8; $p<0.05$) thus CO decreased during C and D and rose in A (-6.1% and -6.2% vs.+25.2% respectively; $p<0.05$). The outcome was a substantial maintaining of MBP. Conclusion Results addressed to the hypothesis that DR overrode the MM in our setting. This outcome is quite different by findings of Tocco et al. (2012) who found a particular cardiovascular response in the second phase of simulated dynamic apnoeas when a delayed increase in myocardial performance and SV occurred and obscured the cardiovascular effects of the DR. Further researches are desirable to clarify hemodynamics during simultaneous diving and exercise. References

COMPARISON BETWEEN TWO DIFFERENT METHODS TO ASSESS STROKE VOLUME DURING DRY STATIC APNOEA

MAGNANI, S., MULLIRI, G., SAINAS, G., GHIANI, G., PINNA, V., SANNA, I., CRISAFULLI, A., TOCCO, F.
university of cagliari

Introduction During apnoea the sympathetic and parasympathetic components of nervous system work simultaneously to achieve a hemodynamic response called diving response (DR). Classically, DR leads to bradycardia and vasoconstriction of selected vascular beds. The result is a reduced cardiac output (CO) with a maintained blood pressure. Considering that stroke volume (SV) changes during apnoea have been poorly investigated in the past, we set this study to estimate SV by means of two indirect methods in elite divers performing dry static apnoea. Methods Sixteen elite divers (8-Females) were enrolled during the AIDA team world championship 2014. Each diver performed 3 minutes of eupnoea (REST), followed by breath-hold (BH) in air until reaching physiological break-point and 3 minutes of recovery. Hemodynamics during rest and immediately after BH in air (REC) was assessed by means of simultaneous echocardiography and impedance cardiography (IC). Echocardiographic evaluation of SV (SVE) were obtained by subtracting end systolic volume (ESV) to end diastolic volume (EDV). Impedance and ECG recorded traces were analyzed employing a digital chart recorder and processed to calculate SV (SVI). The method is described in detail in previous work (Crisafulli et al., 2008). SV values obtained with the two methods were compared by means of two-way ANOVA. Moreover, the Bland and Altman (1986) plot was carried out to estimate agreement between methods. Results Two-way ANOVA revealed no differences between IC and echocardiography measurements (59.94 ± 12.12 vs. 60.01 ± 11.1 at REST and 59.75 ± 13.01 vs. 56.15 ± 10.76 at REC respectively, $p > 0.05$). The Bland and Altman plot showed that the 95% limits of agreement (SVI-SVE) were within +26.04 and -25.9 ml at REST and +42.6 and -35.2 ml at REC. Discussion Bland-Altman plot analysis suggests an acceptable measurement agreement between the two methods at REST (Bias 0.07), instead results were more ambiguous at REC. Actually, limits of agreement were wide and the average of the differences was not close to zero (Bias 3.68). Disagreement at REC probably is determined to the difficult to take echocardiography imagines immediately after the BH. HISTORY AND APPLICABILITY OF THE LACTATE SHUTTLE HYPOTHESIS

BROOKS, G.
University of California

Introduction For almost a century lactate has been regarded as a dead-end metabolite, a fatigue agent and the product of oxygen-limited (anaerobic) metabolism. As the 1970's approached, sophisticated biochemical analyses and isotope tracer technology were introduced into studies of physiology and metabolism and new thinking affected articulation of the Lactate Shuttle (LS) hypothesis (Brooks 1984, Brooks 2009). Methods Assays of lactate concentrations in exercising rodents showed white muscle [lactate] > arterial [lactate] > white muscle [lactate] (Baldwin et al 1977). Radiotracer studies on exercising rats showed lactate production and oxidation to significantly exceed glucose disposal owing to the role of muscle glycogen. Studies with stable isotope tracers on resting and exercising humans confirmed results on rats and other mammals. The major effect of training was to improve lactate clearance via oxidation, although lactate was the main gluconeogenic precursor (Messonnier et al 2013). Western blotting, immunoprecipitation and confocal, laser-scanning microscopy showed the presence of lactate transporters (MCTs) in plasma and mitochondrial membranes (Hashimoto et al 2007). Measurements metabolite exchange across working muscles (Bergman et al 1999) and brains (Brooks and Martin 2014) showed simultaneous uptake and production of lactate, but not glucose. Results Lactate fluxes down concentration and pH gradients owing to presence of a mitochondrial lactate oxidation complex (mLOC). Realization that lactate was a major metabolic fuel and gluconeogenic precursor led to lactate polymers being included in sports drinks and strata for the incubation of stem cells. LS theory has been incorporated into cancer research where disrupting cell proliferation and tumor growth by blocking MCTs is being evaluated. And, in the field of neurobiology and critical care medicine the use of lactate to provide direct (oxidative) and indirect (gluconeogenic) support to traumatic brain injury (TBI) patients (Brooks and Martin 2014). Discussion Although controversial at its inception the LS Concept has survived intellectual and experimental scrutiny. Understanding the LS is key to understanding metabolic regulation. HEART RATE RESPONSE AND LACTATE ACCUMULATION IN JUNIOR HANDBALLERS DURING ION TRIAL MATCH PLAY

GUPTA, S., GOSWAMI, A.
University of West Indies, Faculty of Medical Sciences

Introduction Handball is a high intensity team game, mostly dependent on aerobic metabolism but interspersed by fast running, jumping, and throwing the ball that greatly tax anaerobic metabolism. Heart rate response considered as the best indicator of cardiovascular stress whereas lactate accumulation may give an idea about the metabolic demand of the game. Methods Thirteen junior (U18) Indian handballers were the participants of this study. VO_{2max}, maximal heart rate (HR_{max}), and heart rate at lactate threshold (HRLT) were determined on treadmill by graded exercise protocol. HR was continuously recorded by telemetry at an interval of 5 s, throughout the match. Fingertip blood samples were collected at 15 min, 30 min, 45 min, and 60 min of the match. Data were collected from 4 selection trial matches. Each match was played in two halves (30 min x 2), separated by 10 min interval. Results VO_{2max}, HR_{max}, and HRLT of the handballers (n=13) are 51.6 ± 3.9 ml/kg/min, 199.3 ± 4.1 beats/min, and 172.3 ± 7.4 beats/min respectively. Mean HR of BACK are significantly higher than PIVOT in both the halves of the matches. However, no significant difference was found between 1st and 2nd half of the matches. BACK spent nearly 20% of the total time of match play above the lactate threshold level, which is significantly higher than PIVOT (13.1%). Mean HR for each 5 min of play may vary widely from 149.1 to 169.8 beats/min during the game but such variation does not exist for every 15 min of play (159.1 to 163.5 beats/min). Blood lactate levels of BACK are higher than PIVOT at 30 min, 45 min, and 60 min, although only 45 min value is significantly higher. Peak HR (191.6 ± 4.1 beats/min) of the subjects attained during match play was significantly less than their HR_{max} (172.3 ± 7.4 beats/min). Discussion Although intermittent and high-intensity in nature, handballers, in majority

of the time, play in the low-intensity zone such as low-intensity running, walking or jogging (Povoas et al., 2012, Karcher and Buchheit, 2014). Longer sprints and distance covered by BACK, than PIVOT, is responsible for higher mean HR in BACK. This may also be responsible for higher lactate accumulation in BACK. Frequent sprints, jumps, and throw for defense and attack allow BACK to play more time above the HRLT intensity when compared to PIVOT. Probably, the total number of attacks by both the teams, sprints, slow movements, jumps and throws are fairly equal in each 15 min of play but vary widely for each 5 min of play. Cardiovascular stress in handball, not even occasionally, reaches its tolerance limit References Povoas SC, Seabra AF, Ascensao AA, Megalhaes J, Soares JM, Rebelo AN. (2012). *J Strength Cond Res* 26(12), 3365-3375. Karcher C, Buchheit M. (2014). *Sports Med*, 44(6), 797-814. Email: subirgupta@yahoo.com

DIFFERENCES IN PHYSIOLOGICAL VARIABLES IN ELITE WRESTLERS

RUBIO DEL CASTILLO, E., CASTRO, E.A., PEINADO, A.B., BUTRAGUEÑO, J., ROMERO, N., BENITO, P.J.

Polytechnic University of Madrid

Introduction Previous studies have discussed the differences in lactate (LH) before and after bouts of Free Wrestling and Greco-roman Wrestling (Kraemer, Fry et al., 2001; Nilsson, Csergö et al., 2002; Karninčić, Tocilj et al., 2009; Barbas, Fatouros et al., 2011; Chino, Saito et al., 2015). Nevertheless, few studies have investigated the variation in aerobic characteristics (Yoon, 2002). The aim of this study was to compare Free Wrestlers and Greco-roman Wrestlers during recovery, specifically investigating the LH and aerobic variables. Methods Twenty-three elite male wrestlers, 113 Free Wrestlers (FW) and 10 Greco-roman Wrestlers (GRW), body weight 60–120 Kgl, participated in the present study. Blood samples were taken all in the first, third and seventh minute of recovery. Also, aerobic variables were controlled during the recovery period. Student's t test were utilized to compare means between FW and GRW Results The results of this study did not show any significant differences in LH, maximum oxygen consumption, maximum carbon dioxide production, maximum ventilatory rate, rating expenditure rate and breath frequency between Free Wrestlers and Greco-roman Wrestlers ($p>0.05$). Discussion To our knowledge, there is currently no literature investigating the differences in LH and aerobic variables in recovery between FW and GRW. Few articles discuss the differences in physical fitness between these two modalities, achieving significant results only in certain tests (Demirkhan, Kutlu et al. 2014). Others compare recovery in other modalities; some authors found differences in LH peak and in LH recovery between long distance, sprint and middle distance athletes (Bret, Messonnier et al. 2003; Vučetić, Možek et al. 2015). Additionally, LH peak and LH recovery were different between karate athletes of distinct levels (Ravier, Dugue et al. 2006). However, our results did not show differences in LH and aerobic variables recovery between the two modalities of wrestling, this could be due the modalities studied being similar in time and technique. LH variation appeared between the modalities when duration differences were significant. References Barbas I, et al. (2011). *Eur J Appl*, 111(7): 1421-1436. Bret C, et al. THE PHYSIOLOGICAL PROFILES OF SAUDI ELITE JUDO ATHLETES

ALAHMADI, M.A.

King Saud University

One of the most highly physiologically demanding combat sports is Judo, which requires an excellent level of physical fitness in order to be successful in international competitions. Therefore, the aim of this study was to assess the physiological profiles of Saudi elite judo athletes. 14 judo athletes (mean \pm SD, age, 17 \pm 4 years; body mass, 66.7 \pm 21 kg; height, 160.2 \pm 13.6 cm) performed the Special Judo Fitness Test (SJFT) and a maximal multistage 20-m shuttle run test to estimate maximal oxygen consumption (VO_{2max}). Body fat percentage (BF%) was determined by bioelectrical impedance scale. Hand grip strength was measured by hand grip dynamometer and flexibility was determined by using Sit-and-Reach Test. The mean (\pm SD) of the index of the SJFT and VO_{2max} were 16.2 \pm 1.6 and 42.5 \pm 8.5 (ml/kg/min), respectively. The mean (\pm SD) of BF%, hand grip strength, and flexibility were 24.1 \pm 7.2 (%), 31.4 \pm 11.5 (kg), and 34.6 \pm 6.7 (cm), respectively. It is concluded that the SJFT was lower and BF% was higher in Saudi Judo athletes, compared to international elite Judo athletes.

ROLE OF ATP INFUSION IN POST-EXERCISE FOREARM VASCULAR CONDUCTANCE RECOVERY

PEINADO, A.B.1, RANADIVE, S.M.2, SHEPHERD, J.R.A.2, DINENNO, F.A.3, CURRY, T.B.2, JOYNER, M.J.2

1: Technical University of Madrid (Spain), 2: Mayo Clinic (Rochester, USA), 3: Colorado State University (Fort Collins, USA)

Introduction Adenosine receptors appear to have a role in the post-exercise attenuation in cutaneous blood flow (McGinn et al., 2014). However, there is limited data evaluating the effect of exogenous administration of adenosine (ADO) and adenosine triphosphate (ATP) on the recovery forearm blood flow after moderate intensity exercise. The aim of this study was to evaluate the influence of ATP and ADO infusions on post-exercise blood flow during the first minute of recovery. We hypothesized that exogenous administration of ADO and ATP would accelerate the decrease in post-exercise muscle blood conductance. Methods Forearm blood flow (FBF) was measured using Doppler ultrasound during brachial artery ATP ($n=9$; 30.1 \pm 4.4 years) and ADO ($n=9$; 29.4 \pm 4.4 years) infusions. Participants performed a rhythmic handgrip exercise at 20% of the maximal voluntary contraction for four minutes. Rest and exercise trials were performed under saline infusion (saline) to serve as the control. During the ATP and ADO infusions measurements were recorded at minute 5 (trial 1), 30, 60, 120 and 150 (trial 5). FBF (ml•min⁻¹) was determined from the simultaneous measures of brachial artery mean blood velocity and diameter. Forearm vascular conductance (FVC; ml •min⁻¹•100mmHg⁻¹) was calculated. Results ATP infusion increased significantly FBF and FVC at trial 1 (541.96 \pm 36.14; 606.61 \pm 42.05, respectively) and 5 (559.08 \pm 61.43; 595.73 \pm 74.43, respectively) compared to saline (280.51 \pm 47.81; 309.5 \pm 50.29, respectively) during the first minute of recovery. The recovery slopes calculated as percentage of the maximum value of FBF during ATP versus saline infusion were -0.35 \pm 0.23 (trial 1), -0.89 \pm 0.18 (trial 5) vs. -1.05 \pm 0.11. The slopes of FVC were -1.09 \pm 0.07 (saline), -0.38 \pm 0.20 (trial 1) and -0.97 \pm 0.21 (trial 5). The slopes of FBF and FVC were similar between saline and trial 5 ($p>0.05$), while trial 1 was significantly lower compare to saline ($p<0.05$). FBF and FVC during ADO infusion were similar among trial 1, trial 5 and saline during the first minute of recovery. The recovery slope of FBF (-0.75 \pm 0.15, -0.53 \pm 0.11, -0.75 \pm 0.18, respectively) and FVC (-0.88 \pm 0.20, -0.55 \pm 0.07, -0.85 \pm 0.17, respectively) calculated as percentage of the maximum value was similar among saline, trial 1 and trial 5. Discussion Even though the adenosine receptors play a major role in cutaneous vascular conductance post-exercise, our results show that ADO does not have significant effects on the post-exercise FVC recovery. However, ATP seems to play a role in post-exercise FVC during recovery. References McGinn R, et al. (2014). *J Physiol*, 592(12), 2667-2678. Contact: anabelen.peinado@upm.es

LOWER LIMB AND ENERGY EXPENDITURE DURING CONSECUTIVE DAYS OF A MILITARY LOAD CARRIAGE TASK

SCALES, J., BROWN, M., COLEMAN, D.

Canterbury Christ Church University

Introduction During military exercises, moderate intensity exercise accompanied by heavy load carriage may last for prolonged periods of time (>2hrs), with tasks which may take place over repeated days (Blacker et al, 2010). The energy expenditure of the task and localised muscle fatigue needs to be considered as they are both potential factors which could determine performance outcomes, according to conventional endurance exercise models. The aim of this study was to investigate the relationship between lower limb performance and changes in estimated energy cost of heavy load carriage over consecutive days of exercise. Methods Fourteen participants (8 males: 88.8 Kg \pm 16.8 Kg, 188.72cm \pm 8.5cm; 6 females: 63.4kg \pm 12kg, 164.2 cm \pm 8cm) walked on a level treadmill carrying 32kg across webbing, backpack and rifle, at a speed of 5.4km·h⁻¹ for two hours on two consecutive days. During trials respiratory gases were assessed (Oxycon Pro: Germany) and used to estimate energy expenditure of the task at 30 minute intervals. Peak torque (PT) of lower limbs was assessed pre and post load carriage on day one and day two using isokinetic dynamometry (Biodes System 4, USA) for plantar and dorsi flexion (assessed at 0, 120, 60 °·s⁻¹) and for knee flexion and extension (assessed at 0, 180, 60 °·s⁻¹). Results Estimated energy expenditure at 30 minutes on day 1 equated to ~42 kJmin⁻¹ this value increased by ~5% when compared at the same period on day 2. The end of day 2 was 12% higher than the end of day 1 ($P<0.05$). From the start of the protocol to the end of day 2, significant reductions in PT (range 10-29%) were observed in ankle dorsi-flexors at 60 and 120°·s⁻¹ and knee flexors and extensors at 60 and 0°·s⁻¹. These changes were significantly related to changes in energy expenditure during the two day task; dorsi flexors at 60 ($r=-0.68$; $p<0.05$) and 180°·s⁻¹ ($r=-0.748$; $p<0.05$), knee extensor ($r=-0.6$ and -0.76; $p<0.05$) and flexor ($r=-0.65$ and -0.676; $p<0.05$) at 0°·s⁻¹ and 60°·s⁻¹ respectively. Discussion Two consecutive days of heavy load carriage resulted in substantial decreases in peak torque in specific lower limb muscle groups. These changes were associated with increased energy demands of the task. These findings could help to identify a conditioning strategy associated with economical movement under load carriage conditions. Moreover this could have implications for injury prevention in a military cohort. References Blacker, S.D., Fallowfield, J.L., Bilzon, J.L. and Willems, M.E., 2010. Neuromuscular function following prolonged load carriage on level and downhill gradients. Aviation, space, and environmental medicine, 81(8), pp.745-753. Contact j.scales895@canterbury.ac.uk

PERIODISED AND NON-PERIODISED TRAINING FOR MARATHON RACING BY MILITARY CADETS

JONGERIUS, N.1, HAVENETIDIS, K.2, KARDARIS, D.2, NANAKIS, A.2, BISSAS, A.1

1: Leeds Beckett University (UK), 2: Hellenic Army Academy (Greece)

INTRODUCTION Resistance training practices using periodisation models have shown to elicit better results compared to non-periodised resistance training (Prestes et al., 2009). However, there is lack of scientific information regarding the use of periodisation models on cardiorespiratory endurance performance. Thus, the purpose of this study was to compare periodised and non-periodised training by military cadets aiming at participation in the same marathon event. METHODS One hundred and fifteen (115) male military cadets (matched for marathon race time) with (mean \pm SD of age, height and body mass: 21.3 \pm 1.8 years, 177.0 \pm 6.0 cm and 72.1 \pm 6.4 kg respectively) were randomly divided into five groups (n=23 for each group). The linear periodised (LP), reverse linear periodised (RLP), block periodised (BP), non-periodised intensity focussed (NPI) and non-periodised volume focussed (NPV) group. The training programme was carried out five days per week for a period of ten weeks and involved various forms of running (low-pace, cross-country, intense) and a standardised resistance training program. Training volume was also recorded for each group. Following training all military cadets participated in a marathon race and time was recorded via a BibTag (MYLAPS, NL) timing system. RESULTS Analyses of variances showed a significant effect of group on post-pre marathon time difference (Mdif) ($p=0.001$). Post-hoc revealed Mdif to be significantly different in the NPV group (Mdif=1.6 \pm 5.2) compared to the BP (Mdif=-5.0 \pm 5.7; $p=0.001$) and RLP (Mdif=-3.6 \pm 4.9; $p=0.015$) groups. All other between group comparisons showed no significant results. A significant relationship existed between the average weekly training involving intense running and Mdif ($r=-0.242$; $p=0.009$). More specifically, the average amount of intense running over the first 5 weeks of training correlated to Mdif ($r=-0.268$; $p=0.004$) rather than the average amount of intense running during the final 5 weeks ($p=0.256$). Once corrected for average intense running in week 1-5, the significance of the group effect on Mdif was reduced ($p=0.049$). DISCUSSION BP and RLP training showed to be the most effective periodisation strategies for improving marathon race performance in a group of military cadets. The amount of time spent at high intensity during the first 5 weeks of this 10 week program seems to be the main factor causing the group effect. This study therefore suggest that a large body of intense running should be scheduled in the early period of training before the event using a block periodised or reversed linear periodised training schedule. Mini-Orals**MO-BN06 Motion Analysis 1****ACCURACY OF JOINT ANGLES USING MARKERLESS SILHOUETTE-BASED TRACKING AND HYBRID TRACKING VS. TRADITIONAL MARKER BASED TRACKING**

BECKER, L.1, RUSS, PH.2

1University of Magdeburg, 2Simi Reality Motion Systems

Introduction Markerless tracking is seen as a potential method to make movement analysis quicker, simpler and better available in many different areas of biomechanical application. Since this technology is still new in the fields of sports, markerless systems have to be evaluated for sufficient accuracy to serve as a valid tool. Therefore, the aim of this study was to assess the accuracy of the new silhouette-based tracking software "Simi Shape" for markerless and hybrid tracking versus traditional marker based tracking. Methods Specific joint movements and complex sports movements have been analyzed simultaneously using marker, silhouette and hybrid tracking (silhouettes + markers). Angles of shoulder, elbow, hip, knee and ankle joint have been compared using the three different methods by means of Spearman correlation coefficient and standard deviation of angle difference. In case of insufficient results based solely on measurements with markerless tracking, hybrid tracking solutions have been assessed additionally. Results Markerless tracking shows highly

accurate results for knee, ankle and shoulder movements in the sagittal plane ($r_s = >0.9$). Using hybrid tracking comparable results could be achieved for all angles in all planes. Reasons for accuracy problems based on markerless tracking have been identified to occur mainly if segment rotations do not cause the silhouette to change. In this case hybrid markersets have been provided to improve the accuracy of these segment rotations. Discussion The results of this study indicate markerless and hybrid tracking to be efficient methods in terms of accurate joint angle data assessment, which present a promising technology in areas of sports and medical motion analysis. As this study only compared markerless/hybrid data with marker data for one single subject, further research should provide more information about methodological difficulties concerning intra- and inter-tester reliability in-between and between days using the different methods. As no accurate marker placement is needed for markerless or hybrid tracking this method might be superior compared with marker based systems in terms of reliability. Contact: philipp@simi.com

AUTOMATED VIDEO-BASED ANALYSIS OF GAIT USING DIRECTIONALLY-GROUPED CUBIC HIGHER-ORDER LOCAL AUTO-CORRELATION

YOSHIKAWA, F.

Biwako Seikei Sport College

In kinematical analysis of human gait, motion capture technologies are commonly used. Motion capture systems are commercially available for measuring kinematical characteristics of parts of interest during a variety of activities, recording and representing the data in real time or in delayed time. However, such technologies have been often used in experimental context, but not in practical context. In recent years, on the other hand, video-based time-motion analysis employing computer vision and pattern recognition techniques have attracted a great deal of attentions by virtue of the applicability in practical context. This paper presents a model-free and marker-less video-based system for time-motion analysis of human gait. The core technology utilized in the system is a motion feature extraction method called directionally-grouped cubic higher-order local auto-correlation (DgCHLAC) and has already been proposed by the first author (2011). This method follows the preprocessing in which the input color image sequences are segmented into either 1 (moved) or 0 (static) by using the Otsu's threshold selection method. For motion recognition tasks, Kobayashi and Otsu (2006, 2009) have proposed a scheme of adaptive vision system employing cubic higher-order local auto-correlation (CHLAC) motion features. They successfully applied the proposed method to gait recognition using the NIST gait dataset which was the largest one available. Their scheme outperformed the other existing approaches in all probes at that time. DgCHLAC motion features are obtained by classifying and integrating CHLAC components into predefined directions and positioned as meta-features over CHLAC. The present method can automatically extract motion characteristics such as orientation and speed of a moving object. In addition to such functions, the method possesses the following properties: the method requires neither prior knowledge, heuristics about objects nor time-consuming computational cost, as well as CHLAC. Applying the DgCHLAC motion features, the proposed system automatically extract some characteristics, such as durations of more detailed phases in walking cycle, number of steps and displacement speed. For performance evaluation of the proposed system, some public gait datasets consisting of videos captured by a stationary camera were used. As experimental results, each phases in level straight walking automatically segmented by the proposed method were shown. The proposed method could yield preferable results in the walking scenes after stand-walk transfer. The experimental results for temporal gait characteristic extraction showed the effectiveness of the DgCHLAC method for time-motion analysis of human gait. These results present the potential prospect of our approach toward development of gait analysis systems.

ACCELERATION OF THE WEAPON HAND DISCRIMINATES BETWEEN ELITE AND NON-ELITE FENCERS

MENTZ, L.1, WEICHENBERGER, M.1, HESSLING, M.2, LIU, Y.1, STEINACKER, J.M.1

1 University of Ulm, Ulm, Germany 2 Ulm University of Applied Sciences, Ulm, Germany

Introduction Fencing is influenced by physiological determinants such as speed, endurance and strength. Movement analysis of upper and lower limbs is useful to analyze performance in fencing. Especially velocity of the weapon hand is related to the level of the fencer. Due to theoretical and methodological reasons, it seems advantageous to measure acceleration of the weapon hand. However, it is not known if acceleration is also a characteristic of top level fencers. To this end, we analyzed if acceleration of the weapon hand distinguishes between elite and non-elite fencers. Methods 31 male épée fencers of the German national team were examined. The group consisted of $n = 18$ international level (elite) and $n = 13$ national level (non-elite) fencers. The elite fencers were further divided into three subgroups, according to their national qualification outcome. 16 infrared markers of a 3D-Motion-Capture-System (AS 300, Lukotronic/Steinbichler, Austria) were attached to important landmarks of the body. Two markers at the wrist and the dorsum of the weapon hand were of interest. The system recorded movements and calculated the velocity of the weapon hand. Three different attacks were analyzed, namely touch, lunge, and flèche. A custom-built fencing dummy with 10 target areas was used during the experiment. Each attempt was triggered randomly by an optical signal of the target area by a green light. Then the fencer had to attack the target area as explosively and quickly as possible. For each attack the subjects had five attempts. By mathematical differentiation of the markers' velocity data, the acceleration of the weapon hand was obtained. Data was smoothed using a moving average filter. Results Elite fencers showed a significantly higher acceleration of the weapon hand than non-elite fencers in all three attack modes ($p < 0.001$). There was no significant difference between the three subgroups of elite fencers. The flèche proved to be the movement with highest acceleration values throughout all groups. These values were significantly higher than those of the lunge and slightly higher than the touch. Discussion The results demonstrate that acceleration of the weapon hand distinguishes elite from non-elite fencers. This is a relevant result, because acceleration is easier to be measured than velocity and is furthermore a better indicator for explosiveness and initial speed. Since acceleration of the weapon hand was not related to performance within the elite group, it remains unclear if improvements in acceleration above a certain threshold will help to improve performance. Conclusion We conclude that acceleration of the weapon hand is a determinant of fencing performance. Since it is easily to be measured, it has potential to become a part of routine performance analysis.

IDENTIFYING THE ROLE OF COCKING PHASE DURING JUMP THROWING IN HANDBALL USING 3D KINEMATIC ANALYSES

AKL, A., HASSAN, A.

Alexandria University, Mansoura University, Karl-Franzens-University Graz.

Introduction In handball throwing, acceleration phase is very important and the most researchers focused on it. Although, it depends on the cocking phase, there is a lack of research that regarding to determine the role of cocking phase during jump throwing in handball. Therefore, this study aimed to determine the role of cocking phase using 3D kinematic analyses. Methods Ten Handball players participated in this study (age: 20.8 ± 1.21 years; body mass: 82.8 ± 8.57 kg; height: 189.6 ± 8.65 cm). After 15-minute warm-up, the participants completed jump-throws from the 7-m penalty line after three running steps. A total of five successful attempts were recorded for each participant, one minute rest between attempts. The best attempt was selected for 3D analyses. Eight synchronised high-speed cameras were used at a 100 Hz frequency. SIMI 3D motion analyses system was used for capture and analyses. The 3D coordinates were the X (medio-lateral), Y (anterior-posterior) and Z (vertical) directions respectively. Results There are significant correlations between ball velocity with linear and angular kinematics (displacement, velocity, acceleration) at cocking phase more than acceleration and following phases, displacement of COM Y ($r=0.710$, $p<0.05$), velocity of COM Y ($r=0.838$, $p<0.01$), shoulder velocity ($r=0.686$, $p<0.05$), velocity of COM Y at acceleration phase ($r=0.892$, $p<0.01$). Discussion Results emphasised the role of cocking phase, according the strong correlation significant between displacement and velocity in the anterior-posterior dimension (movement direction) with ball velocity. Furthermore, the relationship of cocking displacement and velocity indicated to these contributions to increase both of displacement and velocity in the acceleration phase to gain maximum work and power. In addition, shoulder velocity is one of the important parameters that associated with the increase of ball release (Wagner et. al., 2011). References Wagner, H., Pfusterschmied, J., Duvillard, S. EFFECT OF 24 DAYS BASEBALL THROWING ON THE BALL SPEED AND KINEMATICS IN NON-SKILLED THROWER

KUBO, S.1, SUZUKI, T.2, MIYAZAKI, S.2, KINUGASA, R.2

1:The Open University of Japan, 2: Kanagawa University

Introduction For the skilled throwers, it is revealed that trunk segment twist, shoulder internal rotation, elbow extension and wrist flexion angular velocity at release contribute the translational velocity of the fingertip (VF) at the release (Hirashima 2007). On the other hand, it is unknown whether non-skilled thrower's contribution to VF (C-VF) at release of each angular velocity was similar to the skilled thrower's characteristics or not. If non-skilled thrower's characteristic of C-VF at release differ from skilled throwers, we need to capture how non-skilled throwers improve throwing performance in long term. Therefore, we investigated the ball speed, as a throwing performance outcome, and C-VF at release on novice for throwing during 6weeks throwing practice. Method One female volunteer participated in this study. As a task, the subject was required to throw a baseball 60 trial as possible as fast in a day and performed this task 24 days (4 days per week), thus, total number of throwing trials were 1440. Marker coordination data attached to subject's body and baseball were collected during throwing. The ball speed, subject's segment angular velocity and joint angular velocity was calculated from marker coordination data and then the VF at release and C-VF at release of selected angular velocity was also calculated. Results The ball speed and VF at the last throwing (1440 trial) increased approximately 50% compared to them at first throwing (1 trial). The C-VF of elbow extension angular velocity were highest of all measured angular velocity in 6 weeks. Later phase in this experiment, C-VF of angular velocity of shoulder internal rotation and trunk segment twist were higher than early phase. Discussion On the early phase, even though VF and C-VF of angular velocity of shoulder internal rotation, wrist flexion and trunk segment twist were half or less of skilled throwers, C-VF at release of elbow extension angular velocity was similar to value of skilled throwers. This result would support previous study that forceful throwing the ball of non-skilled throwers mainly use the elbow extension movement at release (Atwater 1979). In conclusion, we were able to capture the characteristics of long term change and C-VF at release on non-skilled thrower. Reference Hirashima M. Kudo K. Watarai K. Ohtsuki T. REPRODUCIBILITY OF A TENNIS SERVE PROTOCOL

TUBEZ, F., FORTHOMME, B., CROISIER, J.L., BRÜLS, O., DENOËL, V., KREMENRSCKI, A., SCHWARTZ, C.

University of Liège

INTRODUCTION Serve in modern tennis game is a real offensive weapon for players. In kinematic analysis, it is the most studied stroke of this game because it is the only stroke played in a closed skill. Players have a maximum of control on this stroke. It is unclear whether 3D kinematic tests are reproducible for the same player under identical conditions and if a familiarization session is necessary. In practice, with professional players, who have little time available to perform tests, familiarization sessions are difficult. The aim of our study is to measure the reproducibility of a 3D serve protocol test. METHODS Nine tennis players (righties, regional level, 20 ± 2 years) were asked to hit first flat serves in a 1 m^2 area placed on the 'T' zone of deuce diagonal of the tennis court. Two identical tests are performed one week apart. For each test, we selected the three best serves of the 25 trials (with the highest speed and the highest accuracy). Kinetics measurements were performed using a 3D analysis system (Codamotion), a force platform (Kistler) and a radar gun. 28 markers were placed on the players' bodies to measure kinematics of the movements: ankles, knees, hips, trunk, shoulder, elbow and wrist dominant side. We measured ball speed, leg drive, linear velocity of the racket and joints, joints range of motion and maximum angular velocities at different positions (armed, maximum external rotation and impact) (1). RESULTS All analyzed parameters (linear speeds of racket and joints, leg drive force, joint angles and angular velocities) are reproducible with exception of a small part of them. Our study shows that 5,7% (7 of 122 measurements) joint position parameters and 8,3% (4 of 48 measures) angular velocity parameters are not reproducible from a session to another. DISCUSSION Various errors sources encountered in 3D analysis can justify the presence of non-reproducible parameters (2-3). However, after this work, we can state that the established protocol provides reproducible results when analyzing the tennis serve. REFERENCES 1. FLEXOR HALLUCIS LONGUS MUSCLE MECHANICS DURING HUMAN WALKING

PÉTER, A., FINNI, T., HEGYI, A., CRONIN, N.J.

University of Jyväskylä

Introduction Flexor hallucis longus (FHL) is a deep ankle plantar flexor muscle that, according to cadaver studies [1, 2], works rather isometrically during walking. We aimed to examine in-vivo the fascicle length changes of FHL muscle during overground walking at different speeds. Methods Ten healthy men walked overground at three different speeds (preferred (p) speed, 30% slower (s) and 30% faster (f) than preferred speed). Fascicle length change was recorded with ultrasonography at 80 Hz. One-way repeated measures ANOVA was used to test the differences between maximum length, minimum length, range and mean fascicle velocity across the stance and push-off phases of each walking speed. The minimum level of statistical significance was set at $P < 0.05$. Results Maximum, minimum and range of fascicle length did not change with speed in the stance or push-off phase. In both phases, mean fascicle length change velocity increased significantly with speed ($F = 14.835$, $P_{sp} = 0.015$; $P_{sf} = 0.004$; and $F = 12.451$, $P_{sp} = 0.033$, $P_{sf} = 0.01$, $P_{pf} = 0.045$, in stance and push-off, respectively). Discussion During the whole stance phase we found that FHL fascicles worked at approximately the same length. Our results support previous cadaver findings [1, 2] that FHL muscle works near-isometrically during walking, which is associated with economical muscle work. We also found that with increasing walking speed, fascicle length change velocity increased but the operating range was similar. Although healthy subjects were examined in this study, the possibility to measure FHL mechanics in vivo may enable the study of impairments such as Achilles tendinopathy or flatfoot which have been found to be associate with altered FHL electrical behaviour [3] or morphology [4], respectively. LOWER EXTREMITY BIOMECHANICS DURING FORWARD STEPPING MOVEMENTS IN BASEBALL CATCHERS

PENG, Y.C.1,2, LO, K.C.3, WANG, L.H.4

1: PE-NCKU (Tainan, Taiwan), 2: GIACS-NTSU (Taoyuan, Taiwan), 3: PE-KSU (Tainan, Taiwan), 4: PEHL-NCKU, (Tainan, Taiwan)

Introduction The catcher should receive as much attention as a pitcher does in determining the factors involved in infield defense (Barzun, 1973). In a baseball game, catchers make more throws than other position player. Baseball coaches' main focus to maintain fast yet proper footwork, align the front shoulder with target, take out the ball quickly and pass it out in an actual situation (Fortenbaugh et al., 2010). Therefore, the aim of the present study was to investigate the lower extremity biomechanics involved forward stepping throwing and non-stepping movements in squatting postures. Methods Healthy college baseball catchers ($n=12$) were recruited for the study. An eight-camera Expert Vision Raptor motion analysis system (Motion Analysis Corp., Santa Rosa, CA, USA) was used to collect the position of the reflective markers at a sampling rate of 500 Hz. The tri-axial measurement of ground reaction force of catcher's pivot foot is carried out with two force plates (1000 Hz) made by Kistler Instrument Corporation (Type 9281B: 2 sets, Kistler Instrument Corp, Winterthur, Switzerland). Results A number of significant differences were seen between the forward stepping throwing and non-stepping throwing, most notably ball speed (forward stepping throwing: $29.36 \pm 3.63 \text{ m}\cdot\text{s}^{-1}$; non-stepping throwing: $25.734 \pm 2.03 \text{ m}\cdot\text{s}^{-1}$) ($p = 0.000$). In pivot foot, the adduction and abduction of knee and hip joint in non-stepping throwing were significantly greater than forward stepping movement ($p=0.000$). When forward stepping movement is performed, the upward-forward ground reaction force of the pivot foot is significantly greater than in non-stepping throwing ($p = 0.000$), and this difference continues to the stride period. Discussion In a previous study by Plummer and Oliver (2013), catchers passed the ball on knees. It was found that when lower limbs could not perform footwork, they were able to contribute little to energy generation in ball-passing movement, which put more loading on upper limbs and increased injury risk. Through forward stepping movement, this study identified that the greater upward-forward ground reaction force in the pivot foot appeared at the stride phase to push off and generate the driving force. Moreover, previous investigators founded Weight-shift (forward stepping) throwing caused the flexion angle for greatest hamstring activation in the midst of the stride phase and pivot throwing occurred directly after the stride phase (Plummer and Oliver, 2014). To sum up, which is a possible reason for the higher ball speed and less injury risk in forward stepping movement. These information suggested helpful when training and developing efficient throwing mechanics. References Barzun, J. (1973) God's country and mine. Connecticut: Greenwood Press Reprint. Plummer, H. REACTION TIME IN THE PERIPHERAL VISUAL FIELD IN THE DIFFERENT DEPTHS

INOUE, Y.

Osaka Institute of Technology

Introduction Many studies showed the reaction time (RT) took longer in the peripheral visual field than the central one (Ishigaki, 1983; Osaka, 1976; Ando et al., 2005) and the RT for the peripheral visual field is much longer when attention is paid to the central field. However, it has not been clear whether the RT in the peripheral visual field is different in depth. The purpose of this study is to examine the reaction time in the peripheral visual field that is different in depth from the central visual field. Methods Fifteen college students participated in the experiments 1 and 2. A head-mounted display was used to do the central task (CT) and peripheral task (PT). In the CT a character (either a number or an English letter) was presented in the center, the position of 50cm in depth, at random every second and the participants were asked to answer how many times the number was shown. In the PT, eight balls were shown at a view angle of 30 degrees in the eight different directions, at a 50cm depth in the experiment 1. In the experiment 2, they were presented in the four different directions, at a 20cm or 80cm depth. The RT was measured until participants perceived the change from a white ball to red one and pushed the button corresponding to each position of the ball. The electroencephalogram (EEG) at Cz, and the horizontal and vertical electro-oculogram (EOG) were recorded. Results The RT in the horizontal direction decreased significantly relative to the RT in the vertical

direction in the experiment 1. In the experiment 2, the RT at a 20cm depth decreased significantly relative to the RT at a 80cm depth. The vertical EOG (indicating eye blinking) changed 1.3 seconds after the ball turned to red. The event-related potentials (ERPs) appeared 0.4 seconds after the ball turned red, but there were no significant differences in the directions. Discussion The experiments showed that the RT was shorter (1) in the right and left directions and (2) on the front side. One of the reasons for (1) would be that binocular visual field was wider in the horizontal direction than the vertical one. (2), on the other, would be because the balls on the front side come into view more easily and because the apparent size of balls on the front side is bigger than that on the back side in the virtual reality world. The EOG suggested that the eye blink might be related to the change of characters but it tended to be inhibited when the characters and the balls happened to change simultaneously. THE EFFECTS OF SENSORIMOTOR TRAINING AND WHOLE BODY VIBRATION ON PATIENTS SUFFERING FROM CHEMO-THERAPY-INDUCED PERIPHERAL NEUROPATHY

STRECKMANN, F.1,3, LEHMANN, H.C.2, HELLER, A.1, SCHÜRHÖSTER, A.1, FAUDE, O.3, BLOCH, W.1, BAUMANN, F.T.1

1 German Sport University Cologne; 2 University Hospital Cologne; 3 University of Basel

Chemotherapy-induced peripheral neuropathy (CIPN) is a highly prevalent and clinically relevant side-effect of chemotherapy. Depending on the agent, 60-90%[1] of patients are affected. The motor and sensory symptoms, not only severely diminish patients' quality of life, but represent a decisive limiting factor for medical therapy, consequently affecting the clinical outcome. To date approved and effective treatment options are lacking[2]. Promising results have now been achieved with specific exercise interventions[3]. Our objective was therefore, to analyze the effects of sensorimotor training (SMT), as well as a further neuromuscular stimulating exercise intervention, whole body vibration (WBV)[4], on the relevant side-effects of CIPN. We conducted a prospective, four-armed, randomized, controlled trial, to evaluate the feasibility and effects of SMT and WBV on patients with a neurologically confirmed CIPN. Patients (N=40) were randomized either into one of the intervention groups or a control group and matched by gender and age with a healthy control. The intervention groups had to participate in the supervised exercise regime at least twice a week for six weeks. Primary endpoint was the patient reported reduction of CIPN related symptoms. Secondary endpoints were balance control, nerve conduction velocity and amplitude, peripheral deep sensitivity, Achilles- and Patellar tendon reflex, proprioception, quality of life, CIPN-related pain and the level of activity. Patients in both exercise interventions (SMT and WBV) profited. They were able to reduce symptoms and regain functions comparable to healthy controls. Both groups showed improved reflexes, peripheral deep sensitivity and quality of life in comparison to the control group. The interventions targeted slightly different symptoms. SMT for instance, induced higher performance in balance control while WBV was more efficient regarding peripheral deep sensitivity. Further results will be ready for presentation at the conference. We conclude that SMT and WBV are not only feasible in patients with CIPN but also behold a large potential that is of high clinical relevance, to reduce CIPN-related symptoms and improve patients' quality of life. 1. PROLONGED VIBRATION TO VASTUS INTERMEDIUS INFLUENCES FORCE FLUCTUATION OF QUADRICEPS FEMORIS DURING A LOW-LEVEL FORCE-MATCHING TASK

SAITO, A.1, ANDO, R.2, AKIMA, H.2

1: Waseda University (Tokorozawa, Japan), 2: Nagoya University (Nagoya, Japan)

Introduction When attempting to match a target during steady contraction, afferent inputs from Ia fibers in muscle spindles are essential to control the generated force. Prolonged vibration has been applied to muscle-tendon units to manipulate the synaptic input from Ia afferents onto α -motor neurons (Roll et al., 1989). Vastus intermedius muscle contributes up to 50% of knee extension torque from quadriceps femoris during low-level torque generation (≤ 20 Nm) (Zhang et al., 2003). Thus, the present study aimed to test the hypothesis that prolonged vibration to vastus intermedius increases force fluctuation of quadriceps femoris during a low-level force-matching task. Methods Nine healthy men (25.1 ± 4.3 years) performed a submaximal force-matching task of isometric knee extension before and after mechanical vibration to superficial region of vastus intermedius for 30 min. The force-matching task involved knee extension for 15 s to match target forces displayed on a monitor. The target force was 2.5%, 10%, and 30% of maximal voluntary contraction (MVC). Force fluctuation was determined by coefficient of variation (CV) of force. Surface electromyography (EMG) from four synergists of quadriceps femoris was recorded (Watanabe & Akima, 2009), and then the EMG amplitude and frequency were calculated. Results After prolonged vastus intermedius vibration, the CV of the force at 2.5%MVC was significantly increased, but CVs at 10% and 30%MVC were not significantly changed. EMG amplitudes of four muscles of the quadriceps femoris at each target level were not significantly changed after the prolonged vibration. A significant decrease in EMG frequency at 2.5%MVC was observed in vastus intermedius following the vibration. Discussion Application of prolonged vibration to vastus intermedius increased force fluctuation of quadriceps femoris during a very low-level force-matching task. This supports the present hypothesis. The finding suggests that prolonged vastus intermedius vibration modulates Ia afferents onto α -motor neuron loop, and torque-dependent contribution of vastus intermedius influences the fluctuation of knee extensor force. An increase in low-frequency EMG signal is influenced by alterations in firing rate of motor units (Broman et al., 1985). Thus, a reduction in the EMG frequency at 2.5%MVC may indicate that modulation of the firing rate of motor units of vastus intermedius affects the steadiness of quadriceps femoris. CORTICOSPINAL AND TRANSCALLOSOAL MODULATION OF BILATERAL AND UNILATERAL CONTRACTIONS

ŠKARABOT, J.1, PERELLÓN ALFONSO, R.2, BON, J.2, STROJNIK, V.3, AVELA, J.1

1University of Jyväskylä, 2University Medical Centre Ljubljana, 3University of Ljubljana

Introduction Bilateral deficit (BLD), a phenomenon of a reduction in the amount of force from a single limb during bilateral actions, has been studied extensively but the underlying mechanisms remain obscure. Interhemispheric inhibition (IHI) through the transcallosal pathway may be responsible for the occurrence of the phenomenon (Oda & Moritani 1995). Bilateral (BL) training may reduce BLD and athletes who perform predominantly BL actions (e.g. weightlifters) have been shown to exhibit even bilateral facilitation (BLF) (Howard & Enoka 1991). Conversely, unilateral (UL) training may increase the magnitude of BLD and thus athletes from sports where performance is ultimately limited by UL force production (e.g. long jumpers) may exhibit greater magnitude of BLD. Therefore, if IHI is truly the underlying cause of BLD it is of interest whether the nature of IHI is reflective in the magnitude of BLD. Methods 20 male subjects were recruited (ALL) and additionally split into three groups: bilateral (5 weightlifters, 2 powerlifters), unilateral (4 long jumpers, 1 high jumper) and control. Subjects performed maximal UL and BL isometric knee extensions during which electrical stimulation and both contralateral (c) and ipsilateral (i) transcranial magnetic stimulation were performed. Variables of interest included peak torque for calculation of bilateral index (BI), RMS EMG for calculation of BI in EMG activity (BIE), voluntary activation level (VA), motor evoked potentials (cMEP and iMEP), and silent periods (cSP and iSP). Results Significant BLD was observed only for ALL ($BI = -8.76 \pm 13.43$, $p = 0.009$), but not for any of the groups. No BLD was noted in EMG activity and no parallelisms between force and EMG BIs were found. VA was significantly higher during BL compared to UL contractions (~ 97% vs. 93%, $p = 0.045$), with no differences between groups. MEPs and iMEPs during BL were significantly bigger (~6%, $p = 0.042$, and 27%, $p = 0.005$, respectively) than during UL contractions with no differences between groups. No differences in cSP and iSP were noted regardless of grouping. Discussion BLD was observed only for ALL, but not for the subgroups, likely due to poor testing specificity. Unaltered SPs do not support the concept of inhibition at the cortical level in relation to BLD. On the other hand, higher cMEP, iMEP and VA values during BL when compared to UL could indicate involvement of some facilitatory mechanisms. However, we cannot exclude the possibility of inhibition located upstream of the primary motor cortex or at the subcortical level. References Oda, S., Moritani, T. (1995). Eur J Appl Physiol 72, 1-5. EXAMINING THE RELATION OF CEREBRAL LATERALIZATION, HAND PREFERENCE AND GRIP STRENGTH IN ELITE FENCING ATHLETES

GÜMÜŞ, M., AKALIN, T.C.

Bülent Ecevit University

Introduction Cerebral Lateralization is defined as the anatomical and functional differentiation between the right and left hemispheres of the brain. Each hemisphere has different functions and the dominant hemisphere fulfills its duties better than the other. One of the hemispheres being heavier than the other is an anatomical lateralization; however, the hand preference, which shows the functional asymmetry related to the brain best, is accepted as a functional cerebral lateralization. The grip strength in hand functions is a significant function for the continuity of daily life activities. Therefore, the grip strength is accepted as an objective measurement in performance evaluation of the upper extremity. Accordingly, the goal of this study is to examine the relation of cerebral lateralization, hand preference and grip strength in fencing, which provides health, endurance, speed, strength, agility, flexibility, balance, reflexes, coordination, intuition, timing ability, quick thinking and decision-making for your body. Methods 117 elite fencing athletes, attended Interuniversity Fencing Championship, voluntarily participated in the study whose ages range from 18 to 25. Hand preference was confirmed by Oldfield Survey and evaluated between +100 and -100 according to the Geschwind Score. Two sportsmen were excluded from the study as they were ambidextrous. In the intergrouping comparisons right-handed and dominant right-handed were grouped as right-handed, left-handed and dominant left handed were grouped as left-handed. Hand grip strength was measured by Jamar hydraulic dynamometer. Data was evaluated after it was transferred to the SPSS for Windows 21.0 programme. Average values were shown as "arithmetic average * standard deviation". In the intergrouping comparisons Mann-Whitney U and Pearson correlation analysis were used. Analysis results were evaluated in the %95 confidence interval. Correlation factor was adopted as 0.000-0.250 weak or none, 0.251-0.500 intermediate, 0.501-0.750 strong, 0.751-1.000 very strong relationship. Results %48,1 of the subjects attended our study were dominant right-handed, %40,3 were right-handed, %10,2 were left-handed and %1,4 were dominant left-handed. Dominant hand grip strength was 44.2 for the right-handed and 43.9 for the left-handed. For the nondominant hand it was in order of 42.8 and 41.5. Discussion This functional laterality may due to the dominance of left hemisphere. The results were compared to those in literature. It is significant to make similar evaluations intended for hand and hand performance on more subjects and different ages and different competition categories in which hand performance is improved by active use. References Oldfield R.C., The assessment and analysis of handedness the Edinburgh Inventory, Neuropsychologia 1971;9: 97-114

ACUTE EXPOSURE TO MODERATE ALTITUDE INCREASED SPINAL EXCITABILITY

TOMAZIN, K.

University of Ljubljana

2: University of Granada, Department of Physical Education and Sport, Granada, Spain Introduction Muscle power output (PO) during rapid actions, such as bench-press, could be enhanced at altitude (Feriche et al., 2014). The main reasons were attributed to a reduction in the aerodynamic resistance. Since 50 m front crawl time also improves at moderate altitude compared to sea level, the reduction in the external resistance could only partly account for improved PO. Improvement in PO has been mainly attributed to muscular; e.g. hypertrophy and neurological factors; e.g. enhanced firing frequency of motoneurons (MN) and enhanced spinal reflexes. Increased spinal excitability was already observed in artificial hypoxic condition (Delliaux, Jammes, 2006). Accordingly, increased MN excitability could be one of the mechanisms, which enhance rapid power production in altitude. To date, little is known about the consequence of acute exposure to hypobaric hypoxia - HP (i.e. moderate altitude) on spinal excitability, measured as changes in H-reflex amplitude. Therefore, our study was designed to test the effect of acute exposure (15 min to 6 hour) to moderate altitude on alfa-motoneuron excitability at rest. Methods Fifteen male and female physical education students (22 ± 2 years, 69 ± 8 kg, 176 ± 6 cm) participated in the study. Hmax/Mmax ratio of the soleus muscle was measured every three hour (11:00am, 14:00pm, 17:00pm) on two consecutive days in normoxia - NO and HP (2230 m.a.s.l.). Control H-reflex amplitude was always measured at 8:00am in NO. Fifteen minutes before the first measurements (at 11:00 am) participants ascended in altitude. Results Control Hmax/Mmax ratios were 0.39 ± 0.16 and 0.38 ± 0.17 ($P > 0.05$). At 11:00am ratio increased

in HP (~48%) and NO (~13%; both $P<0.05$). The increment was greater in Hypo compared to NO ($P=0.058$). Three and six hours later a decrement (both ~10% and $P<0.05$) in ratio was observed in HP, however ~27% (at 14:00pm) and ~20% (at 17:00pm) higher ratio (both $P<0.05$) was still observed compared to control. In NO ratio slightly increased at 14:00pm and stayed the same at 17:00pm. There were no differences in ratios at 14:00am and 17:00pm between NO and HP. Discussion It seems that acute HP induced initial facilitation of the H-reflex. Although, after three hours a reduction in HP was observed (compared to initial value in HP), the ratio was still a little higher than in NO (~27% vs ~23%; $P>0.05$). Initial facilitation may result from the direct effects of hypoxemia on the supraspinal structures controlling the H-reflex (Delliaux, Jammes, 2006). References Delliaux S, Jammes Y. (2006). EFFECTS OF THREE WEEKS OF WINGATE-TYPE HIGH-INTENSITY INTERVAL TRAINING ON MUSCLE FATIGUE AND RYR1 EXPRESSION

NEYROUD, D.1, SCHLITTLER, M.2,3, TANGA, C.1, WESTERBLAD, H.2, KAYSER, B.1, PLACE, N.1

University of Lausanne

Introduction High-intensity interval training (HIIT) is a time-efficient training paradigm eliciting similar skeletal muscle molecular adaptations as traditional forms of endurance training (Gibala et al. 2006). Recently, neuromuscular alterations induced by a single HIIT session were found to be similar between recreationally active participants and elite-endurance athletes (Place et al. 2015) while the sarcoplasmic reticulum Ca^{2+} -channel (ryanodine receptor 1; RyR1) integrity was changed only in recreationally active participants. We now trained recreationally active subjects for three weeks with HIIT to investigate whether this would improve RyR1 integrity. Methods Eight healthy and recreationally active males (27 ± 6 years, 77 ± 8 kg) volunteered to participate in nine HIIT sessions (3 sessions per week) consisting of initially four and later six 30-s "all-out" cycling bouts (i.e. Wingate) interspersed by 4 min of rest. An incremental cycling test (+1W every 2 s) was performed before and after the 3 week training. For the first and last HIIT sessions, knee extensor neuromuscular function was evaluated before and immediately after as well as 24 h after. Maximal voluntary contraction (MVC) force was assessed and 100-Hz paired electrical stimulations (PS100) were delivered during and following each MVC to assess central and peripheral fatigue. Muscle biopsies were collected from the vastus lateralis before and 24 h after the first and last training sessions. RyR1 protein expression was analyzed with Western blots. Data are presented as mean \pm SD. Results Nine HIIT sessions resulted in an $8 \pm 5\%$ increase in maximal power output during the incremental test. Similarly, the overall work performed during one HIIT session was increased by $8 \pm 6\%$. Interestingly, this greater work led to a similar reduction in MVC ($-41 \pm 20\%$) and PS100 ($-49 \pm 22\%$) forces immediately after a HIIT session. The maximal voluntary activation level remained unaltered at all time points. Preliminary data suggest that RyR1 expression was decreased 24 h following the first HIIT session, while it was less altered after the 9th HIIT session. Conclusion Nine HIIT sessions were sufficient to substantially improve recreationally active participants' endurance performance. Interestingly, the preliminary molecular data suggest that this performance improvement is accompanied by improved RyR1 integrity. References Gibala et al. J Physiol 575.3: 901-911, 2006 Place et al. EFFECTS OF ELECTROSTIMULATION ON MUSCLE OXYGENATION AND MUSCLE CONTRACTILE PROPERTIES

LAZA-CAGIGAS, R., DOMÍNGUEZ-CASTELLS, R., MONTALVO-ZENARRUZABEITIA, Z., CALLE-HERRERO, J.

Spanish Agency for Health Protection in Sport

Introduction Neuromuscular electrostimulation (NMES) is well known for its variety of applications, such as strength training, rehabilitation and post-exercise recovery. However, the effects of NMES on muscle oxygenation (OXY) and muscle mechanical response are poorly understood. The aim of this study was to investigate the effects of NMES on muscle oxygen saturation and muscle contractile properties. Methods The motor point of the vastus medialis was determined in nine physically active men (age: 23.0 ± 3.7 years, height: 178.1 ± 5.8 cm, body mass: 71.9 ± 3.9 kg) and electrodes placed to apply a NMES protocol. The NMES protocol consisted of 5 cycles of 72 seconds (Is contraction/Is recovery), with a total of 36 contractions per cycle at 40Hz. The intensity was set at the individual tolerable limit. Additionally, measurements of tensiomyography (TMG, Dm: maximum displacement; Td: delay time; Tc: contraction time) were taken before the NMES protocol (PRE), 30 seconds after the end of each cycle (NMESn), and every 5 minutes during the 30 minutes recovery (POSTn). A muscle oxygen saturation monitor was placed on the vastus lateralis during the experiment. Results Dm was higher in NMES1 than in PRE (8.36 ± 1.39 vs 7.21 ± 1.46 , $P < 0.05$). Td and Tc were lower in NMES1 than in PRE (20.84 ± 1.57 vs 21.77 ± 1.09 , $P < 0.05$; and 21.76 ± 2.70 vs 22.87 ± 2.71 , $P = 0.07$, respectively). Neither of the following TMG measurements of the NMES cycles were significantly different from PRE. During recovery only Td was significantly different in POST5 compared to PRE. The differences in oxygen saturation between PRE and the five NMES cycles were, respectively: +1.7%, -19%, -15.3%, -12.3%, -12.3% ($P < 0.05$ for NMES2,3,4,5). Conclusion Dm increment and Tc and Td decrease suggest a better muscle contractile function after only one NMES cycle. However, further NMES cycles did not improve muscle contractile function, probably due to the progressive increase of fatigue. However, the decrease of the oxygenation on the vastus lateralis during the NMES cycles could suggest muscle co-activation and also significant muscle stimulus as a result of the NMES protocol. In conclusion, one single NMES cycle may improve muscle contractile properties. Moreover, the NMES protocol demanded a significant muscle oxygen desaturation. CONTACT: r.laza@alumnos.upm.es

NEUROMUSCULAR ELECTRICAL STIMULATION SUPERIMPOSED TO A NUMBER OF SIT-TO-STAND MOVEMENTS REDUCES ASYMMETRICAL LOWER EXTREMITY LOADING EARLY AFTER ACL RECONSTRUCTION

LABANCA, L.1, ROCCHI, J.E.1,2, LAUDANI, L.1,3, MARIANI, P.P.1,2, MACALUSO, A.1,2

1: University of Rome "Foro Italico" (Rome, Italy), 2: Villa Stuart Sport Clinic (Rome, Italy), 3: Cardiff Metropolitan University (Cardiff, UK)

Introduction It has been recently shown that asymmetrical lower extremity loading, as early as one month after surgical reconstruction of the anterior cruciate ligament (ACL), is a predictive factor of long-term functional recovery (Labanca et al. 2015). Neuromuscular electrical stimulation (NMES), in combination with functional movements, has the potential to contrast asymmetrical loading since the early phases of rehabilitation. The aim of this study was to investigate the effects of introducing NMES superimposed to a number of sit-to-stand movements (STS), as early as two weeks after surgery, on lower limb asymmetrical loading. Methods Nine patients with Tegner Activity Scale level 5, who were ACL reconstructed using bone-patellar tendon-bone graft, underwent 60 days of a traditional physiotherapy protocol and were randomly assigned to one of the 3 groups: the first group (NMES+STS) underwent an additional treatment based on superimposing NMES of the quadriceps femoris muscle to an increasing number of STS movements, from the 15th to the 60th day after

surgery; the second group (STS only) underwent an additional treatment based on an increasing number of STS only; the third group received no additional treatment (NAT). Patients were assessed for lower limb asymmetrical loading by recording ground reaction force during a STS on two force platforms 15, 30 and 60 days after surgery. In addition, maximal voluntary isometric contraction (MVIC) was measured in the knee extensor muscles 30 days after surgery. Side to side symmetry was quantified for peak forces during STS and MVIC using the limb symmetry index (LSI), which was calculated as the ratio between the involved and unininvolved limb expressed as a percentage. Results Thirty days after surgery, patients in the NMES+STS group had higher STS LSI than patients in the STS only and in the NAT group (86.7 ± 3.8 , 59.2 ± 2 and 57.3 ± 1 , respectively). Sixty days after surgery, patients in the NMES+STS group had higher STS LSI than patients in the NAT group (94.8 ± 3.3 vs 52.5 ± 3.9), with no differences with the STS only group. Sixty days after surgery, patients in the NMES+STS group had higher MVIC LSI than patients in the STS only and in the NAT group (70.6 ± 2.5 , 54.0 ± 5.7 and 45.5 ± 5.0 , respectively). Discussion These preliminary pilot data suggest that NMES superimposed to STS is an effective treatment to reduce asymmetrical lower extremity loading early after ACL reconstruction. VO₂, VCO₂ AND VE BETWEEN-DAY RELIABILITY OF THE VYNTUS CPX METABOLIC CART DURING PROGRESSIVE CYCLING

POULSEN, M.K., ROKKEDAL-LAUSCH, T., LARSEN, R.G., THOMSEN, L.P., FRANCH, J., KARBING, D.S.

Aalborg University

Previously, the Oxycon Pro (Jaeger) has been found both reliable and valid compared to the Douglas Bag method (DB) (1, 2, 3). The Vyntus CPX (CareFusion) has been developed to replace the Oxycon Pro. To our knowledge, the Vyntus CPX has yet to be evaluated for reliability, which was the aim of this study. 6 male subjects (age = 28 ± 2.3 yr [mean \pm SD], height = 1.81 ± 0.04 m, weight = 75 ± 3.5 kg, VO_{2max} = 59.4 ± 5.8 mlO₂/kg/min) performed graded cycling trials (Cyclos 2). First, the subjects exercised for 3×6 min at ~55%, 65%, 75% VO_{2max}. After 15 min of rest, a VO_{2max} test was performed starting at ~75% VO_{2max} with 25 W/min increments until volitional exertion. The trial was repeated after 24 hours. VO₂, VCO₂ and VE were recorded as 30 sec means of breath-by-breath data and analyzed on the last minute of each stage. Before each trial, gas calibration and manual flow calibration was performed with a 3L syringe (Hans Rudolph). Inter-trial reliability was investigated at each exercise intensity by mean \pm SD and CV of difference and repeated measures two-way ANOVA (Bonferroni correction), and across intensities by Pearson correlation (R²) and Bland Altman plots with Limits of Agreement (LoA) corrected for repeated measures(4). Mean \pm SD [CV] inter-trial differences were: VO₂(ml/min) = (2413 \pm 121 [5.0], 2929 \pm 87 [2.9], 3398 \pm 77 [2.2], 4485 \pm 100 [2.2]); VCO₂(ml/min) = (2150 \pm 132 [6.1], 2655 \pm 90 [3.4], 3181 \pm 124 [3.9], 5169 \pm 315 [6.1]); and VE (L/min) = (56 \pm 2.7 [4.9], 71 \pm 5.2 [7.3], 86 \pm 3.6 [4.1], 170 \pm 3.6 [3.3]) at ~55%, 65%, 75% VO_{2max}, respectively. Bias (LoA) [R²] across intensities were: VO₂ (ml/min) = -10 (-206, 185) [0.98]; VCO₂ (ml/min) = -25 (-391, 341) [0.97]; and VE (L/min) = 1.2 (-7, 10) [0.99]. While there were no differences between test days, significant differences between intensities were found for all parameters. The CV was less than or equal to previously reported results with Oxycon Pro (1). Results showed strong correlations with similar bias but more narrow LoA for VO₂ and VE and wider for VCO₂ compared to previous results with DB (5). The wider LoA for VCO₂, depended largely on a single outlier, removing this would result in similar LoA as for VO₂. Some of the observed differences might be explained by physiological variation or measurement accuracy, which according to the manufacturer is 3%. Mixing chamber could reduce LoA, but would limit analysis of VO₂ kinetics (2). We conclude that the Vyntus CPX produces reliable breath-by-breath measurements between days. 1. VO₂-KINETICS AT AND ABOVE MAXIMAL LACTATE STEADY STATE INTENSITY

BRAEUFER, E., SMEKAL, G.

University of Vienna

VO₂-KINETICS AT AND ABOVE MAXIMAL LACTATE STEADY STATE INTENSITY Introduction: "Anaerobic threshold" has been considered as the highest intensity at which a steady state of oxygen uptake (VO₂) occurs (Pringle & Jones, 2002). However, in previous studies, various methods have been used to identify "anaerobic threshold". The "maximal lactate-steady-state" has often been referred to as "gold standard" to determine endurance capacity, which is corresponding to "anaerobic threshold" of individuals (Baron et al., 2003). To our knowledge, only few studies exist which deal with VO₂ kinetics at MLSS-intensity. The aim of this study was to investigate, whether "maximal lactate-steady-state" reflects the highest intensity at which a VO₂-steady-state can be found. Methods: Following the method of Heck et al. (1985), 46 subjects underwent several 30-minutes constant load tests on a cycle ergometer to evaluate "maximal lactate-steady-state" (in our case: no lactate increase of more than 0.5 mmol.l⁻¹ within the last 20 minutes). According to Bell et al. (2001) a 3-component model was utilized to estimate the exponential increase of VO₂. The MLSS-test (MLSS) and the test just above MLSS-intensity (MLSS+1) were analyzed to evaluate the above mentioned question. Wilcoxon-Test and Interclass Correlation were used for statistical analyses. Results and Discussion: There was no significant difference ($p > 0.05$) in VO₂-behavior between the both tests (MLSS vs. MLSS+1). Only a minimal increase of VO₂ was detected at MLSS-intensity: median 0.048 ml.kg⁻¹.min⁻¹ (quartile 1: 0.032, quartile 3: 0.089) and MLSS+1: median 0.041 ml.kg⁻¹.min⁻¹ (quartile 1: -0.003, quartile 3: 0.073). The Interclass Correlation coefficient of 0.94 shows very high accordance of the VO₂ kinetics at both intensities. Therefore the main finding of our study is that VO₂ reaches a steady state at MLSS-intensity as well as at intensities just above MLSS-intensity, demonstrating that MLSS-intensity does not describe the maximum load at which a VO₂ steady-state occurs. RELATIONSHIPS BETWEEN HEART RATE AND OXYGEN UPTAKE

SALIER-ERIKSSON, J., ROSDAHL, H., SCHANTZ, P.

Swedish School of Sport and Health sciences

Introduction. Measuring the energetic demands of habitual commuter cyclists is essential to create more accurate methods for measuring active commuting so as to be able to objectively determine the impact that cycle commuting can have on population health. Heart rate (HR) can be used as an indicator of aerobic processes while commuter cycling as long as the relationship between oxygen uptake (VO_2) and HR is established in laboratory conditions. However in the field, environmental aspects might introduce effects of stress that change the relationship. Thus measurements need also to be performed in the field in order to explore the HR- VO_2 relationship between the two conditions. Methods. Metabolic measurements were performed in the laboratory as well as in the field using 20 habitual commuter cyclists (10 males and 10 females) aged 44 ± 3 yrs. A validated stationary as well as a portable metabolic system was used (Rosdahl et al. 2010; 2016; Salier-Eriksson et al. 2012). A comparison was made between the laboratory and field conditions of the HR- VO_2 relationship. Results and Discussion. Based on the average heart rate, the measured oxygen uptake was about 2.5 % lower (n.s.) than the expected levels based on the steady state HR- VO_2 relationships in the laboratory. Thus, the results indicate that the HR- VO_2 relationships in the field were comparable to those measured in the laboratory on a group level. However, relatively large individual differences were found. References Rosdahl, H., Gullstrand, L., Salier Eriksson, J., Johansson, P. & Schantz, P. 2010. SKIN BLOOD FLOW RESPONSES TO LOCALLY DELIVERED ACETYLCHOLINE FOLLOWING A 10-DAY HEAT ACCLIMATION PROGRAM

COSTELLO, J.1, MALEY, M.2, NEAL, R.1, EGLIN, C.1, TIPTON, M.1, CORBETT, J.1

1: University of Portsmouth, UK, 2: University of Wolverhampton, UK.

Introduction It is well established that individuals who undergo chronic heat exposure have improved ability to thermoregulate, especially while exercising in a hot environment (Corbett et al., 2014). It is believed that skin blood flow plays an integral role in this adaptation; however, the specific mechanism(s) by which skin blood flow during exercise is augmented following a period of heat acclimation remains unclear (Lorenzo and Minson, 2010). Therefore, the aim of this study was to examine the effects of heat acclimation on skin blood flow responses to locally applied acetylcholine. Methods Eleven trained male cyclists [mean \pm SD maximal oxygen uptake: 56.8 ± 7.4 mL.kg. min^{-1} ; peak power output: 351 ± 53 W] underwent a heat acclimation programme consisting of 10 days of cycling (maximum 90 min.day $^{-1}$) in a hot environment (40°C , 50 % RH) to elicit isothermal heat strain (target rectal temperature: 38.5°C). Iontophoresis was used to apply acetylcholine (1 w/v %) to the volar forearm and non-glabrous finger 24 to 48 hours before and again after the heat acclimation. Laser Doppler flowmetry was utilised to measure changes in skin blood flow presented as percentage change from baseline (i.e. prior to iontophoresis) and area under the curve. Results Heat acclimation was confirmed by reduced thermal and cardiovascular strain during subsequent exercise in the heat. Not all participants could receive an iontophoresis charge in the finger; these participants were therefore excluded from the analyses leaving an n of 8. Skin blood flow and local temperatures at baseline were similar ($p > 0.05$) before and after the heat acclimation. Acetylcholine evoked similar responses before ([maximum change from baseline] finger: 515 ± 241 % (n=8), forearm: 1716 ± 661 %) and after (finger: 600(353) %; $p = 0.34$, forearm: 1963 ± 1090 %; $p = 0.27$) the heat acclimation intervention. Similarly, no differences ($p > 0.05$) in area under the curve were observed in the forearm or finger. Discussion Endothelial reactivity remained unchanged in response to transdermal application of acetylcholine after a 10-day heat acclimation program. Acetylcholine mediates increases in skin blood flow via multiple pathways, with a profound role for prostaglandins and lesser roles for nitric oxide, especially at the lower doses (Lorenzo and Minson, 2010). Therefore, further studies examining the role of other pathways, including nitric oxide, on the enhanced skin vasodilatory response after heat acclimation are required. THE EFFECTS OF MUSCLE BLOOD FLOW RESTRICTION DURING RUNNING TRAINING ON MEASURES OF ENDURANCE PERFORMANCE

PATON, C., ADDIS, S., TAYLOR, L.A.

Eastern Institute of Technology

Introduction: Performing weight training sessions in combination with blood flow restriction (BFR) has been shown to improve muscle mass and strength. However little is known of BFR effects when performed during aerobic training. The purpose of this study was to determine the effect of BFR performed during sessions of moderate-intensity running on endurance performance and physiology. Methods: Sixteen recreationally trained, males and females (age 24.9 ± 6.9 years, height 172.9 ± 7.8 cm, weight 75.1 ± 13.8 kg) initially completed an incremental treadmill test to determine peak running velocity and Maximum Oxygen uptake; participants also completed a time to exhaustion test (TTE) at peak running velocity. Participants were pair-matched and randomly assigned into either a BFR training group or a control (CON) training group for 4-weeks of training. Both training groups completed eight sessions of the same progressive training regime consisting of 2-3 sets of 5-8 minute (30 seconds work, 30 seconds rest) runs at 80% of individual peak running velocity. Subjects in the BFR group completed all training with lower limb BFR using elastic knee wraps. Percentage changes in performance and physiological measures (Mean \pm 90% confidence limits) pre to post training were estimated and the magnitudes of changes interpreted using the effect size statistic (ES). Results: Maximal Oxygen uptake increased in both the BFR ($6.3 \pm 3.5\%$) and CON ($4.0 \pm 3.3\%$) groups following training with only trivial differences between groups (ES=0.18). Similarly TTE increased by $26.9 \pm 9.3\%$ and $17.0 \pm 6.4\%$ respectively for the BFR and CON groups. Effect size analysis indicated small beneficial improvements in peak running velocity (ES= 0.34) and TTE (ES= 0.31) in favor of the BFR group compared to CON. Analysis of heart rate data obtained during training indicated that the BFR group exercised at a higher (ES=1.3) percentage of their peak heart rate in comparison to the CON group ($76.0 \pm 5.0\%$ vs $69.8 \pm 5.1\%$) despite

both groups training the same relative running velocity. Discussion: Sessions of moderate intensity interval training with, and without blood flow restriction improves physiology and performance measures in recreationally trained individuals. Using BFR during training appears to confer additional small but potentially beneficial improvements in several endurance performance measures compared to CON despite only trivial differences in physiological adaptation. The beneficial adaptations observed with BFR may be related to its effects on exercise heart rate during training or local muscle adaptations caused by metabolic acidosis. Further research is required to elucidate the likely adaptive mechanisms responsible for performance improvements. Contact: cpaton@eit.ac.nz

CLASSIFICATION OF INDIVIDUAL BODY FUNCTION BY METABOLIC RESPONSE

SASAKI, T.

Hokusei Gakuen University

Introduction: The purpose of this study is to reveal the individual body function by using metabolic response. Methodology: Seven volunteer athletes that were three short distance athlete and four long distance athletes were cooperated. Three different metabolic tests were performed with seven athletes. The first of all, the step exercise were performed for determining other two individual metabolic functions that were known as the aerobic threshold (Aer-T) and as the anaerobic threshold (An-T) in seven athletes. After the step exercise test, athletes performed two different metabolic tests that were steadied the load in the Aer-T level and were steadied the load in the An-T level. Results and Discussion: The metabolic functions of athlete are classified by the distance of a period between the Aer-T and An-T. Short distance athletes had longer period of appearance time in the Aer-T and An-T than long distance players. Aer-T in the short distance athletes appeared earlier than long distance athletes. However, the An-T of long distance was appeared lately that near by VO_{2max} level. There were hardly found differences in the VO_{2max} among each athletic event players. Short distance athlete had longer period between Aer-T to An-T than the period of long distance athlete. In both group, long time steady state about 20 min appeared in the load of Aer-T. In the load level of An-T, long distance athlete continued 20 min or more times, on the other hand, short distance athlete finished their performance not to reach until 20 min. However, even in long distance athletes, their oxygen consumptions reached almost maximum. Therefore, as a future training target, it need to be improved for more longer performance period than the current metabolic level in each athlete. For example, the performance of current metabolic level of An-T should be expected to achieve as level as the Aer-T.

METABOLIC OPTIMIZATION OF THE BASKETBALL JUMP-SHOT

PADULO, J.1,2, ČULAR, D.2, VANDO, S.1, GALASSO, M.1, LO STORTO, D.1, NIKOLAIDIS, P.3, ARDIGÒ, L.P.4

1: University eCampus (Italy), 2: University of Split (Croatia), 3: Hellenic Army Academy (Greece), 4: University of Verona (Italy)

Introduction Due to its mixed physical-technical-tactical nature, basketball like other team sports needs attention on likely relationships between all its facets, e.g., metabolic power and technical skill. A common fundamental is the Jump-Shoot (JS), which can be shot both when just come off the bench and when fatigued by previous actions. Our aim was to study the effect of different metabolic power conditions on successful JS percentage (JS%). Methods 22 male (Under 17) basketball players (age 15.7±0.9 y, height 179±6.9 cm, mass: 66.4±9.2 kg, sport experience 7.9±1.0 yrs). The participants threw JSs under three randomized testing sessions one week later than a Yo-Yo Intermittent Recovery test level 1 (Yo-Yo IR1) (Castagna et al, 2008) administered to measure HRMAX as a proxy of maximal metabolic power. All sessions consisted in 10 consecutive JSs from five different significant field spots 5-m far from the basket (two counter clockwise "laps") at different heart rates (HR): rest (0HR), after warm-up (HR at 50%HRMAX [50HR], 80%HRMAX [80HR]). The same procedure was repeated one week later to evaluate measures reliability. After a 15' standard warm-up running each participants threw 10 consecutive JSs sessions at different HRs (0HR - 50HR - 80HR). Each HR (continuously monitored with Cardio-SuuntoTM) was achieved by low/high intensity shuttle running (15+15 m). Reliability of the shoot accuracy measure at 0HR, 50HR and 80HR was assessed by Intra-class Correlations Coefficient (ICC) according to a previous study (Padulo et al, 2015). A one-way ANOVA within subjects was performed to check for the differences between the three sessions with post-hoc LSD test. The level of statistical significance was set at p<0.05. Results ICC showed a good reliability at 0HR (0.89), 50HR (0.92) and 80HR (0.95). Yo-Yo IR1 HRMAX was 195.6±6.1 bpm. ANOVA showed difference in JS% over sessions ($F(1,20)=4.257$ and $p=0.018$) with 660 JSs. LSD test did not show any significant 0HR-50HR JS% difference (-9% and $p>0.05$), while 80HR elicited significantly lower values with respect to both 0HR and 50HR (-41 and -28% with $p=0.006$ and $p<0.05$, respectively). Discussion Our study provided two practical indications to keep high JS%: 1) preliminary warm-up does not improve JS%, because the 0HR-50HR difference was not significant; and 2) 80HR decreases JS% significantly, providing therefore scientific support to the usual behavior by players, who aim always at resting as much as possible between game-play pauses. References Castagna C, Impellizzeri FM, Rampinini E, D'Ottavio S, Manzi V. (2008). The Yo-Yo intermittent recovery test in basketball players. *J Sci Med Sport*, 11, 202-208. EFFECTS OF BODY POSITION ON EXERCISE CAPACITY AND PULMONARY VASCULAR PRESSURE-FLOW RELATIONSHIPS

FORTON, K., MOTOJI, Y., DEBOECK, G., FAORO, V., NAEJUE, R.

Université Libre de Bruxelles

Background: Echocardiography coupled to cardiopulmonary exercise testing (CPET) is integrating clinical practice for the evaluation of unexplained dyspnea. However, there still is a problem of standardization as we do not know if maximal exercise capacity (VO_{2max}) can be reached on an echocardiographic exercise table and in a supine position as used during right heart catheterization. Secondly, it remains unclear if exercise stress measurements of the pulmonary circulation and the right ventricle must be expressed either as a function of workload, oxygen uptake (VO₂) or cardiac output (CO). The relationship between these variables is considered linear but may vary with body position. In particular, one does not know the relationship between workload and VO₂ in the semi-recumbent position with lateral tilting during exercise echocardiography. Methods: We therefore revisited the relationship between VO₂, CO and workload in 26 healthy subjects (13 men/13 women, 23 ± 2 years, 172 ± 10 cm, 67 ± 11 kg). All subjects performed 3 randomized incremental cardiopulmonary exercise tests with measurement of cardiac output in different positions: upright (on a classical cyclo-ergometer), semi-recumbent (on an echocardiographic exercise table tilted 35° to the left), and supine position (cycling table). The CPET were performed with a warm-up of 3 min at 60W for men and 30W for women and workload increase 30W/min for men and 20W/min for women. Gas exchange was registered every 5 seconds (HypAir, Medisoft, Dinant, Belgium). Cardiac output was measured during last 30 seconds of each step by echocardiography (CX50 CompactXtreme Ultrasound System; Philips, Amsterdam, The Netherlands). Results: VO₂ max was

not affected by the CPET body position (upright: 43 ± 10 ml/min/kg, semi-recumbent: 43 ± 10 ml/min/kg ; supine: 42 ± 9 ml/min/kg) as well as maximal CO (upright: 18.4 ± 3.4 l/min, semi-recumbent: 18.5 ± 3.5 l/min, supine: 18.4 ± 3.1 l/min) while the maximal workload was lower in the semi-recumbent position compare to the other positions (upright: 240 ± 75 W, semi-recumbent: 215 ± 71 W, $p < 0.01$, supine: 233 ± 68 W) and maximal heart rate was higher on upright position (upright: 189 ± 11 bpm, semi-recumbent: 181 ± 11 bpm, supine: 180 ± 13 bpm). There is no significant difference in final RER. Conclusion: The important finding of the present study is that the gold standard of the evaluation of aerobic exercise capacity VO_{2max} remains valid in different body positions such as used in clinics, while maximum workload is not. Because CO is increased in response to increased metabolic rate rather than mechanical work and is not affected by body position as well, we recommend that measurements of the right ventricle and the pulmonary circulation during exercise be titrated as a function of VO₂ or CO in place of workload.

MO-BN04 Biomechanics: Mixed Session

ON THE EFFECT OF SITTING POSITION, IN SIMULATED CROSS-COUNTRY SIT-SKIING

LUND OHLSSON, M.1, HÖÖK, M.2, LAAKSONEN, M.S.1

Mid Sweden University

1: Mid Sweden University, Swedish Winter Sports Research Centre 2: Swedish Ski Association, Cross-Country Skiing Introduction In Cross-country sit-skiing (CCSS), athletes with severe reduced trunk control are mainly seated with the knees higher than the hip (KH; arm and trunk powered). However this posture is hypothesized to have high risk for lower back and shoulder injuries. Therefore, a new seat was created where the knees were lower than hip and the trunk frontal supported (KL), to improve spinal curvature. Thus, the aim of this study was to examine performance between these two different sitting positions. Methods 10 female abled-bodied elite cross-country skiers (age 25.5 ± 3.8 years (mean \pm standard deviation), height 1.65 ± 0.05 m and weight 61.1 ± 6.8 kg) were tested on a skiing ergometer (ThoraxTrainer, ThoraxTrainer A/S, Kokkedal, Denmark) in a 30 s all-out test (WIN), a submaximal incremental test with 3-6 levels of 3 min (SUB), and a maximal 3 min time-trial test (MAX). The SUB and MAX tests were monitored breath-by-breath with a stationary metabolism meter (Quark CPET, COSMED, Italy). Aerobic metabolism and gross efficiency were computed from oxygen uptake, and anaerobic metabolism were estimated from net blood lactate concentrations. Muscle oxygenation saturation (SmO₂) in right vastus lateralis (VL) was monitored with NIRS methodology (Moxy Monitor, Fortiori Design LLC, Minnesota, USA). Results Higher performance (W·kg⁻¹) was observed for KH both in WIN (KL: 1.13 ± 0.33 , KH: 1.40 ± 0.30) and MAX (KL: 0.67 ± 0.14 , KH: 0.88 ± 0.19) compared to KL ($p < 0.01$). No differences were observed in breathing rate, cycle rate, oxygen consumption or aerobic metabolic rate neither in SUB nor MAX. The KH position showed higher gross efficiency and lower anaerobic metabolic rate and minute ventilation. SmO₂ was higher for KH compared to baseline bench ($12.2 \pm 7.2\%$) whereas no difference was observed between baseline and KL position ($3.2 \pm 5.5\%$). During SUB levels 1-4, higher SmO₂ was observed for KH compared to KL when normalizing data with baseline bench ($p < 0.05$). Discussion This study showed that abled bodied athletes perform better and have higher efficiency in KH compared to KL. The position using larger part of the body (joint range of motion and amount of active muscle mass) have higher gross efficiency, lower lactate concentration and lower ventilation, also shown by Lajunen (2014). It was also concluded that SmO₂ was higher in KH compared to KL, and thus there might be a smaller risk for injuries in the legs connected to circulation. This study of abled-bodied athletes have the potential to serve as a control for future studies of para-athletes. References Lajunen K (2014). Effect of sitting posture on sit-skiing economy. LIMB SYMMETRY INDEX AND LEG DOMINANCE IN AUSTRIAN YOUTH SKI RACERS

PÉREZ-DEL RÍO, A., MÜLLER, L., HILDEBRANDT, C., PATTERSON, C., RASCHNER, C.

University of Innsbruck

Introduction Alpine skiing is a sport with high demands on physical fitness of the lower extremities. Identifying asymmetries between legs is important for performance and injury prevention. Limb asymmetries greater than 10% may indicate a higher injury risk (Abrams et al., 2014). The aim of this study was to analyze the limb symmetry index (LSI) in Austrian youth ski racers and its implication for testing the lower limb dominance. Methods Sixty Austrian youth ski racers (39 males, 21 females; age: 12.5 ± 1.2 years; body mass: 43.5 ± 8.7 kg, body height: 153.5 ± 8.7 cm) performed 3 different one-leg tests: stability test (ST), speedy jump test (SJT) (Hildebrandt et al., 2015) and Y-Balance test (Y-BT) (Smith et al., 2015). The LSI was calculated for each test (LSI = dominant/non-dominant $\times 100$). LSI results were categorized in 4 ranges: within 10% (1st), 15% (2nd), 20% (3rd) and above 20% (4th). Additionally, 3 tests were performed to identify the subjective dominant leg. The normal distribution was assessed using Shapiro-Wilk. ANOVA with repeated measurements (Bonferroni correction) was performed. Statistical significance was set at $p < 0.05$. Results No significant differences were found in the LSI between the 3 one-leg tests ($p > 0.05$). At least 90.0% of the subjects were in the 1st range (SJT and Y-BT). For ST, 53.3% of participants were in the 1st, 18.3% in the 2nd, 13.3% in the 3rd and 15% in the 4th range. According to the 3 subjective tests for leg dominance, for 92% the right leg was the subjective dominant leg. When comparing the results of the 3 subjective dominant leg tests to the LSI test results, the subjective tests identified the dominant leg correctly only in 55% (ST), 63.3% (SJT) and 55% (Y-BT) of the subjects respectively. Discussion Austrian youth ski racers do not have limb asymmetries in most tests. The asymmetry range was within 10% in the SJT and the Y-BT, which indicates a lower rate of injury risk (Abrams et al., 2014). Therefore, it can be concluded that the injury due to lower limb asymmetry of these ski racers is low. However, in the ST, only 53.3% participants were in the 1st range. Additionally, it could be shown that the subjective tests for identifying the dominant leg of Austrian youth ski racers were not precise, since only 55-63% were identified correctly. LSI tests should be included in the test battery of youth ski racers to evaluate leg dominance and asymmetries. GENDER DIFFERENCE IN MUSCULARITY OF THE QUADRICEPS FEMORIS IN VARSITY ROWERS: RELATION TO KNEE ALIGNMENT

EMA, R.1, WAKAHARA, T.2, HIRAYAMA, K.3, KAWAKAMI, Y.3

Shibaura Institute of Technology

Introduction Muscle size of the quadriceps femoris is related to rowing performance (Yoshiga et al. 2002). Our study (Ema et al. 2014) reported that male rowers had unique muscularity among four constituents of the quadriceps femoris: the rectus femoris (RF) volume comparable to untrained men despite 30% greater volumes of the vasti (vastus lateralis, VL; vastus medialis, VM; and vastus intermedius). It is unclear whether such unique musculature also exists in female rowers. There is a gender difference in knee alignment such as Q-angle (Horton and Hall 1989) and knee alignment is one of the factors that influence the quadriceps femoris muscle size in untrained men (Tsakoniti et al. 2008). It is therefore hypothesized that male and female rowers have different quadriceps femoris muscularity, being related to the variability of Q-angle. This study tested this hypothesis. Methods A series of magnetic resonance (MR) images of the right thigh were obtained from 26 experienced varsity rowers ($n = 13$ for each gender) and 20 untrained students ($n = 10$ for each gender). From the images, muscle volume of each constituent of the quadriceps femoris was determined and normalized to body mass. The Q-angle of the rowers was measured during quiet standing. Ten of the rowers joined a 1-year follow-up survey of MR measurements. Results and Discussion In each gender, rowers had significantly greater normalized volumes of the vasti than untrained students, whereas no difference was found for RF. Relative volumes of VL in males and VM in females to those of the total quadriceps femoris were significantly higher in the rowers than untrained students, and vice versa for RF in both genders. There were no gender differences in the fractions of individual muscle volumes in untrained students. The Q-angle was significantly greater in the female than in male rowers. When the data of rowers were collapsed over genders, Q-angle was positively correlated with the percentage of VM volume ($r = 0.46$, $P < 0.05$), and with the ratio of VM to VL ($r = 0.52$, $P < 0.01$). One year of regular competitive training significantly increased volumes of the vasti but not RF. The relative change in VM volume was positively correlated with Q-angle ($r = 0.65$, $P < 0.05$). The results indicate that the rowers' quadriceps femoris muscularity is different between genders, which likely stems from the variability in the knee alignment. TRAINING INDUCED CHANGES IN THE GROUND REACTION FORCE PATTERN OF HIGH KNEE SPRINTING IN TRACK AND FIELD JUMPERS

ROUSANOGLOU, E., BOUDOLOS, K.

National and Kapodistrian University of Athens, Greece

Introduction A widespread coach belief is that high knee sprinting (HNS) improves the speed components by increasing the stride length and the body's forward propulsion (Thompson et al., 2009; Young, 2012). To the best of our knowledge, there is lack of data regarding the HNS ground reaction force (GRF) pattern. The purpose of the study was a) to compare the HNS GRF pattern between track and field jumpers (TFJ) and untrained controls (CG) and b) to test the TFJ training induced changes. Methods Twelve young women TFJ (14 to 19 yrs, elite level for their age category) performed HNS in place (Kistler forceplate, 9286AA, 1000 Hz, 15s, as fast as possible). TFJ were tested during the beginning of the preparation period (Pre) (regular training thereafter) and 5 months later (Post). The CG ($n = 12$ age matched young women) was tested at same time period as the TFJ. Data included HNS frequency and, for the leading (LdL: limb of initiating knee lifts) and trailing (TrL) limb, respectively, contact time, flight time, peak vertical force, time to peak vertical force, total vertical impulse and reactivity index (flight to contact time ratio). Paired t-tests were used for the differences between TFJ and CG, as well as, between Pre and Post in each group (SPSS, 21.0, $p < 0.05$). Results No significant Pre to Post difference was found for CG. In the TFJ, all HNS variables remained unchanged between Pre and Post, except for the increased HNS frequency (Pre: 3.8 ± 0.4 Hz, Post: 4.1 ± 0.2 Hz). Compared to CG, the TFJ had significantly higher frequency only in Post (TFJ: 4.0 ± 0.2 Hz, CG: 3.6 ± 0.6 Hz). In both Pre and Post, TFJ had shorter contact times ($p < 0.05$), greater LdL reactivity index ($p < 0.05$) and, greater LdL impulse ($p < 0.05$). Discussion HNS in place shows significant differences between TFJ and untrained CG already at the initiation of the preparation period with the TFJ training induced changes in reflecting a positive outcome for improved speed (Thompson et al., 2009). The advantageous impact of HNS lies in the increased pre-stretch of the gluteus and the hamstrings muscles of the swing leg when the hip joint comes to a position of greater flexion (Schache et al., 1999; Thompson et al., 2009). Together with the greater limb acceleration due to greater angular range of thigh motion, HNS allows an increased GRF during contact phase, which is positively related to increased speed (Schache et al., 1999; Thompson et al., 2009). RELATIONSHIP BETWEEN VERTICAL JUMP AND BODY POSTURAL STABILITY IN MALES AND FEMALES AGED 6-18 YEARS

ROSSI, A.1, FORMENTI, D.1, TRECROCI, A.1, ROI, G.S.2, ALBERTI, G.1

1:Università degli studi di Milano (Milano, Italy) 2:Isokinetic Medical Group, Education and Research Department (Bologna, Italy)

Introduction Body postural stability and vertical jump can be influenced by age, as well as anthropometric characteristics and sport participation (Jallai et al., 2011). However, uncertain correlation between BPS and vertical jump height have also been reported. In pre-pubescent children and adolescents no correlations have been found (Granacher and Gollhofer, 2011), albeit good correlations have been reported in young soccer players (Gualtieri et al., 2009). Thus, the aim of this study was to investigate the relationship between body postural stability and vertical jump height in males and females aged 6-18 years. Methods Nine hundred and eighty-five subjects from 6 to 18 years took part in this study (699 males and 286 females). Body postural stability and vertical jump height were measured by balance test (BPS; Libra board, Easytech, Prato, Italia) and countermovement jump test (CMJ; Optojump, Microgate, Bolzano, Italia), respectively. To assess the interaction between sex and among ages, two-way multivariate analysis of variance (MANOVA) was performed. If Wilk's lambda achieved statistical significance, the univariate test (ANOVA) was examined for the individual dependent variables applying a Bonferroni's adjustment of alpha. The partial eta squared (partial eta²) was used to detect the magnitude of the differences. In order to detect the relationship between BPS and CMJ in males and females, the Pearson Correlation Coefficient controlled by age (partial correlation) was computed. Results The two-way MANOVA showed statistical interaction among age and between sex (Wilks lambda=0.96; $F=2.35$; $p=.04$; partial eta²=0.20). Univariate analysis of variance found a statistical interaction only for CMJ ($F=2.35$; $p=.04$; partial

eta²=0.20). Partial correlation showed statistical significance in both males ($r=-0.410$, $p<0.001$) and females ($r=-0.169$, $p=0.01$). Discussion The difference between sex and age in CMU could be explained by the different maturation of nervous, endocrine, muscular, and cardiovascular systems during growth (Roemmich and Rogol, 1995). However, these adaptations did not affect the BPS between sex. The correlation found between BPS and CMU, especially in males, suggests that training one of these abilities could affect the other one. References Granacher U, Gollhofer A. (2011). ELECTROMYOGRAPHIC ACTIVITY DURING SPRINTING ON HORIZONTAL, UPHILL AND DOWNHILL SURFACES

PARADISIS, G.1, COOKE, C.2, BISSAS, A.3

1: National & Kapodistrian University of Athens, 2: Leeds Trinity University, 3: Leeds Beckett University

Electromyographic activity during sprinting on horizontal, uphill and downhill surfaces Paradisis, G.1, Cooke, C.2, Bissas, A.3 1: National & Kapodistrian University of Athens, 2: Leeds Trinity University, 3: Leeds Beckett University Introduction Previous research has shown that sprinting on sloping surfaces provides a unique training stimulus leading to significant improvements in sprinting performance (Paradisis et al., 2009). Whilst kinematic data have been acquired during sprinting on slopes to understand movement patterns associated with positive training adaptations, there are no data on muscle activity during uphill-downhill sprinting to back kinematic driven inferences about muscle conditioning. This study presents comparative qualitative electromyographic (EMG) data for key leg muscles during sprint running on horizontal, uphill and downhill surfaces (3° slope). Methods EMG activity (Mega ME3000P8) was recorded from the vastus lateralis, rectus femoris, biceps femoris, semitendinosus and gastrocnemius (lateral and medial heads) of the right leg of one female participant (age = 24 years, height = 1.68 m, mass = 73 kg). The sprints were filmed with video camera (Kodak Ektapro 1000) at 125 Hz. A qualitative analysis of the raw EMG signal was conducted to observe any differences in muscle activation across the different running conditions. Results and Discussion The EMG activity during horizontal sprints displayed expected patterns for all muscles. Downhill Sprint: The analysis revealed that the downhill slope forced the quadriceps to a shorter and lower activity, compared to horizontal sprinting, throughout the whole stride due to postural changes. On the other hand whilst the activity pattern of hamstrings was similar to the horizontal it is clear that they play a very important role in the generation of the supramaximal speed as the magnitude of their activity, especially during leg recovery, was highly augmented. As to gastrocnemius, both heads showed higher activity, compared to horizontal, during the whole contact phase which infers their critical role as a balancing lever for the whole body and their contribution to longer strides. Uphill Sprint: Compared to other sprints, the quadriceps showed a longer activity period on the ground but with a similar amplitude whereas the hamstrings remained highly active during the whole contact phase in contrast to horizontal and downhill, where their activity had ceased earlier. With the gastrocnemius showing a similar activity to the horizontal, it is evident that quadriceps and hamstrings, especially biceps femoris, contributed significantly to the body propulsion forwards-upwards. Overall, EMG analysis revealed that uphill-downhill training could be beneficial for the conditioning of key leg muscles, especially the hamstrings group given their pattern and size of activity. THE EFFECT OF COMPRESSION GARMENTS ON CONTROL FORCE OUTPUT FOLLOWING HEEL-RISE EXERCISE

KATO, E., NAKAMURA, M., TAKAHASHI, H.

Japan Institute of Sports Sciences

Introduction Recently, there has been an increase in the use of compression garments (CG) during exercise to improve performance (Bannet, 2006) and to attenuate exercise-induced muscle damage (Kraemer, 2010). There are reports about the effect of CG on maximal strength (Kraemer, 2010), but in many sports activities, it is more important to control submaximal force output than to exert maximal strength. However, few reports show the effects of CG on control force output. The purpose of this study was to elucidate the effects of CG on control force output after strenuous exercise. Methods Fifteen healthy volunteers completed tasks both with and without CG (control: CON) on two separate days at least two weeks apart. Both tasks included a heel-rise exercise from maximal dorsiflexion to maximal plantar flexion 20 times on one leg. The subjects performed 3 sets and rested for 2 min between sets. Before and after heel-rise exercise, elasticity of the calf muscle and maximal voluntary contraction (MVC) of plantar flexion were measured. As an index of postural control, we also measured the areas of the center of pressure (COP) for both anterior-posterior axis and medial-lateral axis with subjects standing on both legs with eyes closed. To measure steadiness, 20% MVC for plantar flexion torque was held for 20 s as steadily as possible. Results Repeated two-way analysis of variance (ANOVA) (CG/CON × time) indicated a decline in all parameters immediately after heel-rise exercise for both CG and CON. MVC and COP did not show different tendency between CG and CON, but muscle elasticity and steadiness decline was smaller in CG than in CON (muscle elasticity, steadiness: $p < 0.05$). Discussion Despite significant MVC decrease under both CG and CON conditions, steadiness showed a small decline for CG alone. Kraemer et al. (2001) speculated that "dynamic casting" by compression may promote stable alignment of muscle fibers and attenuate inflammatory response and pain. The lack of significant differences between CG and CON for COP results was because the subjects performed heel-rise exercise on one leg, but stood on both legs for measurement of COP. Muscle elasticity showed a difference between CG and CON. Chleboun et al. (1995) stated that CG temporarily decreased swelling and muscle stiffness. In conclusion, CG may have positive benefits for control force output following strenuous exercise. References Bannet A. (2006). Sports Med, 36, 781-796. Chleboun GS, et al. MO-PM15 Muscle Damage

CHANGES IN BICEPS BRACHII MUSCLE HARDNESS AFTER ECCENTRIC EXERCISE OF THE ELBOW FLEXORS

MURAYAMA, M.1, NOSAKA, K.2, INAMI, T.3, SHIMA, N.4, YONEDA, T.5

1: Keio Univ. (Japan), 2: Edith Cowan Univ. (Australia), 3: Waseda Univ. (Japan), 4: Tokai-gakuen Univ. (Japan), 5: Juntendo Univ. (Japan)

Introduction Our previous study [1] showed that biceps brachii muscle hardness assessed by a pressure meter (PM) increased by 30-80% at 1-5 days after maximal eccentric exercise of the elbow flexors. Recently, real-time tissue elastography (RTE) is used in many studies to assess muscle hardness changes after exercise including eccentric exercise. However, the relationship between the muscle hardness measured by PM and RTE is not known. The present study compared changes in biceps brachii muscle hardness assessed by PM and RTE after eccentric as well as concentric exercise of the elbow flexors. Methods Ten young men performed 5 sets of 10 eccentric contractions (ECC) with non-dominant arm and concentric contractions (CON) with the other arm using a dumbbell set at 50% of their maximal voluntary isometric contraction force (MIF) of the elbow flexors at 90°. The dumbbell was lowered from a flexed (130°) to an extended elbow position (0°) in 5 s for ECC, and lifted from the extended to the flexed position in 3 s for CON. MIF, relaxed (RANG), extended (EANG) and flexed elbow joint angles, passive tension of elbow joint, upper arm circumference, muscle soreness and plasma creatine kinase activity were measured before, immediately after and 1-4 days after exercise for each arm. Biceps brachii muscle hardness was assessed by PM (TK-HS100, Tokushu-keisoku, Japan) and RTE (Prosound F75 : Hitachi Aloka Medical, Japan) for both arms at RANG and EANG while the participants were lying on a bed. Results Significant and prolonged ($P<0.05$) changes in all variables were evident after ECC, but the changes were small and returned to the baseline by 1 day post-exercise after CON. No significant changes in muscle hardness assessed by PM were found after CON, but after ECC, muscle hardness measured at EANG increased ($P<0.05$) from 21.6 ± 2.0 kPa (baseline) to 30.1 ± 3.7 kPa (4 days post-exercise), although no significant changes at RANG (baseline: 19.4 ± 1.4 kPa, 4 days post-exercise: 20.4 ± 1.7 kPa) were evident. RTE showed an increase in muscle hardness indicated by a decrease in strain ratio immediately after CON by 30%, but muscle hardness increased from 1 to 4 days after ECC by 20-28%. No significant correlation between the PM and RTE changes was found. Discussion The changes in muscle hardness after ECC were similar to those of the previous study [1], which was very different from the changes in muscle hardness assessed by RTE. It is concluded that muscle hardness assessed by RTE is different from that by PM. This may be associated with the smaller deformation of the skin and muscle tissue in RTE than PM. THE MORPHOLOGICAL ADAPTATIONS OF HUMAN SKELETAL MUSCLE TO ECCENTRIC AND CONCENTRIC RESISTIVE TRAINING ARE REGION-SPECIFIC

ELLIS, R., FRANCHI, M., QUINLAN, J., MAGANARIS, C., PHILLIPS, B., GREENHAFF, P., SZEWCZYK, N., ATHERTON, P., SMITH, K., BATT, M., NARICI, M.

Centre for Sports Medicine and Arthritis Research UK Centre for Sport, Exercise and Osteoarthritis, University of Nottingham Hospitals NHS Trust, MRC-ARUK School of Graduate Medicine, Nottingham, UK.

We recently reported contraction-specific muscle adaptations to eccentric (ECC) vs. concentric (CON) resistive training (RT) [1,2]. While these two exercise paradigms yielded similar hypertrophy of the vastus lateralis (VL) muscle, different architectural changes were found at the mid-portion of VL by ultrasound imaging. We here report new findings based on Extended Field of View (EFOV) ultrasonography, enabling the visualisation of entire muscles, showing regional changes in muscle architecture in response to ECC and CON RT. Methods: Eleven healthy males were randomized into 3 groups: ECC (n=4), CON (n=4) or CTRL (n=3). CON and ECC groups underwent 8 wks RT at 60% of 1RM. EFOV images were collected from the right VL at baseline and 8-wks to assess Fascicle Length (Lf), Pennation Angle (PA) and Muscle Cross-Sectional Area (CSA). Results were analysed with two-way ANOVA, statistical significance was set at $P<0.05$. Data are presented as means \pm SD. Results: After 8 wks of ECC training, CSA increased at all muscle sites but more so distally, near the MTJ (0-20% Lm) compared to the mid-portion (20-40% Lm) and to the proximal region (40-60% Lm) ($7.3\pm3\%$, $P<0.01$ vs. $4.8\pm1.6\%$, $P<0.01$ vs. $5.3\pm1.8\%$, $P<0.01$, respectively); no significant changes were observed for CON and CTRL groups at any muscle regions. PA increased after CON and ECC training, with larger increases in the CON group at all regions: $22.7\pm10.0\%$ at 0-20% Lm ($P<0.05$), $11.7\pm6.0\%$ at 20-40% Lm ($P=0.06$) and $6.0\pm3.5\%$ at 40-60% Lm ($P<0.05$). Increases in the ECC group were $11.0\pm4.0\%$ at 0-20% (N.S.) Lm, $6.0\pm4.0\%$ at 20-40% Lm (N.S.) and $7.0\pm3.0\%$ at 40-60% Lm ($P<0.05$). Lf also increased after training in the ECC group and more so in the distal and central regions, $8.0\pm1.0\%$ at 0-20% Lm ($P<0.01$) and $7.5\pm3.5\%$ at 20-40% Lm ($P<0.05$), $3.0\pm3.0\%$ at 40-60% Lm (N.S.). Instead, Lf decreased in the CON group. No changes in CSA, PA and Lf were found in the CTRL group. Conclusions: These findings show that human skeletal muscle responds very differently to ECC and CON training, matched for relative load, and that its morphological adaptations are muscle region-dependent. The observation that, in response to a training load of 60% 1RM, muscle hypertrophy only occurred with ECC loading, strongly suggests that one of the most important stimuli for hypertrophy is muscle stretch [3], while this intensity seems insufficient to induce hypertrophy with CON loading. The unprecedented observation that Lf and PA increase more distally suggest that these regions of the VL are more sensitive to mechanical loading. This contention seems supported by our finding that, in response to RT, the activity of mechano-sensitive protein focal adhesion kinase is greater distally than at mid muscle belly [4]. Funding by BBSRC (grant no BB/K019104/1) is acknowledged. References 1) Franchi MV et al. Physiol Rep. 2015;3: pii: e12593. 2) Franchi MV et al. Acta Physiol. 2014; 210:642-54. 3) Moore DR et al. Introduction An initial bout of maximal eccentric exercise (MaxEC) confers protective effect against muscle damage when the same exercise is repeated. This is referred to as the repeated bout effect (RBE), and has been shown for the elbow flexors (EF) and extensors, the knee flexors (KF) and extensors (KE), and other muscles [1,2]. Some studies showed that the RBE was also evident when the same eccentric exercise was performed by the contralateral EF [3] or KE [4], which is referred to as the contralateral RBE (CL-RBE). We reported in

ECSS 2014 that CL-RBE was evident when the right and left EF eccentric exercise bouts were separated by 1 day, 1 week or 4 weeks, but not by 0.5 hours or 8 weeks. It is not known whether this is also the case for other muscles. The present study investigated the hypothesis that CL-RBE would be still observed when the second bout was performed by the contralateral leg at 1 day, 1 or 4 weeks after the first bout for KF. Methods Untrained young men were randomly placed ($n=13/\text{group}$) to one of three CL-RBE groups based on the interval between bouts; 1 day (1d), 1 week (1wk), and 4 weeks (4wk), or a control group. The control group performed two bouts of 6 sets of 10 maximal KF eccentric contractions with the non-dominant leg in 2-week apart. Other groups performed the same exercise with either dominant or non-dominant KF first followed 1 day, 1 or 4 weeks by the same exercise performed by the opposite KF. Changes in several indirect muscle damage markers before, immediately after and for 5 days after exercise were compared between bouts, and among the groups by a mixed-design two-way ANOVA. Results Changes in maximal voluntary concentric contraction torque, peak torque angle, range of motion, upper thigh circumference, muscle soreness, plasma creatine kinase activity and myoglobin concentration, ultrasound echo intensity and carotid-femoral pulse-wave velocity after the first exercise bout were similar among the groups. The changes in the variables after the second bout were smaller ($P<0.05$) than those after the first bout for the control, 1d and 1wk groups, with significantly smaller changes for the control than the 1d/1wk groups, but without a significant difference between 1d and 1wk groups. Discussion The CL-RBE of the KF was shorter than that found for the EF. The magnitude of the KF CL-RBE was smaller when compared with that of EF. It may be that the shorter and smaller CL-RBE for KF than EF is related to their different exposure to eccentric contractions in daily activities and neurological differences at muscle, spinal and cortical levels. EFFECTS OF PRIOR UPHILL OR DOWNHILL WALKING TRAINING ON DOWNHILL WALKING-INDUCED MUSCLE DAMAGE

MAEO, S.1, MORI, H.2, YAMAMOTO, M.2, KANEHISA, H.2

1: Waseda University, 2: National Institute of Fitness and Sports in Kanoya

Introduction Walking is the most primary physical activity for humans, and the quadriceps muscles work concentrically and eccentrically during uphill and downhill walking, respectively. It is known that unaccustomed eccentric exercise induces muscle damage, and repeated bouts of eccentric exercise result in much reduced damage after the second bout. Whether prior bouts of concentric exercise exacerbate eccentric exercise-induced muscle damage is unclear. Electromyogram (EMG) median frequency is believed to reflect motor unit recruitment patterns, and reported to decrease during eccentric exercise, suggesting selective damage in fast-twitch fibers, and to be lower during the second compared to the first bout, suggesting more involvement of slow-twitch fibers as a neural adaptation for muscle protection (Warren et al. 2000). This study investigated 1) the effects of prior uphill or downhill walking training on downhill walking-induced muscle damage, and 2) whether it is associated with the EMG median frequency during the exercise. Methods Young males were allocated to an uphill training (UTG: $n=12$), downhill training (DTG: $n=12$), or control (CG: $n=10$) group. UTG and DTG underwent an 8-week (30 min/day, 3 days/week) training program using a treadmill (gradient: +25% or -25%, velocity: 3.5 km/h, load: gradually increased through 8 weeks from 0% of body weight to 20%; added to a backpack). Subsequently, all groups performed 60-min downhill walking trial (-25%, 3.5 km/h, 10%), with EMG from the quadriceps being recorded. Before and for 3 days after the trial, plasma creatine kinase activity and muscle soreness were measured as indirect muscle damage markers. Results Symptoms of muscle damage were only observed in UTG and CG without difference between these groups. EMG median frequency decreased over time during the trial in all groups without any group-difference. Discussion No difference between UTG and CG in the degree of muscle damage suggests that prior uphill walking training does not exacerbate subsequent downhill walking-induced muscle damage. Gleeson et al. (2003) reported an exacerbating effect of concentric training on eccentric exercise-induced muscle damage, but they used an upper arm, which is more vulnerable than legs, and performed full range of motion concentric training, which reportedly results in decreased fascicle length and increase the susceptibility to lengthening (eccentric) contraction. Such factors may account for the different results. Also, the EMG results suggest that median frequency could reflect intra-individual changes, but not inter-individual differences, in motor unit recruitment patterns and cannot explain resulting muscle damage. MUSCLE DAMAGE AFTER DOWNHILL-RUNNING WITH BLOOD-FLOW-RESTRICTION

BEHRINGER, M., SUESS, S., JUNG, S., MESTER, J.

German Sport University Cologne

Introduction Exercise induced muscle damage (EIMD) is commonly assumed to be the result of mechanical stress placed on the muscle tissue. However, there is also evidence showing that metabolic stress is able to induce EIMD in the absence of any meaningful mechanical impact (Chen et al., 2000). The aim of the present study was to investigate if adding metabolic stress to an eccentric exercise protocol results in an increased level of muscle damage markers in the blood. Methods Nineteen healthy male adults were assigned to an intervention (IG; $n = 10$) and a control group (CG, $n = 9$). Both groups underwent a downhill-running protocol consisting of 4x5 min intervals at a running speed of 9 km/h and a treadmill decline of 20%. Inflatable cuffs were used in the IG to reduce the blood flow during the 4 intervals. Venous blood samples were taken at pre, post, 2 h, 24 h, and 48 h after the protocol and were analyzed for creatine kinase (CK) and myoglobin (Mb). Results The CK activity significantly increased from baseline ($178 \pm 110 \text{ IU/L}$) only in the IG with a peak value at 24 h ($568 \pm 373 \text{ IU/L}$). No such difference was seen in the CG (Pre: 170 ± 133 ; 24 h: $318 \pm 124 \text{ IU/L}$). By contrast, the Mb values were significantly increased 2 h after the protocol in both groups (IG: $235 \pm 102 \mu\text{g/L}$; CG: $147 \pm 58 \mu\text{g/L}$), when compared to baseline (IG: $61 \pm 10 \mu\text{g/L}$; CG: $72 \pm 29 \mu\text{g/L}$). Nevertheless, there was a clear trend for greater Mb responses in the IG. Discussion Our data indicate that a reduced blood supply during a damaging protocol increased the amount of muscle damage, as evident from two different muscle damage markers (CK and Mb). This stays in contrast to the results of Thiebaud et al. (2014), who concluded that BFR does not affect the EIMD that was induced by low-intensity eccentric contractions of the elbow flexors. In that study no significant differences were found between the restricted and unrestricted condition regarding the maximum isometric force, the range of motion, upper arm circumference, muscle thickness, and muscle soreness. Sudo et al. (2015) even reported that BFR markedly reduced the number of damaged muscle fibers in rats after high-intensity eccentric contractions. That is, in contrast to earlier findings, the present study indicates that BFR increases the amount of EIMD and therefore adds important information on the growing body of literature on BFR-training. PROTECTIVE EFFECT OF PREVIOUS MARATHON EXPERIENCE ON MARATHON-INDUCED MUSCLE DAMAGE, INFLAMMATION AND MUSCLE SORENESS

ISHIKURA, K., TOKINOYA, K., EBINA, K., KAWAGUCHI, Y., KUROIWA, T., MIZUSHIMA, T., YAMAMOTO, D., NABEKURA, K., OHMORI, H.

University of Tsukuba

Introduction Delayed-onset-muscle-soreness (DOMS) is characterized by its occurrence after unusual exercise or eccentric exercise, appearance approximately 24 hours after the exercise, peak soreness between 24 and 72 hours after the exercise. On the other hand, other types of exercise-induced muscle soreness exist, such as immediate onset muscle soreness (IOMS), which occurs earlier than DOMS, immediately after exercise. IOMS is frequently observed in exercise involving running, particularly in long distance running, such as the marathon event. Several studies have reported that the repeated bout inhibited eccentric exercise-induced muscle damage and DOMS (Nosaka et al., 2001; Connolly et al., 2002). This study investigated the protective effect of previous marathon experience on marathon-induced muscle damage, inflammation, and IOMS in non-professional full-marathon runner. **Methods** Subjects were 17 (6 Still experienced marathon runners: SE, 11 First time marathon runner: FT) non-professional runners participating in a full-marathon race. Serum creatine kinase (CK), aldolase, aspartate amino transaminase (AST), lactate dehydrogenase (LDH) activities, C-reactive protein (CRP) concentration were measured as well as systemic fatigue and muscle soreness, before, immediately after, and 1 to 2 days after the event. Systemic fatigue and soreness in seven muscle regions were evaluated using a numeric rating scale. **Results** Serum CK activities at the immediately, 1 and 2 day after the marathon, and serum AST activities and serum CRP concentration at the immediately and 1 day in the FT group was significantly higher than before the event, but not significantly in the SE group. Total muscle soreness at the 2 day after the marathon in the FT group still higher than before the event, but not in the SE group. **Discussion** This study revealed that the effectiveness of previous marathon bout on reducing muscle damage, inflammation, and IOMS after the running of a full marathon as well as repeated bout effect on eccentric exercise induced muscle damage and DOMS. MUSCLE DAMAGE DURING JUNIOR TENNIS TOURNAMENT: EFFECTS OF THE COMBINED RECOVERY METHOD

BAYLAN, N., PINAR, S., KAYA, F., ATIŞ, E.F.

Marmara University

MUSCLE DAMAGE DURING JUNIOR TENNIS TOURNAMENT: EFFECTS OF THE COMBINED RECOVERY METHOD Introduction Tennis movements comprise of acceleration, deceleration and changes in direction. These activities occur with high eccentric contractions of muscles, which are accompanied by symptoms such as muscle damage. The aim of this study was to investigate the muscle damage and the effects of the combined recovery method during junior single tennis tournament. **Method** Sixteen elite tennis players (experimental n=8, control n=8) participated in a 4-day tennis tournament. The experimental group participated in combined recovery method after every match. Blood samples were collected before, immediately after and 48h after the tournament to investigate creatine kinase (CK), lactate dehydrogenase (LDH) and C-reactive protein (CRP) levels. Delayed onset muscle soreness (DOMS) questionnaire was taken before, immediately after every match and 48h after the tournament. Result CK and LDH activity in the blood were increased significantly but there were no significant differences in CRP immediately after the tournament comparing to pre tournament. There were no differences on CK, LDH and CRP between the groups during and after the tournament. During tournament DOMS increased significantly in both groups. In the experimental group DOMS scores significantly decreased comparing to control group 48h after the tournament ($p<0.05$). **Discussion** Our results demonstrated that tennis matches increase significantly blood LDH, CK but not CRP levels. Previous studies have shown that eccentric contractions during sports games can increase CK and LDH enzymes in the blood, which show muscle damage indirectly (Kraemer et al., 2009; Nosaka et al., 2010; Potteiger, Blessing, & Wilson, 1992). Combined recovery method may not changed the blood enzymes but decreased DOMS 48h after the last match. Combined recovery can provide an advantage for being ready for the upcoming tournament. MORPHOLOGICAL CHARACTERISTICS OF SPORT CLIMBERS

HAKAMADA, N., NUMAZAWA, H.

Rikkyo University

Introduction Sport Climbing has become popular for the last decade. However, there is not sufficient research about physical profiles of sport climbers. Thus, the aim of this study was to clarify the anthropometric characteristics of elite competitive sport climbers. **Methods** Body height, arm span, superior reach span, shoulder and pelvis widths, length and girth of both extremities were measured by the Martin-type instrument and from these data several anthropometric indices were calculated. We collected data from male sport climbers (n=12) aged 18-23 years, whose maximum climbing ability ranged from 6c to 8c in the French scale on lead climbing. Data collected from these climbers were compared with the control data, which is the physical fitness standard value of Japan. Further, we also compared in the following two participant groups. Group 1 (n=7) comprised elite sport climbers who had led a climb of a minimum standard of 8a; and Group 2 (n=5) comprised standard climbers who had climbing abilities below 7c+. **Results** We found that sport climbers have significantly thicker forearm girth ($p<0.01$) and thinner calf girth ($p<0.05$). The anthropometric indices which resulted in significant differences between sport climbers and the controls included the ape index ($p<0.01$; climber 1.0167 ± 0.023 ; standard value 0.9947) and the upper extremity girth index ($p<0.01$; climber 0.9749 ± 0.0543 ; standard value 0.9161). We also found that elite sport climbers have significantly lower body mass ($p<0.05$), body fat ($p<0.05$), and thinner arm girth ($p<0.05$), thigh girth ($p<0.05$), calf girth ($p<0.01$) than standard climbers. **Discussion** Sport climbers in this study had significantly higher ape index and upper extremity girth index (forearm girth to arm girth ratio) scores than the controls. This tendency suggests that the development of the upper extremities is an important factor for sport climbing. On the other hand, elite climbers had significantly thinner limbs except the forearms compared with regular climbers. The result

of this study shows that longer upper extremities are fundamental factors for sport climbers, and that a certain amount of muscles, but not too much, for the extremities is needed. Contact hakamadanaoto@gmail.com

ENDURANCE TRAINING INCREASES QUADRICEPS OXIDATIVE PROFILE IN COPD: A RCT OF TWO MAJOR TRAINING MODALITIES

IEPSEN, U.W., MUNCH, G.D.W., RUGBJERG, M., ZACHO, M., PEDERSEN, B.K., HELLSTEN, Y., RINGBÆK, T., THANING, P., LANGE, P.

University of Copenhagen, Rigshospitalet

Exercise is an important countermeasure to skeletal muscle dysfunction in chronic obstructive pulmonary disease (COPD). The two major training modalities in COPD rehabilitation; endurance training (ET) and resistance training (RT) are equally effective at improving muscle strength, exercise capacity and health related quality of life, but the characteristics of muscle fiber type shifting, capillarization and metabolism have not been thoroughly described. Therefore, 30 COPD patients (forced expiratory volume in 1 sec: $56\pm14\%$ of predicted) were randomized to eight weeks of ET or RT. Muscle biopsies (vastus lateralis) were obtained before and after the training intervention to assess muscle morphology, metabolic and angiogenic factors. Symptom burden, exercise capacity, body composition, skeletal muscle blood flow and vascular function were also measured. ET significantly reduced the proportion of type IIa muscle fibers (from $48\pm11\%$ to $42\pm10\%$, $p=0.022$) and differed significantly from the RT group at follow-up ($42\pm10\%$ versus $56\pm16\%$, $p=0.040$). Aerobic metabolism (phosphofructokinase content) was only reduced in the ET group ($p<0.05$). Exercise improved symptom burden and exercise capacity in both groups, but no difference between groups. Based on the improved quadriceps oxidative profile, our results suggest ET as the preferred countermeasure to skeletal muscle dysfunction in COPD.

CURRENT CONCEPTS OF PHYSICAL ALLERGIES

KWAK, Y., YANG, J.

DONG-EUI UNIV

PURPOSE: It is well known that physical activity is beneficial for people with positive results for physical status and mental wellbeing. However, physical exercise decrease the immune response and may induce an allergy anaphylaxis at some situation as follows. A common example is exercise-induced asthma, exercise-induced urticaria, exercise-induced anaphylaxis and FDEIAn. Generally, anaphylaxis is a severe, potentially fatal, hypersensitivity reaction of rapid onset. It is a dramatic clinical emergency. Actually, there are lots of etiologic factors of anaphylaxis, the principal immunologic triggers are foods, insect stings, and drugs. In recent, physical exercise is also related with the anaphylaxis. In this paper, we present the current views of physiological mechanisms underlying physical anaphylaxis within the context of exercise immunology. We also deals with a detailed 2 kinds of EIA (exercise-induced asthma, exercise-induced anaphylaxis) and exercise prescription and medical treatment for exercise-induced asthma, exercise-induced anaphylaxis and CU (chronic urticaria).

METHODS: At first, we analyzed and presented the causes, symptoms, pathophysiology, testing, treatment and prescription of exercise-induced asthma, exercise-induced urticaria, exercise-induced anaphylaxis and FDEIAn through many experiments and references.

RESULTS: Exercise-induced asthma is a typical asthmatic attack which follows a strenuous exercise lasting 5 to 10 minutes in circumstances of dry and cold air situation. Avoid of exercise in that conditions and drug treatment (beta-2 adrenergic agonists) must preferentially be preventive. Physical urticarias are a unique subgroup of CU in which patients develop urticaria secondary to environmental stimuli. Common triggers include cold and heat temperature, water, sunlight and even physical exercise. It is responsible for approximately 20-30% of all cases of chronic urticaria. FDEIAn is induced by different types and various intensities of physical exercise, and this is distinct from food allergy. It is useful to test both *in vivo* and *in vitro* an extensive panel of foods. Avoidance of allergenic foods for at least 4 h before exercise has prevented further episodes in all our patients with specific FDEIAn. **CONCLUSIONS:** It is concluded that anaphylaxis remains a continuous challenge for the diagnosis and treatment. The adequate management of anaphylaxis requires rapid diagnosis, implementation of primary and secondary prevention measures, and immediate administration of subcutaneous epinephrine. Furthermore, patient education is necessary to heighten awareness of the sign and symptoms of 2 kinds of EIA and FDEIAn.

CORRELATES OF OBJECTIVELY ASSESSED LIGHT PHYSICAL ACTIVITY AND PSYCHOLOGICAL WELLBEING IN RHEUMATOID ARTHRITIS

FENTON, S.A.M., KITAS, G.D., VELDHUIZEN VAN ZANTEN, J.J.C.S., METSIOS, G.S., YU, C., ROUSE, P.C., DUDA, J.L.

University of Birmingham

Background: Epidemiological studies indicate participation in light physical activity (LPA) is positively associated with psychological wellbeing. For patients with Rheumatoid Arthritis (RA), reduced functional ability may result in lower LPA engagement and consequently, compromised mental health (e.g., depression, reduced vitality). In particular, lower-limb functional disability in RA may result in fewer sit (≤ 1.5 METS) to stand (>1.5 METS) transitions, in turn, contributing towards lower LPA. Given that physical dysfunction is symptomatic of RA, it is also important to determine modifiable correlates of LPA. Autonomy support for PA is reported to be associated with PA engagement, and may represent a malleable target for interventions that seek to promote LPA in RA. **Objectives:** To test a model examining the implications of 1) functional disability and 2) autonomy support for PA, for levels of objectively assessed LPA engagement and associated positive and negative indicators of wellbeing. **Hypotheses:** 1) Self-reported functional ability to 'rise' (from sitting) would negatively predict LPA, via a positive indirect association with objectively assessed sit-to-stand transitions 2) Autonomy support would directly and positively predict LPA, independently of functional disability 3) LPA would positively predict feelings of vitality and be negatively associated with depression. **Methods:** RA patients (N=50, Mage = 55.52 ± 12.53), completed questionnaires assessing: 1) functional disability to 'rise' (e.g., are you able to stand up from a chair), 2) autonomy support for PA (from a patient-specified important other), 3) depressive symptoms, and 4) subjective vitality. Sit-to-stand transitions and LPA were assessed via 7-days of accelerometry (i.e., number of transitions/day

from <100 counts per min (cpm) to ≥100 cpm, LPA min/day ≥100 cpm). Results: Path analyses supported a model ($\chi^2(6)=8.62$, $p=.20$, CFI=.97, RMSEA=.09), in which functional ability significantly negatively predicted the number of sit-to-stand transitions/day, which in turn, significantly positively predicted LPA min/day. A significant positive association between important other autonomy support and LPA was observed. LPA significantly and negatively predicted depressive symptoms ($R^2=.36$), and was positively associated with vitality ($R^2=.33$). Conclusions: Functional disability to rise from a seated position may result in a reduced frequency of sit-to-stand transitions, and contribute towards reduced LPA participation in RA patients. However, important other autonomy support may represent a modifiable target for interventions seeking to promote LPA in RA, independently of the potential negative consequences of functional disability. Subsequently, increasing LPA may hold implications for psychological wellbeing in RA.

PREVALENCE OF BACK PAIN IN GERMAN ELITE HANDBALL PLAYERS

SURMANN, C., FETT, D., TROMPETER, K., PLATEN, P.

Ruhr-University Bochum

Introduction: Back Pain is one of the most occurring complaints in sports. Handball is a very intensive contact sport that is associated with mechanical strain on the musculoskeletal system. Especially elite handball players are physically stressed due to high training volume and competition. Consequently this might be related with the development of back pain. This study aims to determine lifetime prevalence (LP) and point prevalence (PP) of back pain in German elite handball players regarding the localization at the spine. **Methods:** N=32 handball players ($m=8$, $f=24$, 18.4 ± 2.0 yrs, 177.2 ± 7.8 cm, 71.8 ± 9.5 kg, training volume: 13.8 ± 4.1 hours/week) were asked to fill in an online-questionnaire based on valid Nordic Questionnaire by Kuorinka et al. (1987). Additionally, training volume was collected. χ^2 -statistics were used to determine differences in back pain between sexes, the pearson correlation coefficient was used for analyzing if's relation to age, training volume, body weight and height. **Results:** LP of back pain was 84.4%. Regarding different parts of the spine the LP of pain was 53.1% in the neck, 28.1% in the thoracic spine and 81.3% in the lumbar spine. PP of pain in the total back was 25.0% (neck: 15.6%, thoracic: 6.3%, lumbar: 25.0%). Comparison between sexes showed no significant differences. There was a statistical significant correlation for age and PP of low back pain as well as for age and PP of neck pain ($p<.05$) in female handball players. Also for the females training volume and LP of low back pain showed a correlation ($p<.05$). For male players no significant correlations were found. **Discussion:** The results indicate that back pain is a great problem in German elite handball players. Nearly 85% of investigated handball players had back pain at least once in their life. Especially low back pain seems to be problematical in this sample. This is in line with findings in the literature. Tunas et al. (2015) found LP and PP of low back pain in female handball players to be 63% and 26%. In the present investigation LP was much higher compared to this data. One possible reason could be the high competition level of the sample. The results underline the necessity of back pain prevention in elite handball players. **Acknowledgement:** The study was supported by the Federal Institute for Sport Science, Germany (ZMVI1-080102A/11-18). **References:** Kourinka, I. et al. (1987). ApplErgon. 18, 233-237. Tunas, P. et al. (2015). Kneesurg Sports TraumatolArthrosc., 23(9):2540-2547. Contact: christopher.surmann@rub.de

SHOULDER PAIN IN THE SWISS SPINAL CORD INJURY COMMUNITY: PREVALENCE AND ASSOCIATED FACTORS

BOSSUYT, F.M.1,2, ARNET, U.1,2, BRINKHOF, M.W.G.1,2, ERIKS-HOOGLAND, I.3, LAY, V.1, MÜLLER, R.1,2, SUNNÅKER, M.1, HINRICH, T.4

1: Swiss Paraplegic Research (Nottwil, Switzerland), 2: University of Lucerne (Lucerne, Switzerland), 3: Swiss Paraplegic Centre (Nottwil, Switzerland), 4: University of Basel (Basel, Switzerland)

Introduction: Shoulder pain is a common health problem among persons with spinal cord injury (SCI) that can negatively affect mobility and participation in social life. The aetiology of shoulder problems in persons with SCI is believed to be multifactorial. The aim of this study was to (1) determine the prevalence of shoulder pain and (2) identify factors associated with shoulder pain (including sporting activities as well as sociodemographic and socioeconomic factors, SCI characteristics, health conditions, and mobility independence) in a population based survey. **Methods:** Data was collected in 2012 through a community survey of the Swiss SCI Cohort Study [1]. Swiss residents with SCI aged 16 or older participated in this study (N=1549; age: 52.3 ± 14.8 years; 29% female). Musculoskeletal shoulder pain over the past week (yes/no) as well as other parameters were assessed by self-report. Descriptive data analysis and multivariable logistic regression analysis were used, the latter providing adjusted odds ratios of shoulder pain for sex, age, education, income, SCI aetiology, level and completeness, spasticity, contractures, time since injury, independence in moving 10 to 100 metres, and time spent with sporting activities. The multivariable analysis was adjusted for item non-response (with multiple imputation) and unit-nonresponse (with inverse probability weighting). **Results:** The high overall prevalence of shoulder pain was 36% (95% CI: 33-38). Females had higher odds of shoulder pain as compared to males (odds ratio: 1.89; 95% CI: 1.44-2.47) and when spasticity (1.36; 1.00-1.85) and contractures (2.47; 1.91-3.19) were apparent. In addition, persons with complete paraplegia (1.62; 1.13-2.32) or any tetraplegia (complete: 1.63; 1.01-2.62; incomplete: 1.82; 1.30-2.56) showed higher odds of shoulder pain as compared to those with incomplete paraplegia. Age, education, net equivalent income, etiology, and time spent with sporting activities showed no association. **Conclusion:** Future longitudinal studies will have to search for modifiable factors that are on the causal chain leading to the described associations. **Reference:** [1] Brinkhof MWG, Fekete C, Chamberlain JD, Post MWM, Gempeler A, for the SwiSCI Study Group. (2015). Swiss national community survey on functioning after spinal cord injury: protocol, characteristics of participants and determinants of nonresponse. Journal of Rehabilitation Medicine. EFFECTS OF AN IN-HOSPITAL EXERCISE INTERVENTION IN CHILDREN WITH LEG'S SARCOMA.

PADILLA, J.R.1, SANTANA, E.1, FIUZA, C.1, LASSALETTA, A.3, HERNÁNDEZ, C.3, ANDIÓN, M.3, VARO, A.3, MADERO, L.3, LÓPEZ-MOJARES, L.M.1, LUCIA, A.1.2, PÉREZ, M.1.2

1-Sport Science Faculty, European University of Madrid; 2-Research and Postgraduate Department, European University of Madrid; 3-Niño Jesús University Children's Hospital

Introduction: Maintaining high levels of physical activity during chemotherapy improves the quality of life of children with sarcoma, as well as their functional capacity, which in turn helps them cope with the treatment (Courneya et al. 2001). The objectives of this study are: 1) to analyze the physical condition of pediatric patients newly diagnosed with sarcoma in lower limbs; 2) to assess the effects of an in-hospital exercise program in the cardiorespiratory and muscular fitness of this population. **Material and methods:** Subjects: 18 children with the aforementioned condition were randomly divided into one of two groups: intervention (exercise; n=9 subjects); or standard care (controls; n=9 subjects). **Study end points:** All children were evaluated at baseline and at end-treatment (neoadjuvant chemotherapy period, average duration 20(SD±9)wk): 1) on an arm-crank ergometer to measure their peak oxygen uptake (VO_{2peak}); 2) in a intra-hospital gymna-

sium, to test their 5 repetition maximum (5RM) strength (bench press and lateral row). Combined physical training program. The intervention group performed 3 weekly individually supervised sessions from 45 to 60min duration that included both aerobic arm-ergometer exercise at a heart rate intensity equivalent to the ventilatory threshold and upper-body strength exercises of gradual intensity (3 sets of 15 reps at an initial load ~50% of estimated baseline 1RM). Statistical analysis. We used a two-factor (group and time) analysis of covariance (ANCOVA) with repeated measures. Results We found no significant group ($p=0.969$), time ($p=0.580$) or group*time (interaction) effect ($p=0.969$) for VO₂peak values. In contrast, we found a significant training-induced benefit for bench press ($p=0.875$, 0.026 and 0.001 for group, time and group*time effect, respectively) and for lateral row ($p=0.875$, 0.547 and 0.001 for group, time and group*time effect, respectively). Discussion and conclusion The exercise intervention had a significant beneficial effect on the children's muscle strength. We believe our data are relevant because the bulk of research has focused on pediatric hematological cancer, particularly acute lymphoblastic leukemia(ALL)(Huang & Ness, 2011) and data are much more scarce on solid tumors, which usually require a more aggressive treatment and have a worse outcome compared with ALL(Balamuth & Womer, 2010). Conclusion The baseline functional capacity of children with leg's sarcoma is very low and such low values further decline with chemotherapy. Combined exercise training has a significant, beneficial impact on the decline in muscle strength that naturally occurs with chemotherapy. References Courneya KS, Friedenreich CM. MO-PM30 Performance: Mixed Session

DYNAMICS OF AEROBIC CAPACITY AND FORCE-VELOCITY CHARACTERISTICS OF ARM AND LEG MUSCLES IN JUNIOR CROSS-COUNTRY SKIERS

BUTKOV, A., LYSENKO, E., LEMESHEVA, Y., POPOV, D.

Institute of Biomedical problems of Russian Academy of Sciences

The goal of our study was to evaluate dynamics of aerobic capacity and force-velocity characteristics of arm and leg muscles in junior cross-country skiers during on-snow training season. Six junior subnational level cross-country skiers (19.3 ± 1.1 years old, $V'VO_{2\text{max}} 63.3 \pm 5.9$ ml/min/kg) participated in 4 physiological test sessions from November to March. Maximal anaerobic power (MAnP) of arm muscles was determined in a 10-second maximal effort test by double poling ergometer. Maximal torques of knee extensor muscles at various angular velocities (30 degrees/s – 300 degrees/s) were measured by isokinetic dynamometer. Aerobic capacity [maximal oxygen consumption rate ($V'VO_{2\text{max}}$) and $V'VO_2$ at blood lactate level (La) 4 mmol/l] was evaluated in incremental tests using double poling ergometer and running treadmill. In the beginning and in the end of the test period volume of m. quadriceps femoris and m. triceps brachii as well as body composition were evaluated by magnetic resonance imaging and anthropometry, accordingly. No MAnP increase was found during training period. Knee extensors torque did not change at low angular velocity (30 degrees/s), whereas a decrease (7.8%, $P < 0.05$) was found at 300 degrees/s. Initial $V'VO_{2\text{max}}$ in double poling and treadmill tests were 3.7 ± 0.6 and 4.5 ± 0.6 l/min, accordingly, and did not change during the training period. $V'VO_2$ at La 4 mmol/l in treadmill test was 3.6 ± 0.8 l/min and also did not change. However, $V'VO_2$ at La 4 mmol/l in double poling test gradually rose during the testing period from 2.2 ± 0.8 to 2.8 ± 0.7 l/min. Increase of aerobic capacity in incremental double poling test can be explained by initially very low level of aerobic capacity: $V'VO_2$ at La 4 mmol/l was lower compared with that in treadmill test – 2.2 ± 0.8 and 3.6 ± 0.8 l/min, accordingly. That difference may be associated with low arm muscles training volume over preparation period compared to leg muscles. High volume of leg muscle aerobic training may have negative effect on leg muscle strength and cross-section area. The work was supported by Program № 1.26P from Presidium RAS

THE EFFECTS OF SPEED ENDURANCE TRAINING VS. AEROBIC HIGH-INTENSITY INTERVALS ON ENDURANCE PERFORMANCE IN ELITE DANISH ORIENTEERS

ROKKEDAL-LAUSCH, T.1, LASSEN, T.2, LARSEN, R.G.1, MADSEN, K.2, FRANCH, J.1

1: Aalborg University, Denmark, 2: Aarhus University, Denmark

Introduction It is well-known that a short-term period of high intensity training (HIT) is effective in improving endurance performance in trained athletes(Laursen & Jenkins 2002). However, only few studies have been performed in highly trained endurance athletes and therefore the knowledge about the effects of different types of HIT in elite athletes is sparse(Kilen et al., 2014; Denadai et al., 2006). The purpose of the present study was to evaluate five weeks of speed endurance running (SET, n=8) or aerobic high-intensity running (AHI, n=5) in elite orienteers. Methods Performance measures included a short intermittent (4000m) and a field running endurance performance test (8000m), $VO_{2\text{max}}$ and running economy (RE). Further, blood samples pre and post was evaluated for markers of muscle damage and overreaching (LDH, CK, myoglobin, cortisol) and session rating of perceived exertion (session-RPE) was collected after every HIT session. Thirteen elite orienteers (7 female, 6 male), with mean $VO_{2\text{max}}$ of 61.9 ± 3.3 ml O₂/min/kg and RE of 195 ± 3.2 ml O₂/min/km performed either SET or AHI two to three times weekly for five weeks combined with regular aerobic low-intensity training. In both groups overall running distance was reduced by 20% compared to the four weeks prior to intervention. SET consisted of 4-12x30-sec. at 90-100% of maximal running distance during a 30-second sprint with 3 minutes of active recovery. AHI consisted of 4-8x4min intervals at an average of 90% of maximal heart rate with 2 minutes of active recovery. Results We found no significant differences in relative changes between groups in running performance, $VO_{2\text{max}}$ and running economy. Short intermittent endurance performance was maintained whereas long endurance performance showed a tendency towards being impaired in both groups. When combining the groups there was a significant improvement in running economy performance ($P < 0.05$). $VO_{2\text{max}}$ was reduced in both SET and AHI ($P < 0.05$) whereas maximal lactate accumulation (Lamax) increased ($P < 0.05$). Session-RPE was significantly higher in AHI than in SET ($P < 0.05$) while no changes were observed in markers of muscle damage and overreaching. Conclusion In conclusion, five weeks of SET or AHI, impaired long field running performance and $VO_{2\text{max}}$ while short intermittent running performance was maintained and RE improved. COMPARISON OF FUNCTIONAL MOVEMENT SCREEN RESULTS IN DIFFERENT GROUPS OF ATHLETES

WRIGHT, P., REHFELDT, J.

Chemnitz University of Technology

INTRODUCTION The Functional Movement Screen (FMS) consists of seven fundamental functional movement pattern. Each test represents a specific movement within a kinetic chain model and therefore is classed as a Kinetic Chain Assessment. The FMS is supposed to assess the risk of injury by using a cut-off score of ≤ 14 points (max. of 21 points). The aim of this study therefore was to investigate, if single tests items of the FMS and/or the overall score are effected by the specific conditioning requirements of different sports. METHODS 29 male participants were recruited with 3 different sporting backgrounds – football, climbing and fitness training. The mean age was 26.52 years (± 5.01) and a BMI of 23.20 ($\pm 1.95 \text{ kg/m}^2$). These different sports were thought to cover a wide range of different conditioning methods and were considered extreme opposites. It was hypothesised that this would have an effect on FMS scoring. The following test batteries were conducted: FMS, FMS Y-balance test (YBT), bio-impedance analysis and grip strength. The subjects were randomised and allocated to groups of different test orders to avoid any distortion or transfer-effects on the test results. RESULTS This study found that the climbers performed better in all FMS test items compared to the footballers and the fitness trainees. Results of all participants were in the range of 12-18 points (median: 16 and MV: 15.76 ± 1.53). The climbers achieved the highest score with a median of 17 and a MV of $16.78 (\pm 1.72)$, whereas the fitness cohort scored a median of 15 and a MV of $15.47 (\pm 1.06)$ and the footballers had 15 points and a MV of $14.80 (\pm 1.64)$. Regarding the YBT, the climbers demonstrated the highest score with 104.19% (± 6.47), the fitness trainees had 98.82% (± 5.37) and the footballers 99.23 % (± 3.63). However, this difference was not significant ($p = 0.074$). In the body composition, muscle mass positively correlated with the grip strength ($p = 0.447$) and the FMS score ($p = 0.473$), while fat mass showed a negative correlation to the same parameters ($p = -0.560$). These medium strong correlations are significant with $\alpha = 0.01$. DISCUSSION Our data confirms that functional and whole body movement concepts such as climbing lead to an even musculoskeletal adaptation with strong components of coordination which was reflected in the FMS results. The overall FMS score was higher in climbers than in the other two groups, but not significantly. The fitness trainees showed average results, while the footballers demonstrated below average results. The only significant differences were demonstrated in single FMS test items which are balance related. This was especially the case in the YBT, which can be explained by the specific requirements of climbing, involving core stability, balance and as such coordination.

VISUAL STRATEGIES OF TOP LEVEL BADMINTON PLAYERS

GAWIN, W., LIEBOLD, B., FRIES, U., ORIWOL, D., MAIWALD, C.

Technische Universität Chemnitz

Introduction Visual perception and anticipation of athletes in sports have frequently been subject of investigations to discriminate effective visual search strategies with the aim to improve performance in anticipation (a. o. Abernethy & Russell, 1987; Alder, Ford, Causer & Williams, 2014). The gaze behavior of experts and non (or near)-experts is frequently recorded under laboratory conditions using video tapes. The question arises whether this two dimensional stimulus is a valid approach (Mann, Williams, Ward & Janelle, 2007). In the present study, gaze behavior of internationally ranked badminton players and intermediate level club players was investigated under field conditions with real opponents to induce actual reactions of the players. Methods The gaze strategies of 4 internationally ranked female doubles players (age 27.5 ± 3.4 years) and 5 intermediate club level players (1 female, 4 male, age 32.6 ± 7.8 years) were analyzed using a mobile eye tracking device (SMI ETG 2, sample rate 60 Hz). The participants returned serves in a simulated doubles match. Their visual search strategies were recorded while executing the return and the gaze direction was analyzed frame by frame during one second before racket–shuttle contact of the serve. The locations of gaze direction were categorized in head, trunk, shoulder, arm, hand, racket head and shuttle. Results The locations that were frequently focused on were shuttle, racket head, head, trunk and left hand with noticeable differences between the experts and the near experts. While the club level players focused on the head of their opponents in 28 % of the recorded period, the racket head in 7 % and the shuttle in 17 %, the top players never focused on the head but rather mostly on the shuttle (48 %) and the racket head (28 %). Discussion These findings seem to contradict the results of Alder et al. (2014), who used video tapes as stimulus. They reported that participants seldom focused vision on the shuttle but frequently on the right wrist, a location that was not measured at all in the present study. It is presumable that the research conditions influence the outcome of analyses of visual strategies. References Abernethy, B. & Russell, D. (1987). FIREFIGHTERS' FIT FOR DUTY SCORE-MODEL

LINDBERG, A., WIKLUND, K., ANDERSSON, M., MALM, C.

Winternet

Introduction Physical capacity has previously been deemed important for firefighters' physical work capacity, and evaluation of fitness for duty is common in the pre-hiring process. Various methods have been used to establish cut-off limits, i.e. normative data or expert judges. In accordance with government regulation, both full-time and part-time firefighters in Sweden have to pass a medical examination and a test of physical work capacity for permission to execute smoke diving. The physical work capacity test is a pass or fail test: dressed in firefighting protective clothes and breathing apparatus (total weight 24 ± 0.5 kg), six minutes walking with the incline at 8 degrees and treadmill speed of 4.5 km/h is performed. Inclusion of additional physical tests and appropriate cut-off limits is a decision taken by each individual municipality. The aim of the present study was to create a score model for evaluation of fitness for duty in the pre-hiring process of firefighters. Methods A total of 128 (64 men and 64 women) subjects: full-time firefighters, part-time firefighters and civilians, were included. Subjects performed five simulated firefighting work tasks and a selected battery six of physical tests including; 500 m rowing, grip strength, endurance bench press, track running 3000 m, standing broadjump and upright barbell row. The combined information from subjective evaluated cut-off limits, breakpoint estimation, checkpoint estimation and percentiles were used to create a score-model

for evaluation of fit for duty. Results The models yielded various cut-off limits on the same physical test, depending on the work task investigated, but all tests were scored on a 1-11 scale. Consequently, the maximum total score was 66 and the minimum total score was 6. The recommended minimum total score of six tests is 36. Discussion In this study we created a score-model for evaluation of firefighters' fit for duty in the pre-hiring process. When pre-hiring physical tests are performed, an easily conducted battery of physical tests is important in order to reduce costs but still maintain high validity and reliability. The score-model is easy to understand, performance gives the same score irrespectively of age and sex and makes it possible for the aspirants to prepare for the included physical tests. Since a specific physical test differs in importance in the prediction of simulated work task performance, the lack of performance in one physical test may not be fully compensated with a higher performance in another physical test. Simplifying and generalizing a method makes it practically usable at the detriment of accuracy on an individual level.

DIFFERENTIATION BETWEEN PERCEIVED EFFORT AND DISCOMFORT DURING RESISTANCE TRAINING: RELIABILITY OF TRAINEE RATINGS OF EFFORT AND DISCOMFORT, AND RELIABILITY AND VALIDITY OF TRAINER RATINGS OF TRAINEE

STEELE, J., FISHER, J., MCKINNON, S., MCKINNON, P.

Southampton Solent University

Tools such as rating of perceived exertion (RPE) scales are commonly used in exercise to identify the degree of effort put forth by an individual. RPE scales of many forms have been applied specifically to resistance training (RT) and could be useful tools to determine the degree to which effort as a variable impacts training adaptation. Training to a maximal effort by completing repetitions to momentary muscular failure (MMF) is suggested to be most efficacious in RT but the specific dose response nature of effort is unknown. Thus submaximal measures of effort using RPE scales could be useful advancing understanding of this. However, most RPE scales suffer from conflation of perceptions of both effort and discomfort or other physiological sensations by participants. To address this we have developed two adapted 11 point scales (0-10) along with scripts which are designed to encourage participants to differentiate between 'effort' (RPE-E) and 'discomfort' (RPE-D) during resistance training. The aim of this study was to examine the reliability of trainee ratings of perceived effort and discomfort using these scales in addition to the reliability and validity of trainer ratings of effort. Participants underwent 3 RT trials over a period of three weeks consisting of 5 compound exercises (Chest press, pull down, seated row, overhead press and leg press) performed to a self-determined RM (meaning they determined inability to complete further repetitions if attempted i.e. they predicted MMF on the next repetition). A self-determined RM was chosen as the repetition cessation criteria in order to examine the use of the RPE-E and RPE-D scales during submaximal effort, though in some instances during trials participants did reach MMF thus providing a range of efforts to examine. Intra-rater absolute standard error of measurement (SEM) was calculated for trainee RPE-E, trainee RPE-D, and trainer RPE-E. In addition, in a sub set of participants receiving 2 trainer RPE-E assessments, inter-rater absolute SEM was calculated. Finally, validity of trainer RPE-E was examined as SEM between trainer and trainee RPE-E. Intra-rater SEMs for trainee RPE-E ranged from 0.64 to 0.85 pts, trainee RPE-D ranged from 0.60 to 1.00 pts, and trainer RPE-E ranged from 0.56 to 0.71. Inter-rater SEMs for trainer RPE-E ranged 0.25 to 0.66. SEMs for agreement between trainer and trainee RPE-E range from 1.03 to 1.25. Results suggest that the reliability for both trainee measures of RPE-E and RPE-D, in addition to trainer RPE-E is acceptable. Further, trainer RPE-E appeared to have acceptable validity compared to trainee RPE-E. These results suggest that the scales adopted might be used in research examining the dose-response nature of perceived effort independently of perceived discomfort upon outcomes related to RT. It also suggests that trainers might predict a trainees perceptions of effort with acceptable accuracy and thus be able to use such information in programming.

PHYSICAL FITNESS IN YOUNG MALE NON-ATHLETES WITH NORMAL WEIGHT, OVERWEIGHT, AND OBESITY: BMI CATEGORIES DO NOT REFLECT WEIGHT-ASSOCIATED PERFORMANCE LOSSES

LEYK, D.1,2, RÜTHER, T.1, ROHDE, U.2, NESTLER, K.2, TOFAUTE, K.1, GORGES, W.2, WITZKI, A.2

1: German Sport University Cologne (Cologne, Germany), 2: Central Institute of Bundeswehr Medical Services (Koblenz, Germany)

Introduction There is compelling evidence that physical inactivity and overweight are rising worldwide. Moreover, sedentary lifestyles are adopted at increasingly earlier age (1-4). We examined associations of anthropometric measures and physical performances of sedentary males aged 18-25 years. We tested the hypothesis that weight-associated performances losses are not mirrored by BMI categories and the pinpointed WHO-BMI values of 25 and 30 are inappropriate cut-offs. Instead, we postulated finely graded performance decreases associated with higher waist circumference, body weight, and BMI of non-athletes. Methods Anthropometric, questionnaire, and physical fitness data of 961 inactive men were analyzed. All volunteers performed strength (flexed-arm-hang in chin-up-position) and endurance tests (1000m-run). These performances were compared with respect to 1) WHO-BMI categories: 3 groups with normal weight, overweight, and obese men 2) individual waist circumference, body weight and BMI-values, and 3) BMI-matched groups consisting of overweight men with waist circumferences <94cm or >94cm. Means, standard deviations, and confidence intervals were computed. ANOVA, Duncan Tests, and regressions were used to determine differences and associations between fitness and anthropometric data. Results 1000m-times of normal weight, overweight, and obese men (means+SD: 265+37s; 285+43s; 322+52s) as well as chin-up-times (51.8+20.7s; 31.4+16.5s; 18.2+12.8s) differed significantly between all groups. However, the relations between individual anthropometric and performance data showed smooth declines starting in BMI ranges of 23-27 and revealed no gradations fitting to the BMI categories. The BMI group with smaller waist circumference was significantly fitter than the BMI-matched group with larger waist circumferences (1000m-times: 285+52s; 302+47s; chin-up-times: 29.1+14.3s; 22.2+12.9s). Discussion The results prove that the BMI categories alone are not reliable fitness predictors. Independent from the BMI cut offs 25 and 30 fine graded and continuous performance losses occur. The results of the BMI-matched groups underline the use of waist circumference for health and fitness assessment. With regard to physical fitness promotion and strategy it is important to acknowledge that performances of overweight persons will be reduced even by small weight gains. MO-PM41 Health & Fitness: Children

PHYSICAL FITNESS OF CHILDREN AND ADOLESCENTS IN GERMANY: COHORT STUDY OVER A PERIOD OF 6 YEARS

HANSEN-DOOSE, A.1, ALBRECHT, C.1, MEWES, N.2, WORTH, A.1

University of Education Karlsruhe (Germany), 2: Karlsruhe Institute of Technology (Germany)

Introduction A high motor performance of children and adolescents is associated with a decreased present and future risk for diseases of the cardiovascular and musculoskeletal system and with a better mental health (Ortega, 2011). This paper reports findings on motor performance (MP) of children and adolescents over a period of 6 years. The data originate from the MoMo Study (2003-2006), which offered the first opportunity to assess MP of German children and adolescents aged 4–17 years on a nationwide representative basis. The study started 2003 – 2006 (baseline) and is part of the German Health Interview and Examination Survey for Children and Adolescents (KIGGS). In 2009-2012 a second representative cohort (wave 1) was tested. Methods MP was examined by a comprehensive physical fitness test profile (Woll et al., 2011). In this analysis 7 tests were included covering the relevant dimensions of physical fitness (cardiorespiratory fitness, strength, gross motor coordination, fine motor coordination, and flexibility). The samples consisted of n=4,528 (baseline) and n=3,103 (wave 1) children and adolescents. Data were analysed separately for sex and age groups, so 52 means and confidence intervals (95%) for complex samples were calculated. Effect size was estimated by Cohen's d. Results MP of German children and adolescents did not decrease after 6 years: Analysed over all age groups and both sexes at wave 1, the MP-values increased 24 times significantly and stayed 28 times within the same range. Analysed over all dimensions of MP, the gross motor coordination improved more than other dimensions. Analysed over all age groups the cohort of 6–10 years old children improved more than other age groups. Discussion MP of German children and adolescents changed in the right direction within the observed 6 years, but still seem to be clearly below the values in past with non-representative samples (Bös, 2003). In the last 10 years, a lot of health promoting activities started, of which many aimed at elevating the level of MP of children and adolescents. Our results indicate that activities and interventions started making an impact especially within the children in elementary school age. The data of wave 2 (2014 – 2016), which are currently collected, will give more insights in MP of German children and adolescents. References Bös K (2003). OVERWEIGHT AND OBESITY ASSOCIATED WITH THE LEVEL OF PHYSICAL FITNESS AMONG EGYPTIAN CHILDREN AGED FROM 6 TO 11 YEARS

ABDELKARIM, O.1,2, SOLIMAN, A.2, HÖKELMANN, A.1

1: Magdeburg University (Magdeburg, Germany), 2: Assiut University (Assiut, Egypt)

Introduction Childhood obesity has more than doubled in children in the past 30 years (WHO, 2014). The problem is global and is steadily affecting many low- and middle-income countries, particularly in urban settings. Therefore, the aim of this study is to investigate the overweight and obesity in children, and the association with the level of physical fitness among Egyptian children. Methods Participants were Egyptian children (n = 752) boys and girls aged from 6–11 years ($M = 8.46$, $SD = 1.35$) from 13 public primary schools in Assiut city presenting upper Egypt region. The German motor test (DMT) was used to assess the level of physical fitness including speed, strength, coordination, endurance, and flexibility. Childrens' height, weight, and BMI were measured, respectively. Results Prevalence of overweight and obesity was 12.2% and 10.2% respectively. The rate of overweight was the highest at the age of 10 years and decreased with an increase in age, while obesity increased with an increase in age to be the highest at the age of 11 years. The level of physical fitness were significantly associated with children's BMI ($p=.000$). The overweight and obese children showed the lowest achievement in the test items comparing to their peers with highly significant correlation for balance and endurance ($p=.000$, $p=.001$, respectively). Discussion The overall prevalence on the present study was 22.4%. These results confirm the concern about the rapidity of increasing the prevalence of overweight and obesity in urban environment which has demonstrated a higher percentage comparing to previous studies in Egypt (Hafez AS, et al., 2004; Nora et. al, 2013). By age growing the reduction in physical fitness of overweight and obese children could contribute to negative physical and mental health, and persistence of obesity into adulthood later in life (Castetbon & Andreyeva, 2012). Thus, an intervention programs promoting healthy lifestyle habits, including healthy eating and physical activity, should be offered during the school program and can lower the risk of becoming obese and developing related diseases (CDC, 2014). DIFFERENCES IN BODY COMPOSITION AND OCCURRENCE OF POSTURAL DEVIATIONS IN BOYS FROM TWO RACIAL GROUPS IN SOUTH AFRICA

JACOBS, S.1, DE RIDDER, J.H.2

1. Tshwane University of Technology, 2. North-West University

Introduction Little is known about ethnic differences in developing countries like South Africa, particularly with regard to occurrence of postural deviations and body composition profiles. The aim of this study was to compare the occurrence of postural deviations and body composition among two racial groups in South Africa. Methods The sample (n = 219) consisted of 79 African boys and 140 Caucasian boys. Anthropometric (BMI and percentage body fat) and body posture measurements were performed. Measurements were taken according to the standard procedures of the International Society for the Advancement of Kinanthropometry (ISAK). A posture grid and the New York Posture Test were used for all postural assessments. Results In all three age groups (11 to 13 years) the Caucasian group had a significantly higher BMI and percentage body fat compared to the African group. There were no statistical and practical significant differences in occurrence between age groups. The African group had higher occurrence in most of the deformities with winged scapulae, protruding abdomen and lordosis demonstrating a statistical significance and a practical significance (large effect) with regard to the

Caucasian group. The higher occurrence of kyphosis and pronated feet in the African group was statistically significant, and visible (medium effect) with regard to the Caucasian group. The higher occurrence of flat feet in the African group was statistically significant, but demonstrated a small effect which is not visible. The higher occurrences for uneven shoulders in the Caucasian group was statistical significant and also visible (medium effect) with regard to the African group. Discussion The results of this study support the development of more responsible education and screening programmes in both rural and urban school environment. Early detection and treatment programmes targeted at children, designed to prevent postural diseases from subsequently becoming chronic adult disabilities, should be an important health strategy for the young population. ORGANIZED LEISURE TIME SPORT PARTICIPATION IS ASSOCIATED WITH ACADEMIC ACHIEVEMENTS

SAEVARSSON, E.S.1, JOHANNSSON, E.S.1, ARNGRIMSSON, S.A.1, SVANSDOTTIR, E.1, SVEINSSON, T.2

University of Iceland

Abstract Introduction Many studies show a positive association between sport participation and academic achievements. Most of these studies involve adolescents participating in school sports. This may be affected by the school environment and thus bias the results. Studies on the association between organized leisure time sport participation outside the school environment and academic achievements in preadolescents are scarce, especially where maturity level is controlled for but sports are known to favor the more mature individual. The aim of this study is therefore to examine the relationship between academic achievements and sport participation outside the school environment among preadolescents while adjusting for potential confounding variables. Methods This is a cross-sectional study of 248 nine year old school children. Sport participation was self-reported with parental assistance and results from standardized tests in Icelandic and math retrieved from the National Institute of Education. Fitness was estimated using a graded maximal cycle ergometer test. Results Academic achievements increased with increased sport participation, for both academic subjects. However, one-way ANOVA showed statistically significantly association for math only, where the most active group scored higher than the other two less active groups ($F(2,246) = 4.6, p = 0.01$). The statistically significant finding in math was further established in the ANCOVA analysis with sex, age, maturity level, family structure, parental education, adiposity and fitness as covariates ($F(2, 235) = 3.81, p = 0.02$). Discussion After controlling for the confounding effects of maturity level and other covariates, sport participation outside the school environment is related to academic achievements in preadolescents. This study supports the notion that in addition to the many health benefits of sport participation, used here as a proxy for physical activity, it is also related to improved academic achievements. Concerns about time spent in sport participation rather than in academic studies and homework, are unfounded. Contact Elvar Saevarsson University of Iceland ess13@hi.is

THE COMPARISON OF SCHOOL AND HOLIDAY-BASED SCHEDULES ON SLEEP QUANTITY AND QUALITY, PERCEIVED STRESS AND COPING STRATEGIES IN PRE-ELITE YOUTH ATHLETES.

SKEIN, M.

Charles Sturt University

Pre-elite youth athletes manage the demands associated with their respective sports in addition to academic studies, social activities and employment. The increased demand to manage their schedules during a school term may negate sleep behaviour and perceived stress in youth athletes. Therefore, the aim of this study was to compare pre-elite athletes' management of school-sport schedules, sleep behaviour and perceived stress between school holidays (low school and sport-based commitments) and during a school term (higher school and sport-based commitments). Ten female pre-elite youth netballers competing at a regional representative level (15 ± 1 yr) completed two identical data collection periods (January; low school and sport-based commitments and March; high school and sport-based commitments), each for two weeks in duration. During each two-week period, participants wore an Actiwatch for assessment of time in bed, sleep time, onset latency, efficiency, wake after sleep onset (WASO) and number of awakenings. Sleep diaries were also completed to assess subjective sleep quality. Participants completed a daily schedule outlining the type and duration of their respective activities during the fortnight and at the end of each week participants completed a questionnaire regarding the perceived stress, sources of stress and coping strategies. Results demonstrated a significant increase in WASO from January to March ($P = 0.02$), however there were no significant differences between January and March for all remaining sleep variables ($P > 0.05$). Scheduling indicates there was a significant decrease in time spent in social activities ($P = 0.009$), resting ($P = 0.02$) and sleeping ($P = 0.03$) during March compared to January. Additionally, there was an increase in school ($P = 0.001$), homework ($P = 0.01$), sporting competitions ($P = 0.01$) and travelling to sport time ($P = 0.05$) in March compared to January. Stress was significantly elevated in both weeks of March compared to January (2.4 ± 2.1 and 2.8 ± 2.2 au, vs 6.7 ± 1.3 and 7.8 ± 1.0 au, respectively). Athletes increased the number of people that they relied on to cope with the increased stress during March compared to January ($P = 0.04$). It is suggested that athletes are sacrificing sleep and rest to complete all of their school and sport-based commitments in March, and that may be contributing to an increase in self-reported stress. Pre-elite youth athletes should be aware of a variety of strategies to cope with increased time commitments and stress and be made aware of the negative effects of sleep disruption. DISPLACING SEDENTARY BEHAVIOR WITH PHYSICAL ACTIVITY AND SLEEP: ASSOCIATIONS WITH CHILDHOOD OBESITY

HUANG, W.1, WONG, S.H.2, HE, G.2

1Hong Kong Baptist University; 2 The Chinese University of Hong Kong

Introduction This study examined the prospective associations of reallocating time spent in different types of sedentary behavior, physical activity and sleep with body mass index (BMI) in children using isotemporal substitution analysis. Methods Chinese children in grades 1-3 were recruited into a cohort study in 2009 and were followed up over a two-year period. Reports were gathered from the parents on children's sedentary behavior, sleep duration, and socio-demographic variables. The reported sedentary behavior types were then grouped into three categories: screen time, academic-related activities and other sedentary behavior. Moderate-to-vigorous physical activity (MVPA) and light-intensity physical activity (LPA) was assessed by ActiGraph accelerometry. Isotemporal substitution models were performed to examine the effects of time allocation on BMI. Results A total of 672 children (359 boys, mean age at recruitment = 7.6 yr) who had provided valid accelerometer data for at least one assessment time point were included in the analysis. Controlling for covariates and total behavior time, isotemporal substitution models indicated that the displacing of 30 min/day of other sedentary behavior with equal amounts of screen time ($B = 0.13$, 95% confidence interval: 0.06, 0.20) and academic-related activities ($B = 0.09$, 95% confi-

dence interval: 0.01, 0.17) was associated with higher BMI. Relocating 30 min/day of MVPA with each of the sedentary behavior variables resulted in increased BMI. Discussion Although isotemporal substitution analysis has previously been used in physical activity research in both adults and children (Aggio et al., 2015; Buman et al., 2014), this study extends previous findings by examining substitution effects of different types of sedentary behavior in children. The substituting of screen time or academic-related activities with other sedentary behavior or MVPA was associated with lower BMI in Chinese children. Unfavorable effects of sedentary behavior on adiposity may be mediated by not only replacing them with MVPA, but also by increasing other unhealthy behaviors, such as snacking. MOTOR DEVELOPMENT ASSESSMENT OF TYPICAL CHILDREN WITH MOVEMENT ABC-2: A PRELIMINARY STUDY FOR TURKEY

HURMERİC ALTUNSOZ, I.

Middle East Technical University

Introduction Early childhood period is a sensitive period for children's motor development. If any delays or problems occur in early childhood period, these problems should be diagnosed as early as possible for providing early interventions or movement programs. A variety of motor development tests (such as TGMD-2 and Movement ABC-2) exist to assess children's motor development in the literature (Cools, De Martelaer, Samaey, & Andries, 2009). Majority of the tests has been validated for USA or European children. However, there is no a standardized motor development test that measures children's motor development in Turkey. For this reason, the aim of this preliminary study was to use Movement ABC-2 assessment tool to evaluate typical children's motor development in Turkey and determine the appropriateness of the standard scores for these group of children. Methods For the purpose of this study, forty one children (19 Female & 22 Male) with Mage=53 months recruited from an urban area child care center in the capital city of Turkey. The center serves typical young children. Movement ABC-2 was used to assess children's motor development. This test has been used in many studies and preferred to diagnose any motor delays or level of motor development. It consists of three age bands: 1 (3 to 6 years), 2 (7 to 10 years), 3 (11 to 16 years). Manual dexterity, aiming and catching, and balance are the main components of the test. In this study, Age band 1 was used. Total standard scores and percentiles were identified for children in this study. Results The mean score for standard score was found as 9.6 with a range of 5 to 13 and for percentile score was found as 45.8 score with a range of 5 to 84. Based on the Movement ABC-2 evaluation, two children were identified in red zone (at or below the 5th percentile) showing the children had a significant movement difficulty. No movement problem has been identified for the rest of children (above the 15th percentile) based on the standard score for total test score. Discussion The Movement ABC-2 test might be appropriate to assess motor development of children in Turkey. However, more participants from different regions of Turkey is necessary to confirm validity of the test. Some adjustments might be necessary in the standard or percentile scores. In addition, future studies might focus on the develop appropriate standards in motor development tests for children in Turkey. References Cools, W., De Martelaer, K., Samaey, C., & Andries, C. (2009). Journal of sports science and medicine, 8(2), 154-168. Contact hurmeric@metu.edu.tr

ASPECTS OF VALIDITY AND RELIABILITY OF THE BRUININKS-OSERETSKY TEST OF MOTOR PROFICIENCY-SHORT FORM IN GREEK CHILDREN

VENETSANOU, F.1, VOUKIAS, K.1, ZAVOLAS, G.1, MITSIOS, O.1, KAMBAS, A.2

1: UNIVERSITY OF ATHENS (GREECE), 2: UNIVERSITY OF TRHACE (GREECE)

The Short Fort of the second Edition of the Bruininks-Oseretsky Test of Motor Proficiency (BOT-SF; Bruininks & Bruininks, 2005) is an individually administered tool, broadly used in research and clinical settings for the assessment of the motor proficiency of children and youth, aged 4-21 years. The technical adequacy of the battery is well established in its manual; however, the investigation of the psychometric properties of a tool should precede its application in populations different to the standardization one (Yun & Ulrich, 2002). The aim of the present study was to gather evidence about the validity and reliability of the BOT-SF in Greek children aged 4-7 years, investigating the following criteria: (a) competence of total score to differentiate among age groups, (b) internal consistency, and (c) test-retest reliability. For that purpose, the BOT-SF was administered to 165 children, 4-7 year-old ($M=5.7$, $SD=0.9$ years), typically developing children, who were divided in three age groups (4:0-4:11, 5:0-5:11, 6:0-6:11). Thirty-three of the participants were given two trials of the battery by the same assessor, within a 1-week interval. One-way analysis of variance that was applied on the total BOT-SF point score revealed that there were statistically significant differences among the age groups ($F_{2,162}=84.4$, $p=.000$, $\eta^2=.55$). Post hoc comparisons using Bonferroni test, with alpha set at .05, showed that each age group had higher scores compared to the younger ones. Moreover, the Cronbach's α that was computed in order for the internal consistency to be checked was found .89, while it would have been reduced if any of the items had been deleted. Finally, the intraclass correlation coefficient (ICC) on the total score, that was estimated with a two-way random model and an absolute agreement, yielded a value of .90 (95% confidence interval = .80 and .955), showing an excellent test-retest reliability. From the above results, it can be concluded that the BOT-SF seems to be a valid and reliable measure to assess motor proficiency in typically developing 4-7-year old Greeks. Further research is needed to investigate its usefulness in Greek children with motor delays. References Bruininks, R.H. & Bruininks, B.D. (2005). FOOT CHARACTERISTICS IN NEPALESE CHILDREN AGED 4-16 YEARS

UEDA, K., KOKUDO, S.

Kobe University

Introduction The foot status of children is influenced by many factors, including heredity and environment. It is assumed that the geographical conditions of Nepal, especially the predominantly hilly and mountainous environment, affects growth status and that the foot condition of children in particular is highly influenced by their walking in steeply sloping terrain. This study investigated foot sole parameters in a hilly area of Nepal. Methods The sample comprised 604 healthy children (278 boys and 326 girls) 4-16 years of age, who lived in a rural area near Kathmandu. Their height and weight were measured and their soles photographed in December, 2015. Sole photographs were taken using a two-dimensional foot scanner device (FootLook). Foot length and width, toe form, and planter arch condition were measured from the sole photographs. Results and discussion Mean height among the rural children aged 6-16 years ranged from

110.9 -160.1 cm for boys and, 105.9-151.3 cm for girls. This was smaller than the range among children from an urban area in Kathmandu, which was 114.6-161.9 cm for boys and, 113.3-152.6 cm for girls. Mean weight among the rural 6-16 year olds ranged from 20.0-42.7 kg for boys and was much smaller than the range among urban area children, which as 19.3-53.4 kg for boys. However, the ranged of 17.8-51.7 kg for rural girls was much greater than that of urban area girls, at 18.0-46.4 kg. Mean foot length and foot width show a steady increases from 4-14 years in boys, and also a gradual increase among girls of the same age group. However, mean foot length and foot width decreases among 14-15 year-old boys and girls. The mean width/length ratio increases from 6-14 years in girls. However, those increases fluctuate from 4-14 years in boys. There are significant increases from 14-15 years, and significant decreases from 15-16 in boys. Mean normal arch among the 7-12 years (92.4-91.4%) was much higher than the difference among Japanese children (71.5-79.3%). Nepalese children showed a low rate of flat arch (4.8%). However, mean normal arch among the 5-6 years (75.0-88.9%) were higher than the difference among Japanese children (73.3-78.2%). The shape of the foot is classified into three categories; Egyptian type was 98.0%, Greek type was 2.0% and Square type was 0%. These results suggest that Nepalese children have normal arches. Nepalese children usually wear school-shoes in daily life. However, it was observed that even if high school students they perform physical activities, like soccer and running, without wearing shoes. In addition, when going to school many Nepalese children must walk for more than 30 minutes along a steeply sloping road .It is assumed that such unshod activities and a long walk in the hills explains the lower prevalence of flat arch. Conclusion Nepalese children have a normal foot arch instead of a flat arch. Mean foot length and foot width increases from 4-14 years among boys and girls.

RELIABILITY OF NEW AGILITY TEST, N CHALLENGE, FOR ELEMENTARY SCHOOL CHILDREN

MORITA, N., OKUDA, T., OYAMA, Y., TORASHIMA, T., YAMAMOTO, R., NOMURA, T., KIKUCHI, K., SHIDE, N., KOBAYASHI, T., SATO, T.

Hokkaido Univ. Education, Iwamizawa

Introduction: Agility is one of the main physical fitness components, and is also considered the crucial component for success in many sports, such as tennis, basketball and soccer (Hachana et al., 2014). To improve agility, some types of agility and coordination drills and resistance training are used; however, these training are often less enjoyment, especially for children. The aims of this study were to develop an agility test with enjoyment for children, and to examine reliability of the test in elementary school children. **Methods:** We designed a new agility test which is set an N-shaped (7 m length; 5 m width) run course, which consists of 6-m straight sprint, right turn, 5 small hurdles (20-cm height), left turn, and 6-m zigzag run among 5 poles (1.2 m height; 1.2 m apart). The time to complete the all sections and each section were detected by phototube sensors, and were recorded by a personal computer. One-hundred thirty seven elementary school children (2nd and 3rd graders) performed the test twice. The children answered questionnaires for scoring enjoyment of the agility test. Reliability was assessed by Pearson's correlation between 1st and 2nd trials. **Results:** The time to complete the all sections were 10.9 ± 0.8 , 11.6 ± 0.8 , 10.6 ± 0.7 and 11.0 ± 0.5 sec in 2nd grade boys and girls, and 3rd grade boys and girls, respectively. Correlation coefficients between 1st trial and 2nd trial were 0.80, 0.80, 0.90, and 0.82 in 2nd grade boys and girls, and 3rd grade boys and girls, respectively (all $p < 0.01$). All of children answered "I enjoyed strongly" or "I enjoyed" in 2nd graders and 63 children answered each of them in 3rd graders. However, only 3 children in 3rd graders answered "I didn't enjoy so much". **Discussion:** We developed an enjoyable agility test entitled "N Challenge" for children. By playing the agility test repeatedly, agility performance of children seems to improve and could lead to increase the amount of physical activity. **References:** Hachana Y, Chaabène H, Ben Rajeb G, et al. Validity and reliability of new agility test among elite and subelite under 14-soccer players. PLoS One. 9:e95773, 2014. Contact: morita.noriteru@i.hokkyodai.ac.jp

STATIC, ONTOGENETIC AND MULTILEVEL MODELING OF LEFT VENTRICULAR MASS IN ADOLESCENT BOYS: LONGITUDINAL EFFECTS OF AGE, BIOLOGICAL MATURATION, SIZE AND OBJECTIVELY MEASURED PHYSICAL ACTIVITY

VALENTE-DOS-SANTOS, J.1,2, COELHO-E-SILVA, M.J.2, CASTANHEIRA, J.2, DUARTE, J.P.2, MACHADO-RODRIGUES, A.M.2,3, ELFERINK-GEMSER, M.T.4, MALINA, R.M.5

1 ULHT (Portugal), 2 UC (Portugal), 3 IPV (Portugal), 4 UG (The Netherlands), 5 FACSM (USA)

Introduction Left ventricular mass (LVM) is related to cardiovascular health (Gidding et al., 2013). LVM is generally normalized to determine appropriateness relative to body size (Foster et al., 2013). Accurate quantification is therefore essential to distinguish disease conditions from normal variants (Foster et al., 2013). The present study examined the contribution of body size, biological maturity status, physical activity (PA) and sedentary time to the development of LVM in healthy boys. **Methods** One hundred and ten boys (11.0–14.5 years at baseline) were assessed biannually for 2 years. Stature, body mass, and four skinfolds were measured. Lean body mass (LBM) was estimated. Current height expressed as a percentage of predicted mature height was used as an indicator of biological maturity status (Khamis & Roche, 1994). PA was measured using the Actigraph GT1M accelerometer. LVM was obtained from M-mode echocardiograms using two-dimensional images. **Results** At most age categories, inter-individual allometric coefficients for height did not exceed $k=2.4$ while intra-individual coefficients showed wide variation ($k=0.24-9.73$). The multilevel allometric model with the best statistical fit showed that a gain of 10 cm in height predicted 21 g of LVM when adiposity, LBM, age and biological maturity were simultaneously controlled. No associations were observed between PA variables and LVM. **Discussion** Results of static and ontogenetic allometric analyses were consistent with previous studies of youth showing that height, body mass and/or composition were independent determinants of LVM (Foster et al., 2013). Physical activity and sedentary time were not related to LVM. It is likely that more intense PA as in intensive training is needed to influence LVM over and beyond changes occurring with normal growth and development. In conclusion, results highlight the importance of individual differences in growth of body size dimensions and biological maturation in understanding the growth of LVM among male adolescents 11-16 years. **Acknowledgments** Portuguese Foundation for Science and Technology (SFRH/BPD/100470/2014; SFRH/BD/101083/2014) **References** Foster BJ, et al. OBESITY INCREASES PULMONARY VASCULAR RESISTANCE

FAORO, V.

Faculty of Motricity Science

Background: Obesity, defined as a body mass index (BMI) > 30 kg/m², is a chronic medical condition that can alter cardiac structure and function and is therefore an independent risk factor for cardiovascular disease and heart failure. However, little is known about the impact of overweight on the pulmonary circulation and aerobic exercise capacity (VO_{2max}). **Methods:** Ten healthy obese subjects (39 ± 13 years, 167 ± 8 cm, 98 ± 10 kg, BMI: 35 ± 2 kg/m²) were matched for sex, age, and height to 10 control subjects (36 ± 9 years, 170 ± 5 cm, 65 ± 5 kg, BMI: 22 ± 1 kg/m²). Subjects performed a maximal incremental echocardiographic cycling exercise test in a semi-recumbent position. Workload was increased by 20W/2min and cardiac index (CI) and pulmonary arterial pressure (Pap) were measured at each exercise level. An incremental cardio-pulmonary exercise tests was performed on a cyclo-ergometer with measurements of gas exchange. Workload was increased by 20-30W/min until exhaustion. **Results:** Obesity did not affect resting pulmonary hemodynamics. However, for a given CI, Pap increased to higher levels during exercise in obese subjects as compared to controls so that the mean Pap/CI slopes were increased with obesity (4.8 ± 1.4 mmHg/l/min/kg vs 4.8 ± 3.6 mmHg/l/min/kg, p<0.05). At maximal exercise, VO₂ (23 ± 8 ml/min/kg vs 46 ± 10 ml/min/kg, p<0.001), workload were decreased with obesity, while respiratory exchange ratio and heart rate remained unchanged. The inverse correlation between mPap/Q slope vs VO_{2max} almost reached the level of significance (r=-0.37, p=0.054). **Conclusion:** Despite no impact of obesity on the pulmonary circulation at rest, obese subjects have an altered pulmonary vascular function at exercise. Understanding how this is related to a lower VO_{2max} needs further research.

FACTORS AFFECTING THE EFFECT OF HEALTH PROMOTION PROGRAMS ON BLOOD PRESSURE CONTROL

WANG, Y.P., TSAI, C.F., TSENG, W.M., HSIEH, F.S., TSAI, M.W.

National Yang-Ming University

Introduction: Hypertension (HTN) is one of the common causes of premature death and morbidity (Ezzati et al., 2013). Community-based program is generally acceptable and feasible for elderly, but few study focused on metabolic health (Leite et al., 2015), especially on blood pressure control. In addition, most of the studies investigated the change of BP after intervention (Whelton et al., 2002) instead the responsiveness of BP control from the viewpoint of health outcome. The aim of this study was to identify the potential factors in responders and non-responders on BP control after 12 weeks community-based programs in elderly. **Methods:** This was an exploratory study with a secondary analysis of community-based exercise intervention for health promotion. A total of 136 participants (74.13±5.9 years) were included. The baseline data were extracted as the potential factors, which included social demographic data, health related behavior data and cardiovascular (CV) risk. The outcome variable was the responders on BP control or not. The responder on BP was defined as BP in optimal level (SBP≤ 140mmHg and DBP≤90mmHg) or a significant BP reduction [SBP↓10mmHg or DBP↓5 mmHg] after 12-week intervention. Subjects who failed to achieve the above targets were defined as non-responders. **Results:** The findings declared that 81.6% and 16.4% were BP-responders and BP-non-responders. The BP-responders showed lower SBP (132.94 ± 18.38 mmHg) and less proportion of HTN risk (37.8%) at baseline than non-responders (141.16 ± 16.37 mmHg, 64%, respectively). Active life style could elevate 4-fold in BP responder compared to the inactive elderly [OR(95%CI) =4.071 [1.120-14.796]]. Furthermore, some disparities were found among subjects with or without diagnosis of HTN. In subjects with HTN, higher educational level or more medication taken were likely to be BP responder. In subjects without HTN, those having clusters of abnormal metabolic markers (Hyperglycemia, Hyperlipidemia and elevated BP) or more medication taken had the tendency to be less response on BP control. **Conclusion:** Active life style combined 12 weeks community-based program could elevate benefit to being BP responders in elderly. The health behavior related factors would be also needed to be concerned for health promotion program on BP control. Reference Ezzati M, Riboli E.(2013).N Engl J Med,369:954-64. CARDIOVASCULAR PARAMETERS, LIPIDS AND GLUCOSE IMPROVED BY AN ACTIVE WORKSTATION.

HUBER, M.G., TIRAN, B., SCHARNAGL, H., VAN POPPEL, M.N.

Institute for Sport Science

Introduction: In recent years attempts were made to obtain a shift from passive sedentary workplaces to more active ones. These workstations had promising effects on health indicators. The aim of this study was to investigate the impact of a newly developed active workstation on cardiovascular parameters, blood values and physical activity (PA) at work. **Methods:** In a cross-over study, 30 participants (18 female), aged 23- 57 years, completed one control week and three weeks of intervention within which they were provided with an active workstation (SAM) and were advised to use it at least for 10 minutes every hour during working hours. On one day in the control and the last intervention week, a venous blood sample was taken at fasting state, and participants were equipped with a heart rate monitor. Blood pressure (BP) was measured hourly during morning in control and intervention period. To measure PA, they received an accelerometer for one week in the control and two weeks in intervention period. A standardized meal was consumed in the control and intervention period and blood glucose was measured before (fasting) and each hour till five hours after the meal with a finger prick. HbA1c, total cholesterol, HDL, LDL and triglycerides were measured from the fasting venous blood samples. **Results:** Both, mean bodyweight 75 (± 14.9) kg vs. 74.2 (± 15.1) kg (p = 0.01), and mean resting systolic and diastolic BP (from 122.8 (± 10.9) to 120.3 (± 9.8) mmHg (p= 0.048) and from 93.4 (± 8.5) to 80.4 (± 8.1) mmHg (p< 0.001), respectively) decreased in intervention. Heart rate (HR) increased, from 76.5 (± 9.9) beats per minute (bpm) to 81.8 (± 10.2) bpm, in intervention (p < 0.001). Mean % of time spent in sedentary and light PA during working hours was stable with 86 (± 3.4) % vs. 85.9 (± 1.7) % and 7.4 (± 1.8) % vs. 7.1 (± 1.6) %, respectively, in control and intervention (both p> 0.05). No significant changes in blood glucose values, or in lipids and HbA1c were found (p> 0.05). **Discussion:** Participants body weight decrease significantly, whereas HR increased significantly during intervention and thus correlates with findings in other studies investigating active workstations (Rovniak et al., Koren et al.). In addition a significant decrease in resting BP, both systolic and diastolic was found. Accelerometer data revealed no change in sedentary behavior or PA during working hours. Continuous glucose monitoring (CGM) might be more suitable to obtain precise data of blood glucose, because of more frequent measured points (Buckley et al.). Due to the short intervention period no significant changes in HbA1c or lipid values could be found. However, results with the SAM workstation are promising and further evaluation of the acceptability and effects of this device is warranted. AEROBIC HIGH-INTENSITY INTERVAL EXERCISE IN CARDIAC PATIENTS - TURN POINT-BASED REGULATION OF EXERCISE PRESCRIPTION AND THE ACUTE RESPONSE OF RISK MARKERS

TSCHAKERT, G.1, KROEPFL, J.M.2, MUELLER, A.1, HARPF, H.3, TRANINGER, H.3, WALLNER-LIEBMANN, S.4, STOJAKOVIC, T.4, SCHARNAGL, H.4, HOFMANN, P.1

1: UG (Graz, Austria), 2: ETHZ (Zurich, Switzerland), 3: ZARG (Graz, Austria), 4: MUG (Graz, Austria)

Introduction An adequate and individual exercise prescription is a critical factor for avoiding harmful side effects during intense exercise in patients (Tschakert & Hofmann 2013). Aim of this study was to investigate the acute response of cardiovascular and inflammatory risk markers as well as catecholamines induced by two different aerobic high-intensity interval exercise (HIIIE) protocols compared to moderate continuous exercise (CE) in cardiac patients by using a turn point-based methodological approach. Methods 8 patients undergoing phase III cardiac rehabilitation (7 with coronary heart disease, 1 with myocarditis; 7 males, 1 female; age: 63.0 ± 9.4 years; height: 174.1 ± 4.6 cm; weight: 83.6 ± 8.7 kg; VO₂: 21.6 ± 7.6 ml/kg/min) performed a maximal symptom-limited incremental exercise test (IET) and three different exercise tests matched for mean load (P_{mean}) and total duration (28 min): 1) short HIIIE (peak workload duration (t_{peak}) = 20 s); 2) long HIIIE (t_{peak} = 4 min); 3) CE (target workload (P_{target}) equal to P_{mean} of both HIIIE modes). The intensities during work (P_{peak}) and recovery phases (P_{rec}) for short HIIIE as well as the mean intensity (P_{mean} , P_{target}) for all tests were prescribed in relation to the maximum power output (P_{max}) as well as to the first (LTP₁) and second (LTP₂) lactate turn point determined during IET: $P_{peak} = 100\% P_{max}$; $P_{mean} = P_{target} = 80\% PLT₂$; $P_{rec} = 90\% PLT₁$. Venous blood samples were taken before and after each test. Plasma was separated for subsequent analysis of cardiac biomarkers (high-sensitivity cardiac troponin T (hs-cTnT), N-terminal pro B-type natriuretic peptide (NT-proBNP), creatine phosphokinase MB (CK MB), and Lipoprotein-associated phospholipase A2 (Lp-PLA₂)), and further health-related parameters. Results During short and long HIIIE and CE, the exercise-induced values for cardiovascular and inflammatory risk markers as well as catecholamines were not clinically relevant except for NT-proBNP, which was, however, already elevated at baseline in each test. Between the three test protocols, no significant differences in acute responses were found for any parameter ($p > 0.05$). Discussion By using our methodological approach to interval exercise prescription, both short and long aerobic HIIIE were well tolerated and performed as safely as moderate CE by this study population. Further aerobic HIIIE studies are required particularly in cardiac patients with a lower functional capacity and patients with other chronic diseases. References Tschakert & Hofmann (2013). INTERNAL AND EXTERNAL CAROTID ARTERY BLOOD FLOW DURING RESISTANCE EXERCISE

OGOH, S.1, HIRASAWA, A.1, WASHIO, T.1, SASAKI, H.1, BAILEY, D.M.2, SATO, K.3

1: Toyo University (Saitama, Japan), 2: University of South Wales (United Kingdom), 3: Japan Women's College of Physical Education (Tokyo, Japan)

Introduction Resistance exercise induced-acute hypertension should affect cerebral blood flow (CBF) directly by causing cerebral hyperperfusion. However, Dickerman et al. (2000) reported that middle cerebral artery mean blood flow velocity was unchanged or even attenuated in elite power athletes during maximal weight-lifting. To what extent the arterial hypertension associated with heavy resistance influences the spatial distribution of blood flow to the intracranial arterial bed remains unknown. Our previous study (Sato et al., 2011) suggest that large increase in external carotid artery (ECA) blood flow affects intracranial CBF during dynamic exercise to prevent exercise-induced cerebral hyper-perfusion. The purpose of the present study was to examine the response of internal carotid artery (ICA) and ECA blood flow to resistance exercise. Methods Twelve healthy participants performed one-legged static knee extension exercise at 30 % maximal voluntary contraction for 2 min. Blood flow to the ICA and ECA were evaluated by duplex ultrasonography. Results ICA blood flow increased from baseline ($P=0.001$) before stabilizing at 60 s, while ECA blood flow progressively increased throughout exercise with the most marked changes observed between 60 and 120 s ($P<0.001$). ICA conductance significantly decreased by -14.4 ± 13.8 % at the end of exercise ($P<0.01$) whereas in contrast, ECA blood flow ($P<0.01$), and conductance were shown to increase ($P<0.05$). Discussion The present findings demonstrated that resistance exercise was associated with vasodilation of the ECA that was accompanied by vasoconstriction of the ICA. We propose that the heterogeneity and reciprocal regulation of intracranial CBF reflects an adaptive neuroprotective mechanism that serves to protect the brain and associated vasculature against the structural damage associated with resistance exercise-induced hypertension. CARDIOVASCULAR DYSFUNCTION DURING THE MUSCLE METABOREFLEX ACTIVATION IN PATIENTS WITH DIASTOLIC HEART FAILURE

CRISAFULLI, A., MULLIRI, G., MILIA, R., PINNA, V., SAINAS, G., ROBERTO, S.

university of cagliari

Introduction Activation of the muscle metaboreflex leads to increase in arterial blood pressure. In normal subjects, this result is achieved by means of an increase in both systemic vascular resistance (SVR) and cardiac output (CO)¹. In patients with chronic systolic heart failure an exaggerated vasoconstriction compensates for the reduced capacity to increase myocardial contractility and stroke volume (SV). This fact is however detrimental in the long term, as it may cause vasoconstriction in the working muscle, thereby impairing the capacity to exercise². To the best of our knowledge none has to date verified whether or not this phenomenon is present also in chronic diastolic heart failure (DHF). Methods Ten patients with DHF (5 females, age 34-79 yrs) were recruited. Diagnosis of DHF was based on history, signs, and symptoms consistent with DHF (ventricular ejection fraction >50%). Central hemodynamics during the metaboreflex obtained by the method of the post-exercise muscle ischemia were evaluated by means of impedance cardiography and echocardiography. Their response was compared to that of age matched control group (n= 12, 6 females, age 35-70 yrs). Results The main results were that the DHF group could not properly increase SV and CO in response to the muscle metaboreflex, whereas the CTL group did increase these parameters (-2.92±9.73 vs. 5.77 ± 3.41 ml in the SV response and -225.5 ± 787.6 vs. 549.2 ± 454.9 ml⁻¹l⁻¹ in CO, for the DHF and the CTL group respectively, $p<0.05$ in both cases). Moreover, parameters related to diastolic function could not increase in the DHF group during the metaboreflex. For instance, end-diastolic volume decreased in the DHF group (-1.3±5.27 ml) while it increased in the CTL group during the metaboreflex activation (+6.17±10.06 ml, $p<0.05$ vs. DHF group). Yet, the DHF group reached the target blood pressure mainly by means of an exaggerated SVR increment as compared to the CTL group. Discussion This investigation provides evidence that diastolic function is important for normal hemodynamic adjustment during the metaboreflex and to avoid excessive vasoconstriction. References 1. TOTAL SERUM CHOLESTEROL IS RELATED TO TOTAL RED CELL VOLUME IN HEART FAILURE PATIENTS

AHLGRIM, C., BIRKNER, P., SEILER, F., BAUMSTARK, M.W., GRUNDMANN, S., POTGIESSER, T.

University Medical Center Freiburg

Introduction Several studies have confirmed a positive association between serum cholesterol and hematocrit in healthy subjects. In the past, this relationship has been attributed to hematocrit acting as an indicator for a contracted plasma volume. In contrast to these observations, recent data highlighted that the erythrocyte membrane might, like high-density lipoprotein (HDL), act as a shuttle for cholesterol in the bloodstream and thus can contribute to reverse cholesterol transport. Both, total red cell mass, which is the amount of all erythrocytes in the body, and erythrocyte membrane cholesterol content, are affected by physical exercise. It can be speculated that hematological adaptation might constitute one mechanism by which physical exercise lowers serum cholesterol levels and hence cardiovascular risk. The relationship between red cell mass and serum cholesterol has, however, not been studied before. **Aim of this study** is to investigate whether a relationship between serum cholesterol and red cell mass can be observed. **Methods** For this study, data from 58 heart failure patients who participated in a research project of our department (DKRS Nr.) and for whom cholesterol data were available were analyzed. Red cell mass (RBV) was determined using the optimized CO rebreathing method. Relationship between cholesterol parameters (low density lipoprotein cholesterol (LDL-C), HDL-C, triglycerides, total serum cholesterol) and RBV was analyzed using rank based correlation and stepwise linear modeling ($\alpha=0.05$). **Results** Correlation coefficients of RBV were $r_{RBV, Cholesterol}=-0.31^*$, $r_{RBV, HDL-C}=-0.26$, $r_{RBV, LDL-C}=-0.19$ and $r_{RBV, TG}=-0.19$. Relation between RBV and serum cholesterol was confirmed in stepwise linear regression accounting for influence of age, body-mass-index, gender and statin therapy as well as plasma volume and hematocrit. **Conclusion** Serum cholesterol is significantly inversely correlated with RBV in the heart failure patients group. Cholesterol subfractions also show a trend towards an inverse association with RBV. These observations might point to a direct link between availability of erythrocytes and/or erythropoiesis and lower cholesterol levels. As RBV can significantly be increased by endurance exercise, our observation might thus point towards a cholesterol-lowering effect of exercise through increased erythropoiesis and consequently an elevated RBV.

Mini-Orals**MO-PM24 Women & Osteoporosis****DELAYED MENARCHE AND MENSTRUAL STATUS IN FEMALE ATHLETES**

FUJII, K., ISHIGAKI, T., TANAKA, N., HAYAKAWA, K.

Aichi Institute of Technology

Introduction Delayed menarche, in which a girl's first menstrual cycle comes late, has been suggested in female athletes. The proportion of body fat decreases with the effects of regular sports training around the age of menarche in female athletes, and it is thought that delayed menarche or amenorrhea occurs because body fat percentage does not reach 17–20%. In cases when menarche does not occur even though body fat mass has reached the critical period for the onset of menarche, it has been suggested that the delay in menarche may be due to physical and mental stress. Thus, for female athletes, the problem of delayed menarche or menstrual disorders becomes a big risk both in terms of the physical and mental aspects and the continuation of the sport. **Purpose** The aim of this study was to clarify the relationships with menstrual status or menstrual pain in individual female athletes. **Methods** A survey of general girls and female athletes (Korean girls from grades 1 to 11) was conducted in 2009 using longitudinal growth data on height and questionnaires. Birth date, age at menarche, menstruation status and menstruation pain were checked. Wavelet interpolation was applied to obtain the age at maximum peak velocity (MPV) of growth, which is an indicator of the level of maturity that is a reference point for delayed menarche. A numerical rating scale (NRS) was used to objectively measure the level of menstrual pain. **Results** In general girls (in a suburb of Busan), the age at MPV of height was 11.29 years and the age at menarche was 12.88 years. In female athletes, the age at MPV of height was 11.21 years and the age at menarche was 13.32 years. Compared with general girls, many female athletes were determined to have delayed menarche. Many female athletes also had high levels of pain. In addition, the menstrual cycle in female athletes showed greater variability than that in general girls. The results of determinations of delayed menarche by the sport in which female athletes participated suggested that many girls engaged in track and field, taekwondo, and judo had delayed menarche. **Discussion** Considering the weight restrictions in the weight classes for taekwondo and judo, it may be that delayed menarche occurs as a result of mental and physical stress from reducing body fat and forcing the body to stay under a certain weight. The above indicates that there may be cases when delayed menarche and subsequent menstrual disorders occur as a result of the effects of the physical and mental stress of rigorous sports training and reduced body fat from weight restrictions. **References** Fujii K, and Matsuura Y. (1999) Analysis of the growth velocity curve for height by the Wavelet Interpolation Method in children classified by maturity rate. Am J Hum Biol, 11, 13-30. Contact : b14705bb@aitech.ac.jp

RELATIONSHIP BETWEEN MATERNAL AND PATERNAL PHYSICAL ACTIVITY DURING PREGNANCY

SANTOS, P.C.1,2, FERREIRA, M.2,4, ALVES, O.5, MOREIRA, C.2, ABREU, S.2, SANTOS, R.2,3, MESQUITA, C.1, LOPES, S.1, MOTA, J.2

Department of Physiotherapy, School of Health Technology of Porto Polytechnic Institute of Porto, Portugal 2Research Centre in Physical Activity, Health and Leisure, Faculty of Sport, University of Po

Introduction: Pregnancy is recognized as a unique time for behavior change, and the habits adopted during pregnancy can affect woman's health for the rest of her life. The physical activity recommendations for pregnant women and parturient are the same as those recommended for the general population, at least 150 minutes per week of moderate physical activity. A couple shares different environments and common experiences, which may result in similar options for the life of each, as the case of physical exercise together when the environment is conducive for this. **Objective:** To verify the relation between maternal and paternal physical activity during pregnancy; Analyze the change in maternal and paternal physical activity during the first to the second trimester; Verify a sociodemographic profile associated with active women. **Methods:** The study was applied to a sample of 40 couples, during the first and second trimester. Women physical activity was assessed by accelerometer and the Pregnancy Physical Activity Questionnaire (PPAQ). Physical activity of men was assessed through the International Physical Activity Questionnaire (IPAQ) - short version, in order to get the time spent in mod-

erate and vigorous physical activity weekly. Results: There was no significant correlation between the duration of physical activity of the mother and father ($p>0.05$). However, the first to the second trimester, there was a significant decrease in duration of maternal physical activity and a significant increase in duration of paternal physical activity ($p<0.05$). It was also found that sociodemographic characteristics and lifestyle habits do not significantly affect the duration of physical activity Conclusion: The study suggests that there is no correlation between paternal and maternal physical activity during pregnancy, either a demographic profile associated with more active women. It was also concluded that physical activity decreases in women throughout pregnancy, unlike men, that physical activity increases.

EFFECT OF A MULTIMODAL INTERVENTION PROGRAM DURING PREGNANCY ON MATERNAL BODY COMPOSITION AND MATERNAL BODY WEIGHT ONE YEAR POST PARTUM

FERRARI, N.1, BAUER, C.2, BAE-GARTZ, I.3, BROCKMEIER, K.4, STRUEDER, H.K.2, GRAF, C.2

University Hospital Cologne

1: UK Cologne, Cologne Centre for Prevention in Childhood and Youth/ Heart Center (Cologne, Germany), 2: DSHS, Institute of Movement and Neuroscience (Cologne, Germany), UK Cologne (Cologne, Germany), 4: UK Cologne, Heart Center (Cologne, Germany) Introduction Sedentary lifestyle during pregnancy seem to have negative influences on mother and child, e.g. risk for gestational diabetes mellitus, excessive weight gain or obesity. Excessive maternal weight gain during pregnancy is linked to a higher risk for retaining excessive weight after delivery. Few studies have assessed the impact of a multimodal intervention combining physical activity and dietary intake during pregnancy on postpartum weight change. Therefore, the aim of the present study was to examine the effect of a multimodal program on maternal body composition during pregnancy (T0: 16 weeks vs. T1: 36 weeks of gestation) and weight change one-year post partum. Methods 34 women with a mean age of 31.8 +/- 4.1 years, mean pregnancy week of 15.0 +/- 1.8 weeks and a pre-pregnancy body mass index of 22.5 +/- 3.2 kg/m² were randomized to either an intervention group (IG, n=19) or a control group (CG, n=15). The intervention consisted of 60 min supervised endurance training, 60 min strength training for at least twice per week for a minimum of 16 weeks and nutrition counseling four times during the program. Control group received usual antenatal care. Digital scale was used to assess body weight at T0 and T1. Skinfold thickness was measured using a Harpenden skinfold caliper at three points [1] to assess body composition. Self-reported body weight was used to analyze maternal body weight 12 months' post partum. Results Baseline percent (%) body fat was higher in the IG comparing the CG (25.7 +/- 6.0 % body fat vs. 21.7 +/- 3.1 % body fat; $p=0.038$). After the intervention IG showed reduced % body fat (-6.0 +/- 4.3) whereas in CG % body fat was increased (3.1 +/- 2.7; $p<0.001$). Although weight gain during pregnancy and weight retention after 12 months were similar in both groups, % body fat at the end of gestation was significantly correlated with higher maternal body weight after one year ($r=0.565$; $p=0.001$). Discussion A multimodal program during pregnancy can contribute to a significant reduction of % body fat during pregnancy, although no effect on weight gain during pregnancy could be found. Furthermore % body fat at the end of gestation is correlated with maternal body weight 12 months' post partum. As fat mass influences several biomarkers in terms of perinatal programming adequate intervention programs should be implemented during and after pregnancy. FACTORS INFLUENCING CARDIORESPIRATORY FITNESS IN POSTMENOPAUSAL WOMEN WITH PREHYPERTENSION IN RATCHABURI PROVINCE, THAILAND

TANTIPRASOPLAP, S., TANEEPANICHSKUL, S., PIASEU, N., SANGNGERN, L.

Chulalongkorn University, Mahidol University

Background: One of the most important components of physical fitness is cardiorespiratory fitness. Increasing cardiorespiratory fitness indicates increasing the capability of the heart and the cardiovascular system, which serves to supply oxygen and energy to body. Postmenopausal women are at risk for cardiovascular diseases (CVD) due to hormonal change. This cross sectional study therefore aimed to investigate factors influencing cardiorespiratory fitness in postmenopausal women with prehypertension. Method: Through purposive sampling, 84 postmenopausal women with prehypertension were recruited from Donsai Sub-district, Pakthor district, Ratchaburi Province. The data were collected by using the structured questionnaire with face-to-face interview. All of the participants were measured for cardiorespiratory fitness (estimated VO_{2max}). Data were analyzed using descriptive and inferential statistic. Results: The results revealed that mean age of the sample was 55.15 + 7 years old, ranging from 44-69 years. Most of them were married (69%), obtained primary education (76.2%), worked as farmer (76.2%) and none farmers (23.8%). Approximately half of them did not exercise (42.9%). Cardiorespiratory fitness was associated with waist circumference ($r=-.646$, $p=.000$), body mass index ($r = -.562$, $p=.000$), heart rate ($r = -.589$, $p=.000$), age ($r = -.298$, $p=.008$), and occupation ($r = .402$, $p=.000$). There were no relationship between education, income, exercise habit and cardiorespiratory fitness. Conclusion : The results in this study suggest approaches for healthcare providers to develop programs promoting and monitoring cardiorespiratory fitness among postmenopausal women with prehypertension in order to enhance their health status. EFFECTS OF SHUTTLECOCK KICKING ON BMC AND BMD IN POSTMENOPAUSAL FEMALES

DING, H., XIAOHUI, H.

Guangzhou Institute of Physical Education

Introduction: BMC lose rapidly from the beginning of age of 50~60 years, about 1.5%~2.5% annually, BMD decreased rapidly from age of more than 45 years in Chinese postmenopausal females. Therefore, precautions should be taken postmenopausal females' OP to reduce the morbidity and better their life. Shuttlecock kicking (ti jian-zi) is a popular traditional sport for exercise and fitness in China, the purpose of this study is to explore the influence of shuttlecock kicking on BMC and BMD of Chinese postmenopausal females. Method: By randomized controlled study, the 39 participants (50-60 Years old) were be randomly divided into Group I of 20 females who kicking shuttlecock for 2 to 4 hours each time and 5 to 7 times each week, and Group II of 19 females who rarely exercise. After 12 months, observed the changes of the BMC and BMD of 10 parts: Head, T Spine, L Spine, L Ribs, R Ribs, Pelvis, both Arms, both Legs and the total body by dual-energy X-ray absorptiometry (DEXA) .Statistics software of spss18.0 was used to calculate and the differences were compared

through the matching T examination. Results: After 12 months, BMC of the non-dominant leg and total body, BMD of Pelvis, both Legs and total body were significantly higher than before in Group I. There were different degrees of decline on BMC and BMD in Group II. BMC of the non-dominant leg and total body, BMD of Pelvis, both Legs and total body were significantly higher in Group I than in Group II. (P<0.05, P<0.01, respectively) Discussion: Shuttlecock kicking is a whole body periodic exercise, mainly involving in movements of lower limbs. When the shuttlecock goes up and down, the body center of gravity shifts left and right, and the kicking leg swings back and forth or inside and outside. Repeated mechanical stimulation leads progenitor cell proliferation and differentiation of the lower limbs and pelvis. The body mass and leg muscle contraction of kicking shuttlecock produce stress load to bone which changes BMC and BMD. Conclusion: Shuttlecock kicking for postmenopausal females individuals leads a greater acquisition of BMC and BMD in total body, especially in the pelvis and legs. Perseverance Shuttlecock kicking in postmenopausal females has functions on the promotion of human body bone health, the prevention of osteoporosis, worth promoting as exercise prescription.

RISK FACTORS OF THE FEMALE ATHLETE TRIAD AMONG UNIVERSITY STUDENTS

MOLNÁR, A.H., KOVÁCS, V.D., KATONA, ZS., VÁRI, B., MESZLÉNYI-LENHART, E., BALOGH, L.

University of Szeged, Gyula Juhász Faculty of Education

Introduction The diagnosis of female athlete triad (FAT) requires the presence of eating disorder (ED), amenorrhea (AM), and osteoporosis (OP). The relevant literature is controversial about the frequency of FAT among athletes or non-athletes. Our purpose was to determine the prevalence of FAT's risk factors among female collegiate athletes and physically inactive university students to define which population is more vulnerable by FAT. Methods 58 collegiate athletes (AT) and 64 physically inactive (PI) university students participated in the study. We used the method of Torstveit and Sundgot-Borgen (2005) completed with bone densitometry to identify the risk factors of FAT. The risk factors of ED were low BMI, pathogenic weight-control methods (use of diet pills, hunger-repressive pills, laxatives, diuretics, or vomiting to reduce weight), self-reported eating disorder, results over the critical limits in 'Drive for Thinness' or 'Body Dissatisfaction' subscales of Eating Disorder Inventory (Garner, 1983). The risk factors of AM were self-reported menstrual dysfunction (primary amenorrhea, secondary amenorrhea, oligomenorrhea, or short luteal phase). The risk factors of OP were self-reported stress fracture and low bone mineral density (t -score < -1). Results Any risk factor(s) of ED occurred at similar rate in both groups (AT: 32.76%, PI: 40.63%). There was no significant difference in the presence of any risk factor(s) of AM (AT: 56.9%, PI: 50.0%). Incidence of OP risk factor(s) was significantly more frequent in the PI group (AT: 22.41%, PI: 48.44%*). The rates of participants with risk factors of ED and AM together (AT: 22.41%, PI: 21.88%) or ED and OP together (AT: 12.07%, PI: 17.19%) were similar. The common occurrence of AM and OP were more frequent in the PI group (AT: 10.34%, PI: 26.56%*). A not significantly higher percentage of PI university students (84.37%) have one or more risk factor(s) of any component of FAT than ATs (75.86%), but no more than 10.94% of PIs – in comparison to ATs' 5.17% – has one or more risk factor(s) of all the three components of FAT. Conclusion Our results suggest that the risk factors of FAT are very prevalent in the observed population. The most frequent risk factors are the menstrual irregularities. The group of physically inactive university students are more vulnerable than collegiate athletes mainly in the aspect of osteoporosis and amenorrhea from the components of FAT. ACTIV4HER: PROCESS EVALUATION OF A PREVENTIVE WOMEN'S HEALTH PROGRAM FOCUSING ON PHYSICAL ACTIVITY AND HEALTHY EATING

STEPTO, N., BOOTH, V., MCAINCH, A., BANTING, L.

Victoria University

Introduction: The prevalence of chronic disease within Australia is of increasing concern, particularly within our ageing population. Preventive programs targeting unhealthy behaviours such as inactivity and unhealthy eating habits for young women are limited. ActiV4her is an evidence-based program that aimed to create healthy lifestyle change within women who are at risk of developing cardiovascular and metabolic disease. It focuses primarily on physical activity and healthy eating and is underpinned by the Behaviour Change Wheel. The aim of the study was to evaluate the implementation of a multidisciplinary group-based healthy lifestyle intervention (MDG) compared to standard care with an Exercise Physiologist (EP). Method: The MDG program consisted of 16 female participants who attended eight weekly sessions. The EP program consisted of 15 participants who attended 5 individual sessions over 12 weeks with an Exercise Physiologist. In-depth interviews, surveys and physical measures were conducted immediately post-program and at 3 months follow-up as part of a thorough process evaluation of the program. Discussion: Completion rates for the programs were 94% and 87% for MDG and EP. Mean attendance rates were 80% (MDG) and 90% (EP). Thematic analyses revealed three key themes related to the group and multidisciplinary nature of the program; 'information provided' (amount, complexity and diversity), 'group dynamics' (social support, individualisation, and modelling and expectations) and 'intention to maintain' (opportunities for health, self-efficacy and maintaining motivation). Conclusion: Multidisciplinary, group-based interventions offer additional opportunities for women to learn more about their health and initiate self-determined motivation for healthy behaviours but pose additional considerations for health practitioners who must manage group dynamics, diverse client motivations, abilities and preferences. CONFIRMATION FOR EVALUATION OF BONE MINERAL DENSITY BASE

KANI, Y., FUJII, K., SHO, M., KASUYA, K.

Aichi Institute of Technology

Introduction : The incidence of bone fracture in children has increased over more than three decades since 1970 in Japan. To examine this problem, detailed information on the body composition and bone density of Japanese children is necessary. In current bone density measurements dual energy X-ray absorptiometry (DXA) is used clinically as stable method, but DXA has problems in that it exposes subjects to radiation and measurements of children entail great risk. Therefore, to determine bone density simply and without radiation exposure application, application of ultrasound bone assessment values (stiffness values, OSI value) is reasonable. Purpose : Bone assessment values using stiffness values were applied to investigate the age-related changes in 3 to 5 year-old children. We sought to establish uniform measurements of bone density in early childhood by composing population data based on the cohort method, while also attempting to construct a bone density evaluation based on age-related changes and investigating validity of this evaluation. Methods : The subjects were 217 boy and 213 girl preschool children from 2010 to 2013. Population data were obtained with each preschool year. The analysis procedure consisted of bone density measurement of the right calcaneus using a bone density ultrasound machine (A-1000 Insight, Luner). Precise chronological age was calculated from birthdate, and least squares approximation polynomials from first

to sixth order were applied to the bone density measurement items corresponding to that chronological age over a three-year span. A standard regression evaluation chart was constructed from the least squares approximation polynomial judged to be valid, and bone density was evaluated from a 5-step regression evaluation. Results : A one-way analysis of variance was performed for bone density indicator (stiffness, BUA, SOS) statistics in age-related changes of bone density in mixed cohort data, and the results showed significant differences ($P<0.05$) in stiffness and SOS values for both boys and girls. Polynomial regression analysis for stiffness and SOS values was then applied, and significance was seen in the age-related changes in regression polynomials. Consequently, to construct a regression analysis chart for bone density, the best polynomial obtained with least squares approximation was seen to be a third order polynomial for boys and fourth order for girls. Thus, polynomial regression analysis charts with an appropriate order were obtained. Discussion : In an analysis of mixed cohort data, there is considerable significance in demonstrating age-related trends in the preschool years. Construction of bone density evaluation for preschool age based on these findings may provide useful information in terms of deriving health and fitness indicators for young children. These findings are suggestive for the tracking of bone density in adults.

COMPARING THE MEASUREMENT RESULTS OF CALCANEAL QUANTITATIVE ULTRASOUND SYSTEM FROM TWO DEVICES

HUANG, Z.1, SUI, X.1, ZHU, Z.1, LI, Y.1, WANG, P.2

1:Guangzhou Sport University(Guangzhou,China),2:Tsinghua University(Beijing,China)

Introduction Osteoporosis is emerging as a worldwide problem and significantly associating with increasing bone fractures, which in turn negatively affect life expectancy. Dual X-ray absorptiometry (DXA) is currently considered the gold standard for measuring bone mineral density (BMD) and the diagnosis of osteoporosis(Martin, Campbell et al. 1999), but it is expensive and not an ideal choice for screening for bone mass alterations, particularly in resource-limited countries .So our research team designed a calcaneal quantitative ultrasound system (QUS) for predicting fractures and screening low BMD(Thomsen, Jepsen et al. 2015). This study aimed to compare QUS measurement results between ours and SONOST-2000(Steiner, Fernandes et al. 2008). Methods The volunteers consisted of 5 men and 24 women with a global mean age of 55.2 ± 10.1 years (range 29-65 years). Volunteers' ipsilateral calcaneals were measured by our QUS and SONOST-2000 , one after another. Both QUS are able to detect various bone mechanical properties and the trabecular structural orientation through the measurement of parameters represented by the speed of sound (SOS), broadband ultrasound attenuation (BUA ,dB/MHz) and stiffness. Other parameters, such as bone quality index(BQI) T-Score, T-Radio, Z-Sore, Z-Radio also were included. The association between the QUS parameters measurements was determined using the Pearson's correlation r coefficient. Simple regression analysis was used to test for trends among the different variables. Results According to WHO classification criteria, which identify a T-score values >-1 SD as being normal, between -1 SD and -2.5 SD as indicating osteopenia, and ≤-2.5 SD as indicating osteoporosis, the numbers of the samples being normal, osteopenia, osteoporosis are 19, 9, and 1 estimated by our device, while those by SONOST-2000 are 10, 14 and 5, with significant differences between the two instruments($p=0.000$, by Chi-Square analysis), also with significant differences in BUA,T-Radio and Z-Sore($P<0.05$) . The paired samples correlations on T-Score is 0.577, $p=0.001$. There were no significant differences in BQI, T-Score and Z-Radio($P>0.05$). Discussion Our QUS is some different from that of SONOST-2000. Some improvement and veracity could be done for our instrument, maybe including the hardware and the software design. Especially, the software, developed by VisualC# and Matlab, should update the data evaluation standard and some calculation formula according to Chinese feature. References Martin, J. C., et al. METABOLIC RISK FACTORS IN STATIN USERS WITH AND WITHOUT MYALGIA

MONBERG, T.J., MORVILLE, T., DOHLMANN, T.L., KUHLMANN, A.B., TORP, M.M., SAHL, R., HELGE, J.W., DELA, F.

Institute of Biomedical Sciences

Introduction Early metabolic disturbances constitute the core components in the development of cardiovascular disease (CVD) and type 2 diabetes and a cluster of these disturbances are often referred to as the Metabolic Syndrome (MetS). Even though the pathogenesis is still unknown, several studies have suggested visceral adipose tissue (VAT) to be an important component of the MetS. In the primary prevention (PP) of CVD the beneficial effects of statins have been extensively debated. This debate is due partly to possible side effects of statins, the most common being myalgia. We hypothesize that statin users in PP are at higher metabolic risk, and that those experiencing myalgia have even more metabolic disturbances because of a reduced level of physical activity. Therefore the aim of this study is to compare the metabolic profiles of three groups (statin-myalgia, statin-non-myalgia, control). Moreover, the association between VAT and features of the MetS will be considered. Methods The study is cross-sectional and includes 50 subjects (age 50-70, BMI 27-35), divided into 2 groups; a control group (N=22) and a PP statin group (N=28). The latter is subdivided into two groups – one experiencing myalgia (N=11) and one without myalgia (N=17). The metabolic profile of each individual is measured including diagnostic risk factors for the MetS (blood pressure, fasting glucose, abdominal circumference, HDL and TG, HbA1c, VO₂max and VAT estimated by DXA). The risk of having a CVD event within the next 10 years is calculated for each individual using standardized risk assessment tools. A one-way ANOVA or, in cases of unequal variance, a non-parametric test is used to compare groups. Results are mean \pm SD. Results Controls have a significantly lower systolic blood pressure (120 ± 16 vs. 138 ± 16 mmHg, $p<0.01$) and a higher concentration of total cholesterol (5.6 ± 1.2 vs. 4.4 ± 0.6 mmol/L, $p<0.01$) and LDL cholesterol ($p<0.01$) than Statin users. HbA1c, fasting glucose, HDL, triglyceride, VO₂max, VAT, CVD risk and anthropometric measures are similar between all three groups. VAT is negatively correlated with HDL ($p<0.01$, $r=-0.48$) and positively correlated with CVD risk ($p<0.05$, $r=0.31$). Discussion This study shows that statin users in PP have another distribution of metabolic risk factors than

controls, including significantly higher systolic blood pressure and lower total and LDL cholesterol. Moreover the results suggest that statin induced myalgia is not associated with a less active lifestyle and thereby a higher metabolic risk. VAT seems to play a role in both lipid homeostasis and in overall CVD risk, but further statistics needs to be done to evaluate the interrelations of risk factors. Contact: vjl114@alumni.ku.dk

SEGMENTAL FAT FREE MASS DID NOT INFLUENCE MUSCULAR STRENGTH IN OBES AND NON-OBESE BOYS

LOPES, W.A.1, MORAES JUNIOR, F.B.2, SILVA, L.R.2, ARAÚJO, C.T.2, JESUS, I.C.2, COUTINHO, P.R.2, RADOMINSKI, R.B.2, LEITE, N.2

1: Universidade Estadual de Maringá - UEM (Paraná, Brazil), 2: Universidade Federal do Paraná - UFPR (Paraná, Brazil)

Introduction Muscular strength is recognized as an important component of health. In adults, lower levels of muscular strength have been associated with increased risk of mortality. In children and adolescents, it seems that elevated levels of muscular strength are inverse and positively related to metabolic risk and insulin resistance. However, the impact of obesity in muscular strength has been little investigated. Therefore, the aim of this study was to compare the absolute and relative muscular strength to body mass (BM), whole body fat free mass (FFM) and segmental FFM of upper and lower limbs among obese and non-obese boys. Methods Thirty-nine boys, aged 13-17 years-old, were divided into three groups: normal weight (n=11), overweight (n=14) and obese (n=14). BM, height and body mass index (BMI) were evaluated. Body composition was measured by x-ray absorptiometry dual energy (DXA). Maximal muscular strength of upper (leg press) and lower limbs (bench press) was estimated by one maximum repetition test (IRM). One-way ANOVA, Pearson's correlation coefficient and Multiple Linear Regression were used to compare and correlate muscular strength among and within the groups. Results Obese and overweight adolescents presented absolute muscular strength of upper (41.5 ± 9.0 and 45.1 ± 9.8 vs 41.6 ± 11.0 , $p=0.54$) and lower limbs (204.4 ± 55.5 and 199.2 ± 51.0 vs 192.7 ± 40.2 , $p=0.84$) similar to normal weight adolescent. Also, muscular strength of upper (2.2 ± 0.2 and 2.3 ± 0.3 vs 2.3 ± 0.5 , $p=0.71$) and lower limbs (13.0 ± 2.5 and 12.1 ± 1.7 vs 13.0 ± 2.2 , $p=0.44$) relative to segmental FFM were similar between groups. Linear regression showed that BMI explained 59% of the variation in the absolute muscle strength of lower limbs ($\beta=0.59$, $p<0.05$), FFM explained 84% of the variation in the absolute muscle strength of upper limbs ($\beta=0.84$, $p<0.01$) and 68% of lower limbs ($\beta=0.68$; $p<0.01$), while segmental FM was inversely associated with muscular strength of lower limbs ($\beta=-0.53$, $p<0.05$). Discussion Muscular strength levels of upper and lower limbs of obese and overweight boys were similar to those of normal weight boys. These findings are opposed to studies that found higher muscle strength of lower limbs in extremely obese adolescent boys (Abdelmoula et al., 2012) and obese children (Tsiros et al., 2013), but similar to the findings in overweight/obese adolescents girls (Lopes et al., 2013). The results of this study indicate that obesity does not affect adversely the generation of muscle strength in obese adolescent boys. RATING PERCEIVED EXERTION AND STRENGTH EXERCISES IN OVERWEIGHT AND OBESE SUBJECTS

LURUEÑA, J.1, CASTRO, E.A.1, PEINADO, A.B.1, BENITO, P.J.1

technical university of Madrid

Introduction Rating of Perceived Exertion (RPE) in resistance and combined circuits training has been previously studied (Miller et al., 2009; Skidmore et al., 2012), irrespective of body composition and gender. Squat and bench press has been included in many training routines, due to its low complexity and high energy expenditure (Vianna et al., 2011; Bocalini et al., 2012; Maté-Muñoz et al., 2014). Therefore, the aim of this study was to analyze the RPE in squat and bench press between overweight and obese women and men. Methods Forty-four men (S, n=20; SE, n=24) and forty-five women (S, n=23; SE, n=22), aged 18-50 years, performed tests of 15 repetitions maximum (15RM) for squat and bench press. Loads of 50% were individually calculated and the OMNI-RES Scale was immediately measured following each exercise during four weeks. Subjects were randomized into two training groups, strength (S) or combined (SE). Subjects of S group executed strength exercises, while the routine for the SE group consisted of a combination of aerobic exercises intercalated with strength exercises (Zapico et al., 2012). Training frequency was 3 times/week for both groups. Student t tests were performed to identify differences between gender, IMC classification and training groups in the RPE for squat and bench press. Results No differences were found between males and females or between S and SE for any of exercises ($p>0.05$). Overweight individuals obtained greater score of RPE for bench press ($W: 5.11 \pm 1.47$; $O: 4.5 \pm 1.01$, $p<0.05$). Discussion Studies show the relation between OMNI-RES Scale and Resistance Exercise (Vianna et al., 2011). We did not find studies demonstrating the difference between overweight and obese women and men regarding RPE. Our data does not show differences in RPE in squat and bench press between overweight and obese, and between female and male subjects. Although the differences were small, our results indicated greater RPE in bench press for overweight subjects, which could be related to a greater load in 15RM, and consequently a greater load in 50%. WITHIN PARTICIPANT RELATIONSHIPS BETWEEN APPETITE SCORES, PEPTIDE YY IN OVERWEIGHT WOMEN BEFORE AND AFTER EXERCISE PROGRAMME

RIZOU, E., GERASIMIDIS, K., DO CARMO, S., ANGELIDIS, G., MALKOVA, D.

UNIVERSITY OF GLASGOW

Background:Exercise-induced weight loss was reported to modify peripheral hormones in a direction expected to enhance satiety and permit weight loss and/or maintenance. This suggestive causal relationship between exercise and appetite hormone alterations was not found in all studies. Thus, interactions between subjective appetite measures and hormonal appetite regulators require further investigation.Objective:To investigate the impact of a 4-week aerobic exercise programme applied to overweight women on subjective appetite measures, gastrointestinal appetite hormones and to establish whether within-participant relationships between appetite scores, peptide YY are modified by participation in exercise. Design:Study participants were eleven females of 26 ± 1.4 years old with BMI of 29.5 ± 1.0 kg/m². Each participant underwent two 7-hour experimental trials; one before and another after a 4-week aerobic exercise programme

of weekly sessions of progressively increasing duration. During the 7-hour experimental trials blood samples were collected and appetite scores were measured before and after consumption of standardised breakfast and lunch. Commercially available ELISA kits were used to measure PYY concentrations. Results: The 4-week exercise programme had no impact on body weight (Before, $78.8 \pm 2.9\text{kg}$; After, $78.0 \pm 3.1\text{kg}$) and body fat percentage (Before, $37.8 \pm 1.3\%$; After, $37.2 \pm 1.2\%$) but significantly reduced the waist circumference (Before, $84.0 \pm 2.2\text{ cm}$; After, $82.4 \pm 2.1\text{cm}$, $P < 0.05$). Exercise programme did not have an impact on post-breakfast hunger (Before, $32 \pm 4\text{mm}$; After, $33 \pm 4\text{mm}$), post-breakfast satiety (Before, $59 \pm 3\text{mm}$; After, $55 \pm 4\text{mm}$), post-lunch hunger (Before, $24 \pm 3\text{mm}$; After, $25 \pm 4\text{mm}$), post-lunch satiety (Before, $68 \pm 5\text{mm}$; After, $67 \pm 5\text{mm}$), post-breakfast PYY concentration (Before, $94.1 \pm 12\text{pg/ml}$; After, $78.3 \pm 9.2\text{.9pg/ml}$) but significantly reduced the post-lunch concentration of PYY (Before, $102.0 \pm 18.6\text{pg/ml}$; After, $86.4 \pm 17.1\text{pg/ml}$, $P < 0.05$). Relationships between appetite score responses and PYY responses showed significant correlation during before and after the exercise intervention and these relationships were not modified by training status (Table 1). Table 1. Means ($\pm \text{SE}$), 95 CIs for the means of observed slopes and R² values for within-subject relations between appetite scores and PYY before and after training programme Slope 95% CI R² Before Satiety vs PYY $0.92 \pm 0.18^*$ (0.52, 1.32) 0.37 ± 0.07 Hunger vs PYY $-1.01 \pm 0.27^*$ (-1.71, -0.32) 0.37 ± 0.07 After Satiety vs PYY $0.92 \pm 0.19^*$ (0.48, 1.35) 0.41 ± 0.07 Hunger vs PYY $-0.81 \pm 0.27^*$ (-1.42, -0.20) 0.30 ± 0.08 *Mean of the regression slopes significantly different from zero, $P < 0.05$ (Student's one sample t-test) Conclusion: Exercise programmes applied to overweight women result in changes in the peripheral hormones which would be expected to increase appetite. However, these hormonal changes do not modify subjective appetite and thus should not be considered to be responsible for the prevention of body weight loss commonly seen during exercise interventions.

EFFECT OF HIGH INTENSITY INTERVAL TRAINING ON LEFT VENTRICULAR EJECTION FRACTION IN OBESE MEN

MORADI, L., GALEDARI, M.

Islamic Azad University, North Tehran Branch- Islamic Azad university, Ahvaz Branch

EFFECT OF HIGH INTENSITY INTERVAL TRAINING ON LEFT VENTRICULAR EJECTION FRACTION IN OBESE MEN Obesity and overweight are epidemic and has substantially increased in recent years. Overweight and obesity are associated with the prevalence heart structural and functional impairments. Physical exercise improves diastolic function in obese/ overweight subjects and decrease end diastolic Left Ventricular Ejection Fraction (LVEF) in them! Kivistö et al., 2006) and reduced risk of cardiomyopathy in longer term (Schrauwen- Hinderling VB. et al., 2010). High intensity interval training (HIIT) is a proper exercise method to weight loss. Therefore the aim of this study was evaluation the effect of HIIT and caloric restriction as a predictor for heart function. Methods Participants included 24 healthy obese/ overweight males (280.229). EF was increased significantly only in DH group ($P < 0.02$). Discussion We demonstrated that due to 12 weeks of supervised HIIT, LVEF is improved in obese/ overweight male subjects. It seems that decreased cardiac lipid content with weight loss can improve heart function. On the other hand, increasing EF post training may be caused by improving contractility of cardiac as a result of the elimination of cardiac ischemia, because increase of the pre-load improves the blood supply and decreases cardiac ischemia. The beneficial effect of training on systolic and diastolic function has been linked to alteration of Ca²⁺ regulatory system involved in excitation-contraction couple and relaxation process (Kemi et al., 2008) and thus decreased after load. RELATIONSHIP BETWEEN PHYSICAL SELF-DESCRIPTION AND ACTUAL HEALTH-RELATED FITNESS AMONG YOUNG QATARI WOMEN

KNEFFEL, ZS., GHAZI, W., ALREFAEI, J., ALQAWASSMI, D., MAJED, L.

Qatar University

INTRODUCTION Health-related fitness (HRF) explains the capacity to perform physical activities without tiring and include specific components that are objectively measured with standardized physical tests. The physical self-description (PSD) is a subjective judgment of the body and physical abilities that could diverge according for example to cultural backgrounds. Most studies on women's perception of their bodies and physical abilities have been done on western cultures, while limited exist data on Arab ones. The purpose of this study is to analyze the links between actual HRF and the estimated PSD among young Qatari women. METHODS 85 women (18-25 years) were recruited on campus to perform a standardized battery of HRF tests (ALPHA-FIT for adults, Suni et al., 2009). To estimate the physical self-concept the short version of Physical Self-Description Questionnaire (PSDQ) was used (Marsh et al., 2010). The collected data were imported to Statistica v.12 software and correlations were analyzed using Pearson coefficient. RESULTS 69.4% of the participants were classified as overweight (45.8%) or obese (23.6%). Significant correlations were found between: BMI on one hand and self-estimated appearance, body fat and global physical esteem on the other ($r = -0.27$ and $r = -0.29$, respectively), between the 2km-walk performances on one hand and perceived endurance ($r = 0.4$) and global physical esteem ($r = 0.34$) on the other. Although, the jump-and-reach and modified push-up tests correlated significantly with the self-estimated strength ($r = 0.26$, $r = 0.31$, respectively), this was not evidenced between the latter and the strength-related tests (handgrip, $r = 0.18$; dynamic sit-up, $r = 0.11$). Shoulder-neck mobility results were also significantly correlated to perceived flexibility ($r = 0.35$). The lowest fitness scores manifested in handgrip, modified push-up and 2km-walk tests. DISCUSSION Overweight and obesity are still primary issues among young Qatari female. The established correlations between BMI and estimated appearance scores indicated a rational image. However, in some strength related fitness scores (handgrip, dynamic sit-up) participants overestimated their abilities. The low performance in strength and endurance tests could be linked to the awareness concerning muscularity as well as participation in regular physical activity (Youssef et al., 2013). ANGLE FOR POSTURE ESTIMATION

VÄHÄ-YPYÄ, H., HUSU, P., SUNI, J., VASANKARI, T., SIEVÄNEN, H.

UKK-institute

Introduction Sedentary behavior (SB) is a risk factor for health, regardless of the level of concurrent physical activity (PA). Accurate measurement of SB would provide relevant data on total sedentary time and specific patterns in sedentariness. Waist-worn accelerometers are widely used to estimate habitual PA, but they are compromised by low accuracy in classifying the body posture into lying, sitting or

standing. The purpose of this study is to describe an accurate method for waist-worn triaxial accelerometers to classify posture. Classification is based on two facts: Earth's gravity vector is constant and the body walking posture while walking is upright. Methods Thirty healthy adults wore a waist-mounted triaxial accelerometer and underwent an individual array of lying, sitting, standing and walking tasks. The order and duration of these tasks was random. During walking, the accelerometer orientation in terms of gravity vector was taken as reference, and the angle for posture estimation (APE) was determined from the incident accelerometer orientation in relation to the reference vector. Results Receiver operator characteristic (ROC) curve yielded the optimal cut-point APE of 64.9° for lying and sitting and 11.4° for sitting and standing. Lying was perfectly (100%) separated from sitting while standing was separated from sitting with 94.4% sensitivity and 94.5% specificity. Discussion Upright walking provides a valid reference to determine the body posture spent lying, sitting and standing. The proposed analysis of the raw data obtained from waist-worn triaxial accelerometer provides more specific and detailed information about SB and standing.

DAILY VARIATIONS IN RESTING METABOLIC RATE

VUCETIC, V., GRGIC, J., TOMIC, J., BRBOROVIC, H.

University of Zagreb, Faculty of Kinesiology, Croatia; Sisters of Charity Hospital; University of Zagreb, School of Medicine, Andrija Štampar School of Public Health

INTRODUCTION Resting metabolic rate (RMR) are indicators of the amount of calories a person needs during one day at rest. They provide information on the amount of calories burnt on basic body functions and also the amount of calories burned by food intake and physical activity. The purpose of this study was to determine possible daily variations in measured values of resting metabolic rate (RMR). METHODS Twenty male students of kinesiology (A: 24.3±3.3 years, H: 180.83±19.50 cm, W: 80.36±35.10 kg) were tested for RMR via COSMED QUARK CPET during one day, in the morning (8 am) in the midday (1 pm) and in the evening (5 pm). All measurements were conducted at the Sports Diagnostic center at the Faculty of Kinesiology, University of Zagreb. During the test the subject is lying without movement for 16 minutes and the RMR values are based on the last 10 minutes of the test. Statistical analysis was done using repeated measures ANOVA (Statistica for Windows 12.0), and statistical significance was set at $p \leq 0.05$. RESULTS The test results and comparison have shown statistically significant ($F(1,19)=43.99$; $p \leq 0.05$) differences between RMR results of the morning (2071.55±378.93 kcal/day) compared to the midday (2623.50±658.92 kcal/day) and evening data (2668.05±451.41 kcal/day). The results of the morning RMR testing showed that morning values are much lower and closer to the values of basal metabolic rate (BMR) than to RMR. DISCUSSION Obtained results shown that the result of RMR can vary up to 22.36 %. Lower values of the morning testing are associated with the lower activity of the digestive system, because the subjects fasted from food. During sleep the calorie consumption is also lower due to the decreased activity of muscle cells, and central nervous system. CONCLUSIONS RMR results showed daily variability. For the most accurate results, spirometry should be done early in the morning. We strongly recommend following the outlined guidelines for RMR. If RMR testing on COSMED QUARK CPET system is used following the recommendation, this system is a very good and useful tool for measuring resting metabolic rate and ventilation parameters

CAN HEART RATE BE USED AS AN INDICATOR OF ENERGY DEMANDS DURING COMMUTER WALKING IN A METROPOLITAN AREA?

SCHANTZ, P., SALIER ERIKSSON, J., ROSDAHL, H.

The research group for movement, health and environment

Introduction Measuring the energetic demands of habitual commuter walking is essential to objectively relate to the impact that walking commuting can have on health. Hence, evaluating methods for such purpose is of great importance. Heart rate (HR) can possibly be used as long as the relationship between oxygen uptake (VO₂) and HR is established in laboratory conditions and proven to be valid under field conditions. However, e.g. traffic, noise and exhaust fumes may introduce effects of e.g. stress that change the relationship in the field. Thus, the validity of the HR method needs to be scrutinized. Methods VO₂ and HR measurements during three submaximal exercise intensities on cycle ergometer were performed in the laboratory, as well as during normal commuting walking in the individuals' normal field setting in Greater Stockholm, Sweden. 20 habitual commuter pedestrians (10 males and 10 females) aged 45 ± 7 yrs (mean ± SD) participated and validated stationary and portable metabolic systems (Rosdahl et al. 2010; 2016; Salier-Eriksson et al. 2012), and HR monitors were used. A comparison of the VO₂ – HR relationship was made between the laboratory and field conditions. Results and Discussion Interpreting the heart rate levels during walking commuting from the VO₂ – HR relationship in the laboratory resulted in oxygen uptakes that were 13.0 ± 10.6 % lower in males and 10.5 ± 11.5 % lower in females than the correct VO₂ values. Thus, the study indicates that systematic differences between the laboratory and field conditions with respect to the VO₂ – HR relationship are present in metropolitan conditions. The reason for these differences remains to be elucidated. References Rosdahl, H., Gullstrand, L., Salier Eriksson, J., Johansson, P. & Schantz, P. 2010. COMPARISON OF BODY FAT ASSESSMENT METHODS ON FIELD IN ELITE JUNIOR ROWERS

KELSO, A.1, TRAJER, E.1, MACHUS, K.1, TREFF, G.1, MÜLLER, W.2, STEINACKER, J.M.1

(1) Ulm University Medical Center, (2) Medical University of Graz

Introduction There is a large variety of body fat measurements, which differ in validity and reliability, especially for athletes. It is necessary to find a method that quantifies body fat most accurately and that is feasible for field testing. The purpose of this study was to compare

three methods of body fat estimation in rowers of the German National Junior Rowing Team (8 females, 8 males): skinfold-thickness (SKF), near-infrared interreactance (NIR) and ultrasound (US) measurement of subcutaneous adipose tissue (SAT). Methods The examiners were certified by the International Society for the Advancement of Kinanthropometry (ISAK) and Association of Applied Sciences in Medicine and Sports (ASMS). SKF and NIR measurements were taken at three sites and are reported as total body fat percentage (BF%). US measurements were taken at 8 sites and are reported as a sum of SAT (mm) with a distinction made between SUMExcl (without embedded structures) and SUMIncl (including embedded tissues) (10/15 MHz linear transducer L12-3 US, Phillips CX50, Amsterdam, NL). Results Mean BF% via SKF was $10.9 \pm 1.9\%$ and $11.7 \pm 2.9\%$ via NIR. Mean SAT thickness was $46.6 \pm 12.1\text{mm}$ (SUMIncl), respectively $42.5 \pm 11.4\text{mm}$ (SUMExcl). A comparison of the three body fat assessment measurements showed significant correlations between US and SKF (SUMIncl: $p<0.001$, $r^2=0.86$; SUMExcl: $p<0.001$, $r^2=0.86$) and between US and NIR (SUMIncl: $p<0.01$, $r^2=0.38$; SUMExcl: $p<0.01$, $r^2=0.40$). There were also significant correlations between SKF and NIR ($p<0.001$, $r^2=0.56$). Furthermore, a Bland-Altman-analysis showed a 95% agreement between the SKF and NIR method. Discussion Body fat assessment in field testing can be performed by using any of these three methods. US allows the quantification of pure SAT, and the protocol for fat patterning by Müller et al. (2016) permits reliable and valid results. Currently there are no reference data and/or a formula for estimating US-BF (%), and further research is required. The SKF method cannot quantify pure SAT, and NIR has lower accuracy compared to US and SKF. The method of choice depends on the skills of the examiner, number of athletes and available time. For highly accurate SAT measurements, US could be a gold standard once reference data is established. ASSOCIATIONS BETWEEN NECK CIRCUMFERENCE AND ADIPOCYTOKINES AMONG ADOLESCENTS

MOREIRA, C., MOTA, J., ABREU, S., LOPES, L., AGOSTINIS, C., OLIVEIRA-SANTOS, J., OLIVEIRA, A., SANTOS, P.C., SANTOS, R.

Faculty of Sport, University of Porto

Introduction Neck circumference (NC) was recently indicated as a useful parameter for predicting cardiovascular diseases (CVD). Adipocytokines may play a key role in the development of CVD. The purpose of this study was to examine the associations between NC and adipocytokines in adolescents. Methods A cross-sectional, school-based study was conducted on 529 Portuguese adolescents (267 girls) aged 12-18 years-old. Anthropometry, plasma biomarkers (adiponectin and leptin), cardiorespiratory fitness, socioeconomic status, diet and pubertal stage were obtained from each participant. Results NC was significantly and positively correlated with leptin and negatively correlated with adiponectin, after controlling for age, sex, pubertal stage, cardiorespiratory fitness, socioeconomic status and diet ($p<0.001$). Linear regression analyses showed that NC was positively associated with leptin ($\beta=3.722$, $p<0.001$), whereas it was significantly and inversely associated with adiponectin ($\beta=-1.326$, $p<0.001$), after adjusting for the aforementioned confounders. Discussion The main findings of this study suggest that NC, regardless of other potential confounders, predicts status of pre-inflammatory process; therefore, this anthropometric measure can be useful as an additional predictor of cardiovascular and inflammatory risk in adolescents. NC, as an index of upper-body obesity, has already been found to be a simple and practical screening method that can be used to identify CVD risk factors, such as obesity and metabolic syndrome (Laakso et al, 2002; Onat et al, 2009). Conclusions The use of NC as a screening tool for CVD risk factors should be considered. Since the onset of chronic disease risk factors starts in early childhood, it is important to assess the risk predictors in order that effective preventive strategies targeting those at risk start as early as possible. THE EFFECT OF FUcoxanthinol ON LIPOLYtic ACTIVITY IN 3T3-L1 ADIPOCYTES

MAKI, Y.1, TAKASHI, F.1, MASASHI, H.2, KAZUO, M.2, HOYOKU, N.3, TAKESHI, H.1

1Ritsumeikan Univ., 2Hokkaido Univ., 3 Kyoto Pref. Univ. Med.

Introduction Fucoxanthin (FX) is a carotenoid found in edible seaweed such as Undaria pinnatifida. Fucoxanthin suppressed weight gain of white adipose tissue in diabetic/obese KK-Ay mice (Maeda et al, 2007). Furthermore, FX and its metabolite fucoxanthinol (FXOH) inhibited the differentiation of 3T3-L1 through the down-regulation of PPAR γ protein expression (Maeda et al, 2006). However, the effect of FXOH on the cellular mechanisms responsible for lipolysis in mature adipocytes is unknown. The aim of this study was to investigate the effect of FXOH on lipolytic activity and lipolysis-related protein expression in mature adipocytes. Furthermore, we investigated the responsiveness of FXOH-treated cells to catecholamine stimulation. Materials and methods After 8 days of differentiation, mature 3T3-L1 adipocytes were treated with 2.5 μ M, 5 μ M or 10 μ M FXOH for 72 hours. During the treatment, aliquots of the medium were collected and biochemically analyzed for glycerol and fatty acid (FA) contents. Triacylglycerol (TAG) content was also biochemically measured. The expressions of lipid-associated proteins such as fatty acid synthase (FAS), perilipin1, adipose tissue triglyceride lipase (ATGL), comparative gene identification-58 (CGI-58), acetyl-CoA carboxylase (ACC), AMP-activated protein kinase (AMPK) and hormone-sensitive lipase (HSL) were analyzed by Western blotting. After the 72 hours of FXOH treatment, lipolytic activity by catecholamine stimulation was also analyzed biochemically. Results Intercellular lipid accumulation (TAG content) was significantly decreased by FXOH treatment as compared to control in a dose-dependent manner ($P<0.01$). FXOH treatment significantly increased lipolytic activities as estimated by glycerol and fatty acid release compared with control in a dose-dependent manner ($P<0.01$). On the contrary to our expectation, however, the expressions of lipolysis-associated proteins such as ATGL, HSL, perilipin1 and CGI-58 were significantly lower in FXOH as compared to control ($p<0.01$). On the other hand, FXOH enhanced AMPK and ACC phosphorylation ($P<0.05$). Furthermore, the expression of lipogenesis-associated protein (e.g., FAS) was lower in FXOH treated cells than in control ($P<0.01$). In line with the expressions of lipolysis-associated proteins, FXOH treatment significantly decreased lipolytic activity in response to catecholamine stimulation compared with control. Conclusion These results suggest that FXOH activates basal, but not catecholamine stimulated-lipolytic activity, and inhibits the lipogenesis in 3T3-L1 adipocytes. The mechanisms underlying this effect of FXOH might involve suppression of fatty acid synthesis by decreased expression of FAS as well as augmented phosphorylation of AMPK and ACC.

THE RELIABILITY OF THE EXTRA LOAD INDEX AS A MEASURE OF RELATIVE LOAD CARRIAGE ECONOMY

HUDSON, S., COOKE, C., LLOYD, R.

Leeds Trinity University

Introduction The aim of this study was to measure the reliability of the Extra Load Index (ELI) (Lloyd et al, 2010) as a method of assessing relative load carriage economy. The ELI is calculated as $\text{mLO2L} \cdot \text{kg} \cdot \text{min}^{-1} / \text{mLO2U} \cdot \text{kg} \cdot \text{min}^{-1}$, where mLO2L refers to loaded oxygen consumption for the combined mass of the individual and external load and mLO2U refers to oxygen consumption for unloaded walking. This accounts for the energy cost of unloaded walking and thus measures the change in economy associated with load carriage. An ELI value of 1 indicates that the additional energy cost is proportional to the mass of the external load. Values <1 or >1 indicate a relatively lower or higher energy cost respectively. The ELI is independent of the magnitude of external load, walking speed and body composition (Lloyd et al., 2010). Methods 17 apparently healthy volunteers (12 male, 5 female; age 27±10 years; stature 177±8.7cm; mass 77.5±13.9kg) performed walking trials at 3km·h⁻¹, 6km·h⁻¹ and a self selected pace (SS). Trial conditions were completed in a randomised order, separated by at least 48 hours and repeated identically 7 days later. Trials involved 4x4 minute periods of walking, each separated by 5 minutes of rest. The initial stage was performed unloaded, followed in a randomised order, by a second unloaded period and loaded walking with backpacks of 7kg and 20kg. Reliability of the ELI was assessed using a repeated measures ANOVA, limits of agreement (LoA: mean of the differences ± 1.96 SD; Bland and Altman, 1986) and coefficients of variation (CV). Results ELI values did not differ significantly between trials for any of the speeds (main effect speed, $p = 0.46$) with either of the additional loads (main effect load, $p = 0.297$). At 3km·h⁻¹, the LoA were -0.01±0.11 for 7kg and 0.00±0.10 for 20kg, with a CV of 4.17% for 7kg and 2.74% for 20kg. At SS, the LoA was 0.00±0.05 for 7kg and 0.03±0.09 for 20kg with a CV of 1.75% for 7kg and 3.42% for 20kg. At 6km·h⁻¹, the LoA was -0.02±0.09 for 7kg and 0.00±0.07 for 20kg, with a CV of 3.51% for 7kg and 2.51% for 20kg. Discussion The ELI demonstrated good reliability at different walking speeds with both a light and heavy load. The systematic bias was small in all conditions and the largest LoA was within ±0.11. The CV was also small in all conditions (highest magnitude of 4.17%). Therefore, the ELI appears to be a reliable measure of relative load carriage economy. It provides a dimensionless index that can be easily interpreted by developers and manufacturers as well as researchers. We conclude the ELI represents a useful tool for comparing the relative economy of different load carriage systems References Bland JM, Altman DG. PICKING GOODS ASSISTED BY HEAD-MOUNTED AUGMENTED REALITY SYSTEMS IN WAREHOUSES

FASCHING, P., WULTSCH, G., RINNERHOFER, ST., HOFMANN, P.

University of Graz, Austria

PICKING GOODS ASSISTED BY HEAD-MOUNTED AUGMENTED REALITY SYSTEMS IN WAREHOUSES Introduction Picking operations are subject to continuous improvements, as more goods must be loaded on even smaller spaces. As the diversity of products increases, the number of single orders decreases requiring supportive systems for the workers, in order to optimize the working process (Schwerdtfeger et al. 2011). Aim of the study was to compare an optical see-through (OST) prototype vision picking system (VS) with an augmented reality approach, to a conventional voice-controlled system (VC) during a typical order picking activity in terms of physiological impacts on the workers. Methods 20 male subjects (29.9±4.5 yrs) performed a cycle ergometry to determine performance (first lactate turn point, LTP1). Heart rate (HR) and number of steps were obtained for a 10 hour work shift. Gas exchange measures were performed during representative phases of work (Wultsch et al. 2012). Bipolar surface electro-myography (sEMG) recordings were performed every 150 minutes for the right neck muscles and forearm muscles. The volunteers worked for two days each with a different system in a randomized order. Results Maximal power output (Pmax) and maximal oxygen consumption (VO2max) was 236.4±26.6 W and 2.975±0.375 l.min⁻¹. Shift HR (HR10h) (106.6±12.6 bpm; 59.7±5.9 % HRmax) and oxygen consumption during work (1.178±0.189 l.min⁻¹; 39.9±3.3 % VO2max) in VS was significantly different to VC HR10h (99.7±9.6 bpm; 55.9±5.7 % HRmax) and VO2 (1.011±0.139 l.min⁻¹; 33.5±5.5 % VO2max). Subjects handled significantly more goods with VC (1142±222 goods, 7767.2 kg) and walked significant more steps (10448±3014 steps) compared to VS (1066±199 goods, 7529.2 kg; 9477±2254 steps). No significant correlation between pieces of goods and HR10h, VO2 10h, HRmax 10h as well as energy expenditure during the working time (EEW) were found for both systems. Significant changes of the sEMG amplitude were found only for the neck muscles for both systems. Discussion The subjects picked up fewer goods with a significantly higher physiological strain using a new prototype vision system. A higher degree of attention with the vision system, a shorter training phase and a higher weight of the device may explain these differences. Nevertheless, new systems like the HMDs should reduce strain with the same output and therefore development should focus on the weight of systems in order to minimize the risk of neck pain. EFFECTS OF THE DIFFERENT WEIGHT-LOSS PATTERN ON BODY COMPOSITION AND PERFORMANCE IN COLLEGIATE WRESTLERS

SAITO, Y., MOTONAGA, K., KONDO, E., OZAWA, S., ARAKAWA, H., KUMAGAWA, D., SUZUKI, N., ARIMITSU, T., WADA, T., KAMEI, A., NAKAJIMA, K.

Kanazawa Seiryo University

Most athletes participating in sports with specific weight categories compete in a class 5-10% below their habitual weight[1]. It remains common to lose weight by a combination of dietary restriction, exercise, and sweating for 4-5 days prior to competition. The purpose of this study was to examine the effects of the different pattern of weight-loss on body composition and performance. Experimental period consisted of three phases: pre weight-loss, weight-loss and repletion. Evaluation was conducted before(Pre) and at the end of weight-loss (Post) and 14-15h repletion (Recovery). Study 1 is an observational study for six collegiate male wrestlers preparing for competition. In Study 2, the subjects were divided into a moderate weight-loss group(n=6) and a severe weight-loss group(n=6). They were asked to lose 6%/9% of their body weight during 56h/125h through self-determined ways. Measurements were body weight(BW), body composition, urine specific gravity(USG) and dietary intake (daily energy intake and the proportion of carbohydrates, proteins and fats). Vertical jump and wingate test were also examined in Study 2. In Study 1, BW decreased by 4.8±0.5% in Post and reached Pre-value in Recovery ($p<0.05$). Although lean body weight(LBW) showed similar change($p<0.05$), no difference was observed in percent body fat. In Study 2 BW of both groups decreased in Post (6.0±0.1% for the moderate group vs. 8.8±0.2% for the severe group),but it did not reach Pre-value in Recovery ($p<0.05$). Although reduced percent body fat by weight-loss reached Pre-value in Recovery($p<0.05$), LBW did not recover fully in

both groups($p<0.05$). USG increased in Post and sustained higher value above Pre in Recovery in both groups($p<0.05$). Energy intake significantly decreased in weight-loss and increased above pre weight-loss value in repletion($p<0.05$). The carbohydrate proportion increased, but the fat proportion decreased in repletion compared with pre weight-loss($p<0.05$). Although the exercise performances were impaired in Recovery compared with Pre($p<0.05$), the blood lactate change by wingate test was not affected by weight-loss. No group differences were observed in dietary intake and performance. Weight loss over 6% was accompanied with decreased LBW with dehydration, which might impair performance. However, no effects of the weight-loss patterns were observed. 1)Brownell KD, Steen SN, Wilmore JH. FAMILY FUNCTION AND LIFESTYLE IN UNIVERSITY STUDENTS

VALLEJO CUELLAR, L.1,2,3, REYES, P.1,4, RÍOS, A.M., ARIAS, D.1,4, ALARCÓN, J.D.1,4, AMEZQUITA, J.1

1. Surcolombiana University - USCO, 2. Dneuropsy Research Group, 3. INEFC-Barcelona Sport Sciences Research Group, 4. Social Development, Public Health and Human Rights Research Group

Introduction Develop healthy programs in universities is very important, which are involved not only students but also the entire administrative and teaching personnel to prevent physical inactivity, obesity and poor eating habits among others. The aim of this study was to compare family function and lifestyle in the university population among medical students, nursing, engineering, administrative and teachers. **Methods** The study included a total of 220 participants, the sampling was per cluster and the sample consisted of 54 medical students, 36 nursing, 67 in engineering, 38 administrative and 25 teachers members Surcolombiana University. The study logistics complied with the Declaration of Helsinki. APGAR was the instrument to measure family function. APGAR shows how the family perceives the performance family level globally. FANTASTIC instrument was used to measure lifestyle, it have internal consistency and construct validity criteria on Spanish version. It is recommended that the questionnaire be used in primary healthcare and epidemiological studies. Bivariate analyses with chi square and ANOVA analysis of variance of a factor. The SPSS for Windows (version 16.0) was used for statistical analyses. All p values ≤ 0.05 were regarded as statistically significant. Results The general characteristic of the study were 220 participant; mean age of 27, 23 ± 14.4 years. By applying the analysis of variance of a factor only significant difference between family function (APGAR) of nursing students versus administrative with a value $p= 0.04$ were found. As for the comparison of the other groups no significant differences were found. With regard to lifestyle (FANTASTIC) No statistically significant differences were found among nursing students, engineering, medicine, administration and teachers. **Discussion** The lifestyle of the University population evaluated (USCO) is homogeneous and does not differ by academic program (nursing, medicine and engineering) or by the activity they perform (Student Administrative Staff). With regard to family function, only the results differ between administrative and nursing students. **References** Pan American Health Organization. THE EXTRA-TIME PERIOD OF SOCCER: IMPLICATIONS FOR PHYSIOLOGY AND PERFORMANCE

HARPER, L.D., WEST, D.J., STEVENSON, E., RUSSELL, M.

Northumbria University

Introduction Although soccer matches typically last 90 min, when scores are tied at the end of normal time an extra-time (ET) period consisting of two 15 min periods may be required in certain knockout competitions. The demands of 90 min of soccer-specific exercise are well known, however the responses to ET are relatively understudied. This is surprising as 35% of matches in the knockout phase of FIFA World Cup competitions between 1986 and 2014 required ET and indices of physical and skill performance are negatively impacted during ET (Harper et al., 2014; Russell et al., 2015). We aimed to examine the performance and metabolic responses to 120 min of soccer-specific exercise; with a particular focus on the responses elicited during ET. **Methods** Twenty two university standard soccer players completed 120 min of simulated soccer match-play which required following a prescribed intermittent exercise pattern and the completion of soccer dribble testing and 15 m sprints. Participants performed countermovement jumps (CMJ), 20 m sprints and a shooting test (to assess speed and precision) at pre-exercise, 45 min, pre-second half, 90 min and 120 min. Venous blood was taken throughout exercise to measure glucose, lactate, epinephrine, interleukin-6 (IL-6), glycerol and non-esterified fatty acid (NEFA) concentrations. **Results** Data shown as mean \pm SD. Repeated measures ANOVA highlighted that exercise significantly influenced all variables ($p < 0.05$). Sprint velocities (15 m and 20 m) and shooting speed reduced at 120 min compared to 90 min ($-5.7 \pm 4.8\%$, $-4.2 \pm 6.8\%$, and $-4.6 \pm 8.1\%$, respectively; all $p < 0.05$). Compared to 90 min, blood glucose concentrations were lower at 120 min ($-0.7 \pm 0.8 \text{ mmol.l}^{-1}$ $p < 0.05$) and plasma epinephrine ($+1835.8 \pm 1840.0 \text{ pmol.l}^{-1}$), IL-6 ($+4.8 \pm 4.01 \text{ pg.ml}^{-1}$), glycerol ($+114 \pm 101 \text{ umol.l}^{-1}$) and NEFA ($+0.5 \pm 0.6 \text{ mmol.l}^{-1}$) concentrations were elevated (all $p < 0.05$). However, shooting precision, lactate concentrations, and CMJ height remained unchanged in ET ($p > 0.05$). **Conclusion** The ET period elicited perturbations in metabolic and performance responses compared to those observed at 90 min. Depressed blood glucose concentrations with concomitant increases in NEFA and glycerol concentrations indicates increased fat oxidation during ET. Elevated epinephrine and IL-6 concentrations suggest a taxing of muscle and liver glycogen in ET. Decrement in sprinting and shooting velocities are putatively associated with shifts in substrate utilisation. Practitioners working with players who may be exposed to ET should be cognisant of these deleterious effects. Investigations on the efficacy of interventions that seek to attenuate decrements are warranted. **References** Harper LD et al. (2014) PLoS ONE 9(10) Russell et al. MO-BN07 Motion Analysis 2

CONTRIBUTION OF BODY SEGMENTS TO AERODYNAMIC FORCES DURING TAKEOFF IN SKI JUMPING

YAMAMOTO, K., TAKEDA, T., TSUBOKURA, M., BALERIOLA, S., ONISHI, K.

Hokusho University

Introduction In the series of movement involved in the ski jumping technique, the takeoff motion is considered to be the most important phase to determine the performance (Schwameder, 2008, Virmavirta et al., 2009). Since ski jumpers are required to change their posture from the crouching posture to the flight posture within an extremely short period of time, the aerodynamic force acted upon a ski jumper changes dynamically (Yamamoto et al., 2015). The aim of this study was to investigate the contribution of each body segment to the aerodynamic force during the motion. **Methods** Three dimensional surface model of a ski jumper was obtained by 3-D laser scanning of an active ski jumper, and divided the model into 15 body segments with joint mobility. Two sets of motion data were generated using the video analysis of ski jumper's takeoff motion (world-class jumper A and less-experienced junior jumper B). The CFD method adopted for this study was based on Large-Eddy Simulation. The incoming velocity was set to 23.23 m/s. The aerodynamic force, pressure distribution on the model's surface and contribution of each body segment to the aerodynamic force were calculated and then were compared between the two jumpers. **Results** Regarding the lift force, although jumper A's lift force was less in the in-run posture, it became greater than that of jumper B at the end of the movement. Lift forces acted upon Jumper A and B at the posture right before the takeoff were 62.1N and 57.6N, respectively. The body segment which was the most contributive for the lift force was a trunk (A: 63.8%, B: 56.8%). The second contributive segments were the arms (A: 31.5%, B: 32.5%). The drag force acting upon jumper A was weaker than that acting upon jumper B through the whole movement. Those were 60.7N for A and 94.7N for B at the posture right before the takeoff. However, the trunk segment had a great influence to drag as well as lift (A: 40.1%, B: 60.1%), and the contribution of the arms was relatively low (A: 4.0%, B: 9.4%). **Discussion** As for the lift, the total contribution of the trunk and the arms segments reached approximately 90%, and it was suggested that trunk movement was important aerodynamically. The contribution of the trunk segment to drag was also high, but the relatively low contribution of the arms segments was an interesting finding. These results suggested that the movements of the arms would have an influence in increasing lift and restraining drag. **References** Schwameder, H. (2008). Sports Biomechanics, 7(1), 114-136. SLED TOWING: A KINEMATIC ANALYSIS TO DETERMINE THE OPTIMAL TRAINING LOAD

MONTE, A., NARDELLO, F., ZAMPARO, P.

University of Verona

Introduction Sled towing is a popular method for sprint training, frequently used to improve performance in the acceleration phase. The kinematics of both unloaded sprinting and sprinting when towing a sled with different loads were compared, at maximum sprinting velocity. The aim of this study was to establish which load maximizes athletes' mechanical power without inducing detrimental technical changes. **Methods** Thirteen athletes (mean BM=67.88±5.93 kg) performed 5 trials at maximum speed over a 20 m distance: unloaded, +15, +20, +30 and +40% of BM. The following parameters were measured: contact and flight times (CT, FT), step length (SL), velocity, acceleration and hip, knee and ankle angles, by using a 3D body motion system (Vicon MXSystem, UK, 100Hz) in the first 5m, and two cameras (Elixim Casio, 100 Hz) over the remaining distance. All videos were further analysed with SIMI motion software. The leg and vertical stiffness (kleg, kvert) were calculated according to Morin et al. (2005). Mechanical power (P) was calculated according to Samozino et al. (2015). Results CT, kleg and kvert increased whereas SL and FT decreased when sled load increased. Knee and ankle angles decreased while hip angle increased, with increasing load, both at touch down and at take off. Significant changes in these angles were observed at +30% and +40% compared to the initial no load condition (no differences were observed at +15% and +20%). Mechanical power reached its maximum between +15% and +20%. **Discussion** Many studies have demonstrated that resisted sprint training may influence sprint technique (e.g. Cronin et al. 2008). In the present study we found that sled towing affects sprint kinematics during the acceleration phase: indeed, significant differences do exist at different loads on spatio-temporal parameters and lower limb angles. By considering all variables, the +20% condition represents the optimal overload for specific sprint training since at this load the subjects reach their highest power without causing significant angular changes. **References** Cronin J, Keir Hansen K, Kawamori N, Peter Mcnair P. INTRA-INDIVIDUAL DIFFERENCE IN SPATIOTEMPORAL VARIABLES DURING MAXIMAL SPRINTING

NAGAHARA, R., MIZUTANI, M., MATSUO, A.

National Institute of Fitness and Sports in Kanoya

INTRA-INDIVIDUAL DIFFERENCE IN SPATIOTEMPORAL VARIABLES DURING MAXIMAL SPRINTING Introduction Accelerated sprinting ability is of great importance for athletes in many sports. Spatiotemporal variables could provide useful information of characteristics in sprinting. Although a previous study that investigated the relationship among spatiotemporal variables during sprinting employed the inter-individual approach (Nagahara et al. 2014), an investigation of intra-individual difference in spatiotemporal variables during sprinting is limited. Thus, the purpose of this study was to clarify on a step-to-step basis the intra-individual difference in spatiotemporal variables during the acceleration phase of maximal sprinting. **Methods** Fifteen male sprinters ran 60-m with maximal effort for at least three times, during which ground reaction force was recorded with 54 force platforms. Spatiotemporal variables through 50 m were computed from the ground reaction force data, and the changes in variables during acceleration phase were approximated with 4th order polynomial equation. A t-test was used to examine the difference in variables between the best and the worst trials. **Results** The best and worst 60 m sprint times were 7.18 ± 0.17 s and 7.29 ± 0.15 s ($P < .001$). The running speed of the best trial was significantly higher than the worst trial from the 3rd to 22nd step. While there was no significant difference in step length at all steps, step frequency of the best trial was signifi-

cantly higher than that of the worst trial from the 2nd to 22nd step. The support time of the best trial was significantly shorter than that of the worst trial from the 2nd to 6th and from the 8th to 22nd step, although there was no significant difference in the flight time. Discussion The main result showed that intra-individual basis better accelerated sprinting was achieved by higher step frequency through shorter support time. The higher step frequency in the best trial is in line with the study of Hunter et al. (2004). Increase in constant running speed from nearly maximal to maximal is achieved by increase in step frequency, and this increment in step frequency is attributed to greater acceleration of hip and knee joints during swing, driven by hip muscles. Thus, trying to stimulate these hip muscles is possibly being a conditioning solution to accomplish one's best performance in a day. That said, it should be taken into account that the attempt to increase one of step length or frequency maybe result in impairment of a sprint performance, i.e. running speed. Accordingly, further investigation examining the effect of the intervention within a single day is suggested. Reference Nagahara R, Naito H, Morin J.B, Zushi K (2014). Int J Sports Med, 35, 755-761. KINEMATIC PARAMETERS OF FIRST AND FOURTH HURDLE CLEARANCES IN FEMALE SHORT HURDLE RACE

NEMTSEV, O.1, NEMTSEVA, N.1, DOLUDENKO, E.1, KUCHERENKO, J.2, CHERNOVA, T.3

Adyge State University

1: ASU (Maykop, Russia), 2: KC (Krasnogorsk, Russia), 3: KSUFCST (Krasnodar, Russia) Introduction Top female hurdlers run from the start to the third hurdle with marked acceleration and achieve highest speed at the fourth hurdle or later (Hucklekemkes, 1990). This suggests that the techniques of the hurdle clearance during acceleration and in the top speed phase may differ. However, most of the studies have focused on the parameters of clearance in the phase of high speed (Francis et al., 2004 et al.). Therefore, the aim of this study was to compare kinematic characteristics of the clearance of the first and the forth hurdles. Methods Five female hurdlers (age 19.8±4.1, height 1.72±0.06 m, weight 62.0±5.8 kg, 100 m hurdles personal best 14.39±0.88 s) took part in the study. Each participant performed one trial of maximal speed running in five-hurdle race using starting blocks. Videotaping was done with two high speed camcorders (240 Hz) placed perpendicular to the run direction, about 20 m away from the first and the forth hurdles. 2D video analysis was carried out with the help of SkillSpector software. Paired sample t-test was used to examine statistical differences of data. Results Horizontal velocity (HV) of center of gravity (CG) at takeoff before and at touchdown after the first hurdle were significantly smaller than similar parameters at the fourth hurdle ($p=0.041$ and 0.034). It was also found that the vertical velocity (VV) of CG at takeoff (1.84 ± 0.33 and 1.40 ± 0.21 m/s, $p=0.012$), the takeoff angle of CG (15.6 ± 3.6 and $11.6\pm2.7^\circ$, $p=0.007$) and the flight time (0.336 ± 0.028 and 0.327 ± 0.031 s, $p=0.032$) were significantly larger at the first hurdle clearance. The takeoff distance (1.68 ± 0.11 and 1.90 ± 0.09 m, $p=0.001$), the takeoff CG height (1.05 ± 0.04 and 1.07 ± 0.04 m, $p=0.023$) and the stride length (2.86 ± 0.18 and 3.04 ± 0.15 m, $p=0.025$) were significantly smaller at the first hurdle clearance. Discussion Thus, hurdlers tend to perform the first hurdle clearance from shorter distance, with a larger takeoff VV and takeoff angle. However, CG maximal height at the first and the forth hurdle clearances is simply possible due to the lower position of CG at the first hurdle takeoff. Faster HV at the forth hurdle clearance allows runners to decrease their flight time and increase the stride length due to takeoff distance. The study results can be used in technical training of hurdlers. References Hucklekemkes, J (1990). Model technique analysis sheets for the hurdles. Part VI: The Women's 100 metres Hurdles. RELATIONSHIP BETWEEN ISOKINETIC KNEE STRENGTH AND FLIGHT DISTANCE AT DIFFERENT START TECHNIQUES IN EXPERIENCED SWIMMERS

RAMAZANOGLU, N., TATAR, Y., SANLI, G., UZUN, S., PISKINTAS, B., GERCEK, N., YIMAZ, S., GULMEZ, I.

Marmara University

Introduction Lower body strength is one of the most important determinants of start performance (McBride et al., 2009). It directly affects the ability to exert force on block during push-off phase which affects the take off velocity and flight distance (Slawson et al., 2013). The aim of this research is to examine the effect of maximal isokinetic knee strength on flight distance for grab, track and kick start techniques. Methods 17 experienced swimmers (Age; 16.84 ± 1.68 year, Body mass; 72.16 ± 7.16 kg, Height; 179.95 ± 5.80 cm, BMI; 22.28 ± 1.91) participated in this study. Start performance was recorded with two digital video cameras to determine flight distance. Isokinetic peak torque was assessed for the knee extensors and flexors at 60 degree/s and at 180 degree/s (Biodex System 4 Dynamometer). Peak torque value of the best repetition were used for each angular velocities. One way analysis of variance (ANOVA) and Pearson correlation analysis was used to assess the relationship between isokinetic strength variables of the knee and flight distance for three start techniques. Results There was no relation between flight distance and knee flexion-extension peak torques at 60 degree/s for both front and rear legs in all three starting techniques ($p>0.05$). However at 180 degree/s, flight distance was related with knee extension peak torques ($p<0.05$) for front leg in grab start ($r=0.539^*$, $p=0.016$), track start ($r=0.489$, $p=0.046$) and kick start ($r=0.663^{**}$, $p=0.004$). Moreover at 180 degree/s positive relationship was found for rear leg in kick start technique between knee extension peak torques and flight distance ($r=0.506^*$, $p=0.032$). There was no relationship at rear leg in grab and track start techniques ($p>0.05$). Same as 60 degree/s, knee flexion peak torques were not related with flight distance at 180 degree/s in all three techniques. Discussion Our results showed that at 180 degree/s isokinetic knee extension strength was positively correlated with flight distance at front leg for all start techniques. Previous studies have also reported significant correlation between the contractile properties of leg extensor muscles and start performance (Durovic et al., 2015). Differently from grab and track start techniques, at 180 degree/s positive correlation was found at rear leg between knee extension strength and flight distance in kick start technique. In kick start position swimmer's back leg is positioned on an incline plate. Therefore, the horizontal component of ground reaction force on the kick plate during push off is bigger, compared to other techniques. It is reported that bigger horizontal force in kick start leads to higher horizontal velocity, thereby longer flight distance (Honda et al., 2011; Garcia-Ramos et al., 2015). This could mean that the contribution of rear leg extensors to the start performance is more significant at kick start. Contact goktug.sanli@marmara.edu.tr

STROKE VARIABLES OF JUNIOR PADDLERS IN 200-M SPRINT KAYAKING

HIRANO, T., KASHIWAGI, Y., KOBAYASHI, T., FUJITO, Y., YAMAGISHI, M., KATO, T., FUNATO, K.

Nippon Sport Science University

Introduction Sprint kayak is competed over 200-m, 500-m, and 1000-m distance. In theoretically, kayak velocity (V_{kayak}) is a product of stroke rate (SR) and displacement per stroke (DPS). However, previous study has not been reported these classical variables of junior paddlers. Therefore, the purpose of this study was to clarify the relationship between the V_{kayak} and stroke variables in the junior paddlers of the 200-m sprint kayaking. Methods We analyzed 52 junior male paddlers (Race time: 43.177 ± 2.044 sec). Also, subjects were divided into Good ($n = 12$, Race time: 40.486 ± 1.154 sec) and Poor ($n = 15$, Race time: 45.583 ± 1.116 sec) groups according to race time. The race movies were collected at the Japan Canoe Sprint Junior Championship in 2015 in Fujikawaguchiko-machi using three video cameras. During the competition, three parts of durations; 0-25m (Initial part), 100-125m (Middle part), and 175m-200m (Finish part) were selected for the analysis such as V_{kayak} . In each part, consecutive 6 stroke time was determined for the calculation of the SR. DPS was calculated by dividing the V_{kayak} at the SR. Pearson's correlation coefficients were used to examine the relationships between V_{kayak} , SR, and DPS in all subjects. Further, the two-way repeated ANOVA was performed to examine the effect of different groups and sections on V_{kayak} , SR, and DPS. A Bonferroni post hoc multiple comparison test was performed if a significant main effect was observed. In each statistical analysis, the level of significance was set to be $p < 0.05$. Results and Discussion A significant positive correlations were found between V_{kayak} and SR (Initial part: $r = 0.401$, $p < 0.01$, Middle part: $r = 0.733$, $p < 0.001$, Finish part: $r = 0.535$, $p < 0.001$). In addition, a significant positive correlation was found between V_{kayak} and DPS only at the Initial part ($r = 0.382$, $p < 0.001$). These results of the presents study agrees with past findings that SR was significantly related to kayak velocity in adult paddler due to the decrease water phase time [McDonnell et al. 2013]. V_{kayak} and SR of initial, middle, and finish was significantly higher in the good groups ($p < 0.01$, $p < 0.01$), however, DPS was did not differ between two groups. According to a previous study, SR of international adult paddlers was higher than in the national paddlers (Brown et al. 2011). Thus, these results suggest that the kayak performance time differences between good and poor paddlers can be maintain attributes to SR difference. Conclusions Key factor to improve the performance in the 200-m sprint kayaking should increase the stroke rate without loss of the displacement per stroke. Reference McDonnell L. K., Hume P. THE INFLUENCE OF DRAG IN THE EXTERNAL MECHANICAL WORK OF CROSS-COUNTRY SKIING

ZAMPARO, P., OBRELLI, A., MORO, S., MENGHINI, E., MONTE, A., NARDELLO, F.

University of Verona

Introduction Classical cross-country skiing (CSS) can be performed using three main techniques: diagonal stride (DS), double poling (DP), and double poling with kick (DK). In CSS, the mechanical external work (W_{ext}) was recently estimated by Pellegrini et al. (2014) in skiers while they roller skied on a treadmill at $14 \text{ km} \cdot \text{h}^{-1}$ (and a 2° slope) and found to be: 0.87, 0.70 and 0.79 $\text{J} \cdot \text{m}^{-1} \cdot \text{kg}^{-1}$ for DS, DP and DK, respectively. In that paper, external work was calculated based on the kinetic and potential energy changes of CoM at each stride and by taking into account the work done to overcome frictional forces; however, in that study, the effects of air resistance (drag) on W_{ext} was not investigated. The aim of this study was to estimate air resistance (at this slope and speed and in these three techniques) based on intra-cyclic measures of frontal area (as recently proposed by Gatta et al. 2015 in swimming). Methods Four cross-country skiers (3M/1F) were asked to roller ski at $14 \text{ km} \cdot \text{h}^{-1}$ (and a 2° slope) on a treadmill (H/P, Saturn 300/100r, Cosmos, Germany) using DS, DP and DK techniques. All trials were video-recorded with a camera (Elixim Casio, 100 Hz) positioned behind the skier. The ImageJ software was utilized to calculate frontal area (A) in five "positions" during the cycle (DS = left propulsive phase; rolling phase; right propulsive phase; rolling phase; left propulsive phase; DP = pole contact; pole propulsion; propulsive phase; rolling phase; pole contact; DK = pole contact and propulsion; left propulsive phase; rolling phase; right propulsive phase; pole contact). Drag force was calculated by means of the pressure drag equation: $F_d = \frac{1}{2} \cdot A \cdot C_d \cdot \rho \cdot v^2$; where $C_d = 1$, $\rho = 1.18$ and A = average frontal area. Results Average frontal area was 0.930 ± 0.056 , 0.987 ± 0.139 and $0.928 \pm 0.134 \text{ m}^2$ in DS, DP and DK, respectively. The intra-cyclic variations in A were 6.0 ± 3.8 , 12.5 ± 6.5 and $6.7 \pm 1.7\%$ in DS, DP and DK. F_d was 7.46 ± 0.45 , 7.93 ± 1.11 and $7.45 \pm 1.07 \text{ N}$ in DS, DP and DK, respectively. Discussion This is the first study (to our knowledge) that attempts to estimate drag resistance in CCS based on measured values of frontal area. The larger intra-cyclic variations were observed in DP (12.5%) whereas small differences were observed in the other two techniques (6-7%). In % of total external work ($W_{ext} + F_d$) air resistance was of about 9-14%, in all techniques. This indicates that F_d could not be neglected when external mechanical work is calculated in this form of locomotion. References Gatta G., Cortesi M., Fantozzi S., Zamparo P. (2015). Hum. Mov. Sci., 39, 41-54. Pellegrini B., Zoppirolli C., Bortolan L., Zamparo P., Schena F. (2014). J. Exp. Biol. 217 (21), 3910-3918.

Mini-Orals**MO-PM38 Training & Testing: HIIT****HALF-TIME RE-WARM UP WITH REPEATED BOUTS OF EXERCISE IMPROVES SUBSEQUENT INTERMITTENT EXERCISE PERFORMANCE IN FOOTBALL REFEREES**

YANAOKA, T., YAMAGAMI, J., HASEGAWA, M., KIDOKORO, T., KASHIWABARA, K., MIN, D.K., MIYASHITA, M.

Tokyo Gakugei University (Tokyo, Japan)

Introduction The previous review suggested that an active continuous half-time re-warm up is effective for attenuating the reduction of physical performance (Yiannis, 2014). In addition, the review suggested that more research is needed to investigate the effect of different frequencies of exercise during the half-time on subsequent physical performance (Yiannis, 2014). Moreover, there was no literature to investigate the effects of the re-warm up on blood metabolites including creatine kinase (CK), a marker of muscle damage. Therefore, the purpose of the present study was to examine the effects of a re-warm up with repeated bouts of running exercise (RWR) during the half-time period on subsequent intermittent exercise performance and blood metabolites. Methods Ten male referees (22 ± 1 years, $173.6 \pm 5.8 \text{ cm}$ and $67.2 \pm 6.4 \text{ kg}$) were required to complete two trials (i.e., Control (seated rest) and RWR) administered in a randomised counterbalanced order. The two trials consisted of the Loughborough Intermittent Shuttle Test (LIST), half-time and Yo-Yo Intermittent Recovery

Test level 1 (Yo-Yo test) periods. In the half-time period, participants either rested on the chair (Control) or RWR for 15 min. The RWR protocol consisted of repeating 2.15 min of a passive recovery, followed by 2.15 min of running at 70% of HRmax for 13 min. The re-warm up started 1 min after the start of the half-time period and ended 1 min before the start of the Yo-Yo test period. Yo-Yo test performance, plasma glucose, serum fatty acids (FFA), serum triglyceride (TG), blood lactate (BLa), plasma CK, the rating of perceived exertion (RPE), mean heart rate (HR) and maximal heart rate (HRmax) were analysed. Results For the distance covered during the Yo-Yo test, the RWR trial was higher than the control trial (3094.6 ± 102.9 vs 2904.4 ± 133.1 m, $p < 0.05$). Circulating concentrations of glucose, FFA, TG, BLa and CK did not differ between the RWR and control trials. RPE during the half-time period, but not after Yo-Yo test period, was higher than the control trial. Mean HR and HRmax during Yo-Yo test did not differ between the RWR and control trials. Discussion The present findings indicate that RWR improves subsequent intermittent exercise performance and do not affect blood metabolites response (i.e., circulating concentrations of glucose, FFA, TG and BLa). These findings suggested that energy substrates may not be a factor to improve subsequent intermittent exercise performance at least in our study. Moreover, the present study showed that RWR do not affect concentrations of CK.

EFFECT OF HIGH INTENSITY TRAINING AND ISOINERTIAL TRAINING ON MUSCLE FUNCTIONS IN OLDER ADULTS

BRUSEGHINI, P.1, TAM, E.1, CALABRIA, E.1, POGLIAGHI, S.1, CAPELLI, C.1,2

1: University of Verona (Verona, Italy); 2: NCSS (Oslo, Norway)

Introduction Maximal muscle strength is a strong predictor of functional skills and ability to maintain independent living in elderly. Muscle contraction properties has been shown to decline to a greater extent than muscle strength with aging and it has been considered the main responsible of the observed decline in functional status (Izquierdo et al., 1999). Endurance high intensity interval training (HIT), by involving large muscle groups, and eccentric strength exercise (IRT), by producing high mechanical loads, could be used in elderly to improve muscle function and quality of life (Milanović et al., 2015). Therefore, the aim of this study was to examine the changes in muscle properties in elderly after 8 wk of HIT and IRT. Methods 12 moderately active older adults (age: 69.4 ± 4.3 yr; BMI: 22.9 ± 2.7 kg/m²; V' O₂max: 29.5 ± 4.1 mL/kg/min) have completed 8 wk of: i) HIT, 7 two-minute cycling repetitions at 90% of V' O₂max, 3 times/wk, and, after 4 months, ii) IRT performed with an isoinertial leg press (YoYo TechnologyABI) comprised 4x7 maximal concentric-eccentric knee extensions, 3 times/wk. Maximum voluntary contraction (MVC) was measured using a cell load in a custom-made setup (90° knee flexion). Electrically evoked muscle single twitch was superimposed onto MVC: neuromuscular activation (NA) was calculated as the ratio between the amplitudes of the superimposed and resting twitches. Muscle volume of the quadriceps (Qvol) was obtained by MRI scans. Results MVC at 90° knee flexion, increase significantly only after IRT ($P < 0.01$). Both training modalities affected significantly NA ($P < 0.05$): +12.4% after HIT and +14.2 after IRT. Similarly, Qvol increase by 5.1% ($P < 0.05$) after HIT intervention and by 4.9% ($P < 0.05$) after IRT. **Discussion** Our results confirm the feasibility and effectiveness of HIT and IRT to improve muscle qualities: 8 wk of specific training are able to modify muscle mass, MVC and neuromuscular activation in elderly subjects. This stresses the importance of using effective approaches such as exercise treatment with high loads and high intensities in the prevention of disuse in elderly individuals who are currently exposed to the deleterious effects of aging on muscle contractile function and mass (Behrens et al., 2016). We can therefore speculate that the two proposed training modalities may be helpful in improving functional status and prevent frailty in elderly subjects. EFFECTS OF DIFFERENT RECOVERYS IN HIGH-INTENSITY INTERVAL TRAINING: METABOLIC AND PERFORMANCE RESPONSES.

LOPES, C., GERMANO, M.D., AOKI, M.S.

Universidade Metodista de Piracicaba e Faculdade Adventista de Hortolândia

Abstract The aim of this study was to investigate the acute responses of high-intensity interval training (HIT) with different times and types of recoveries in metabolic and performance parameters. Eight physically active subjects (28.0 ± 3.7 years, 75.0 ± 10.5 kg, $174.1 \text{ cm} \pm 3.7$, 49.5 ± 5.9 ml/kg-lmin-1) underwent four protocols in randomized HIT vVO₂máx separated by short passive recovery (PC-2min); long passive recovery (PL-8min); short active recovery (AC-2min) and long passive recovery (AL-8min). Were evaluated for each pause: performance of maximum effort, time limit (Tlim); and the removal of lactate during and after of exercise. ANOVA (1-way) with repeated measures correction factor was applied to compare the metabolic and performance parameters. Significant changes were found in performance between the two active PL and pauses ($P < 0.01$), and between the PC x AL ($P < 0.05$). Significant changes were found between PC Tlim x AC ($P < 0.05$), AL x PC ($P < 0.05$), PL x AC ($P < 0.01$) and PL x AL ($P < 0.01$), respectively. No significant changes were found in blood lactate during exercise in comparing any recovery's ($P > 0.05$). We conclude that the use of recovery PL promotes advantage over active, it allows improvement or maintenance of performance over the maximal efforts, greater Tlim and distance travelled. EFFECTS OF HIGH INTENSITY INTERVAL TRAINING ON BALANCE ABILITY AND RECOVERY TIME IN YOUNG ATHLETES

GULER, O., ERSÖZ, G., SAHİN, F.N., KARABIYIK, H., AKGÜL, M.

Ankara University

Introduction Specifically, high intensive interval training (HIIT) may induce fatigue, which is a natural physiological response. Fatigue decreases dynamic balance ability and subsequently may negatively affect technical performance such as passing, shooting and dribbling. These technical abilities are an important component of soccer players. Therefore the aim of this study was to investigate the effects of HIIT on single leg balance ability(SLBA) and alert time for return to the origin value in young athletes. **Methods** Twenty one soccer players (12 males, 9 females, age = 21.76 ± 3.09 years; wt = 64.5 ± 9.8 kg; ht = 169.4 ± 7.18 cm) with no history of lower extremity injury participated in this study. The Biodek SD balance system was used to determined to non-dominant athletic single-leg stability(ASLS). Monark cycle ergometer was used for high intensity anaerobic exercies. Each subject performed four maximal effort cycling on a electronically braked cycle ergometer against a resistance equivalent to 0.075kg/kg body mass for 30 seconds with a three-minute rest intervals. Subjects were verbally encouraged to continue pedalling as fast as possible throughout the each test. After four maximal cycling, subsequently subjects performed ASLS test and then repeated same test with a five-minute passive rest period for 4 times. **Results** The result of this study has indicated that, HIIT negatively effects SLBA. Furthermore SLBA turn to the baseline status after 5 minutes passive recovery

duration. Discussion The main finding was that HIIT had negative significant impact on SLBA. The finding of this study has similarities with result of previous studies(Toshimitsu et al 2011; Wilkins et al. 2004). However balance recovery time in our study was faster than previous studies(Toshimitsu et al 2011, Susco et al. 2004),these differences may explained by the better dynamic balance on the dominant leg of soccer players(Rosario et al. 2011). INFLUENCE OF HIGH INTENSITY INTERVAL TRAINING UNDER HYPOXIC COMPARED TO NORMOXIC CONDITIONS ON POWER OUTPUT DURING A SET OF TIME TRAILS

DE MARÉES, M., COHRS, J., PLATEN, P., MESTER, J.

Ruhr University Bochum, Germany

Introduction: In sports like cross country sprint events where athletes perform three to five time trails separated by 20 min breaks, the ability to regenerate is one key factor for athletes to compete successfully. The enhancing effect of high intensity interval training under hypoxic (HIIT) compared to normoxic conditions on repeated sprint ability was shown by Faiss et all (1). The questioned raised, whether HIIT under hypoxic conditions may even lead to superior results on repeated time trail ability. Methods: 10 endurance trained athletes were randomly divided into a hypoxic (HG FiO₂ 15%) and normoxic (NG FiO₂ 19.7%) group. They were blinded to the training conditions. Ahead (pre PT) and after (post PT) the training period performance tests were conducted on a cycle ergometer. Tests included a ramp test followed by three time trials (TT) of four min separated by a break of 20 min. HIIT consisted of two sessions per week for three weeks. Sessions included 10 min of low intensity cycling followed by n=12 (for the first four sessions) and n=14 (for the last two bouts) 15-sec all-out-sprints interjected by a break of 45 sec. Power output (PO), heart rate (HR) and lactate concentration (LC) were measured. Results: There were an increase for PO in post PT compared to pre PT for both groups detected. No significant differences were found for any of the analyzed parameters between HG and NG. 30% of the athletes estimated the conditions in which they trained wrong. Conclusion: Six trainings sessions of HIIT didn't lead to superior results compared to the same training regime under normoxia concerning power output, lactate blood concentration, and heart rate during a set of time trials. As we expected higher effects of hypoxic compared to normoxic training we hypothesize that hypoxic training load (two sessions per week for three weeks with a total hypoxic exposure time of 256 min), the delayed time of post PT (ten days after the last trainings session instead of five days according to Voigt et al (2) may have influenced PO development during the TT. Cardiovasc Dis.

SPRINT INTERVAL TRAINING INVOLVING EITHER THE ARMS OR LEGS ELEVATES WORK EFFICIENCY AND ANAEROBIC CAPACITY IN THE CASE OF THE ARMS ONLY

ZINNER, C.1,2, MORALES-ALAMO, D.3, LARSEN, F.J.4, SCHIFFER, T.A.5, BOUSHEL, R.6, ØRTENBLAD, N.2,7, CALBET, J.A.3, HOLMBERG, H.C.2,6,8

The present study was designed to characterize and compare the effects of SIT that engages both the arms and legs on the efficiency and anaerobic performance of the limbs. Methods Sixteen healthy, untrained men (23.9 ± 3.7 yrs; 183.8 ± 6.8 cm; 80.3 ± 14.1 kg (means \pm SD)) performed six sessions of 4-6 30-sec all-out sprints with the legs, then arms (or vice versa) separated by a 1-h recovery over an 11-day period. A 4-min submaximal work economy and anaerobic capacity tests (2 30-sec Wingate tests with 4 min of recovery between) were carried out and muscle biopsies (from the m. vastus lateralis and m. triceps brachii) taken before and after the training period. Results Prior to the training period, the gross efficiency of the legs was higher than that of the arms ($P < 0.05$) and training enhanced this parameter for the arms (~9%, $P < 0.05$), but not the legs. The accumulated VO₂ during the Wingate tests was higher for the legs than arms ($P < 0.05$) and was greater in both sets of limbs following training ($P < 0.05$), with more pronounced improvement in the arms (52 vs. 6%, $P < 0.001$). The O₂ deficit was unaffected by leg cycling, but fell 17% ($P < 0.001$) as a consequence of arm cycling, an effect observed even after taking lean mass into account and in connection with both the 1st and 2nd Wingate tests. Relative to the mean power and lean mass, this O₂ deficit was 4-5 fold greater for arm than leg cycling ($P < 0.001$). When the data for the arms and legs were combined, the proportion of MHC I correlated positively with both the accumulated VO₂ during the Wingate tests ($r = 0.57$, $P < 0.001$) and gross efficiency ($r = 0.60$, $P < 0.01$), while O₂ deficit showed a positive relationship to MHC II ($r = 0.28$, $P = 0.04$). Discussion The arms have higher anaerobic capacity, as reflected by the greater O₂ deficit per kg of lean mass. SIT involving either arm or leg cycling for 11 days increased the accumulated VO₂ in both cases, but enhanced gross efficiency only in the case of the arms. The improvement in performance in both extremities was mostly explained by improvements in aerobic energy system. These findings indicate differences in limb responsiveness to SIT. THE EFFECTS OF INTERMITTENT HEAVY RESISTANCE TRAINING IN HYPOXIA ON DYNAMIC AND STATIC STRENGTH AND ACID-BASE PARAMETERS

KIRMSE, M., SCHÄFER, R., OERTZEN-HAGEMANN, V., PLATEN, P.

Ruhr-University Bochum

Introduction: Intermittent hypoxic resistance training (IHRT) might lead to increase the number of metabolic products and the release of anabolic hormones compared to training under normoxia. This might lead to an increase in protein biosynthesis and, subsequently, strength. The aim of this study was to analyze the effects of a praxis-oriented multi-joint strength training program with a barbell in nor-

normobaric hypoxia compared to the same training protocol in normoxia. Methods: 23 male sport students (23.7 ± 2.9 y, 183.0 ± 7.0 cm, 78.1 ± 7.1 kg) were randomly assigned into a hypoxia (HG, $\text{FiO}_2=14\%$) and normoxia (NG, $\text{FiO}_2=21\%$) training group, with a training period of 9 weeks (65 min/session, 2 times/wk) including squat (SQ), bench press (BP), dead lift (DL) and bent over row (BR) exercises, in a single blinded manner. Maximal voluntary contraction for 5 s and 30 s (MVC5, MVC30) was tested in SQ and BP, and 1RM of SQ, BP, DL and BR were tested prior to and after the intervention, respectively. 4 weeks after completion of the study, 9 participants were randomly selected to perform 2 additional training sessions in a single blinded manner at 14% and 21% FiO_2 , respectively, to determine acute effects on blood lactate concentration and acid-base parameters. Results: Both training groups improved 1RM in SQ [HG: $\Delta 21.9 \pm 9.5$ kg, NG: $\Delta 21.6 \pm 13.9$ kg, $p \leq 0.001$], BP [HG: $\Delta 3.1 \pm 4.5$ kg, NG: $\Delta 4.8 \pm 7.2$ kg, $p \leq 0.01$], DL [HG: $\Delta 21.3 \pm 15.2$ kg, NG: $\Delta 35.5 \pm 21.7$ kg, $p \leq 0.001$], BR [HG: $\Delta 13.7 \pm 7.3$ kg, NG: $\Delta 20.8 \pm 10.8$ kg, $p \leq 0.001$], MVC [BPMVC5= HG: $\Delta 175.2 \pm 201.7$ N, NG: $\Delta 40.4 \pm 128.0$ N, $p \leq 0.01$; SQMVC30= HG: $\Delta 130.2 \pm 245.8$ N, NG: $\Delta 166.0 \pm 303.1$ N, $p \leq 0.05$; BPMVC30= HG: $\Delta 157.2 \pm 76.4$ N, NG: $\Delta 66.6 \pm 139.1$ N, $p \leq 0.001$], without any difference in any strength gain between groups ($p > 0.05$). pO_2 and sO_2 decreased significantly during training in HG but not in NG, while decline in pH, pCO_2 , and cHCO_3^- , and increase in blood lactate concentration did not differ between HG and NG. Discussion: The hypoxic multi-joint strength training protocol improved dynamic and static strength to the same amount as the same training regime under normoxia. The more pronounced decline in pO_2 and sO_2 under hypoxia indicated that hypoxia was effective, but comparable values of pH, pCO_2 , cHCO_3^- , and blood lactate clearly showed that some physiologic adaptation mechanisms like vasodilatation² were able to counter-measure tissue hypoxia under these conditions. In order to induce an additional metabolic stressor, hypoxic strength training should be performed under an even lower normobaric oxygen concentration than 14%. OPEN PUBLIC SPACE AND STRUCTURES OF PHYSICAL ACTIVITY ON NEIGHBOURHOOD ENVIRONMENT AND DAILY PHYSICAL ACTIVITY AMONG BRAZILIAN ADOLESCENTS

GAYA, A.R., DIAS, A., MELLO, J., MOTA, J., REIS, R., GAYA, A.

Proesp- Br. Department of Physical Education, Physiotherapy and Dance. Federal University of The South of Brazil

Introduction Combining the offer of public open spaces and the structures of physical activity (PA) on adequate neighborhoods environment may facilitate daily PA among adolescents and has been recognized an important strategy to promote PA (McCormack et al., 2010). The aim of this study was to identify associations between (1) existence of public spaces; (2) characteristics of structures for PA on public spaces; and (3) quality of the structures of public spaces with levels of daily PA among Brazilian adolescents. Methods This was a cross-sectional study comprised a school-based random sample of 176 adolescents (71 boys) recruited from 10 public schools from a city in Southern Brazil. Levels of daily PA was determined through average daily steps measured by a pedometer during three days. Adolescent's addresses were geocoded and public open spaces and structures for PA were assessed through direct observation using the Physical Activity Resource Assessment. A 500 meters linear radius from each adolescent household centroid was considered to determine individual buffers. The distance from each house to the closest public open space was calculated considering the street network connection. Structural equation modeling was used to verify the associations between variables of open space with levels of daily PA. Results The levels of daily PA of adolescents were approximately 11.590 steps per day. Only 47.2% of students have public spaces in the buffer. Existence of public spaces (β : 1899.03; p : 0.007), structures for PA (β : 2833.85; p : 0.03) and distance from the residence to the public space (β : -27.66; p : 0.001) showed association with levels of daily PA. Discussion There are just a few numbers of studies in Brazil aimed to understand the relationship between open public space and PA in adolescents (Reis et al., 2009; Lima et al., 2013). Our data analysed the relationship between daily PA and public open space by direct observation in a school-based random sample. The quality of PA structures in open public spaces did not showed association with levels of daily PA among adolescents. Nevertheless, our data showed the importance of an open public space near house with structures for PA to improving levels of daily PA and highlighted the importance of public strategies in Brazilian adolescents. DEVELOPMENT A OF SELF-ADJUSTING RESISTANCE BY ROTATING SPEED TO PHYSICAL FITNESS EQUIPMENTS FOR ELDERLY IN NEIGHBORHOOD PARKS

TAI, T.Y., WANG, Y.H.

Institute of Mechanical Engineering

The project combines continuously variable resistance mechanism, friendly environmental requirements and needs of senior citizens to develop the physical fitness recumbent cycle in neighborhood parks. The major mechanism consists of centrifugal rollers, drive pulley, driven pulley, and rubber belt. The position of rubber belt in the drive and driven pulley changes as pedaling speed varies. The process is mechanically controlled by the centrifugal force produced centrifugal rollers. No sensors and electricity is applied in this design. When centrifugal force is larger than the spring torque set up in the drive pulley, driven pulley will start to have axial displacement pushed by centrifugal rollers. This leads to the continuous variation of resistance transmission, and has effective muscle training. Further, active aging can be achieved by this physical fitness recumbent cycle. Since the gradually coming of the aging society, making elderly enjoy life through healthy promotion becomes more and more important. This project develops and establishes elderly physical fitness recumbent cycle in the neighborhood, where is easily accessed by the elderly in their daily life. Through exercises, bone and muscle system can be strengthened. Demands of the elderly based on different healthy condition can be provided by this continuously variable resistance mechanism. Meanwhile, the physical functions of elderly can be improved, and the cost of medical care will be reduced. Finally, high quality and longevity of life can be pursued through aging in place and active aging.

EFFECTS OF OUTDOOR ACTIVITIES ON ONE'S SENSE OF SPIRITUALITY.

KIJI, M., MITSUISHI, H., NIGORIKAWA, T.
RIKKYO UNIVERSITY

Introduction Many studies have shown that human's health and spirituality have close relations. Moreover, our previous study revealed that there would be certain relations between the habits of daily exercise and the tendency of spirituality. It was also shown that daily exercise might strengthen one's tendency of spirituality. On the other hand, several studies mentioned that staying in the natural field could enhance one's sense of spirituality. Therefore, in this study the hypothesis that outdoor activities in the natural field can strengthen one's tendency of spirituality more than competitive sports was proposed. The purpose of this study was to examine this hypothesis. **Methods** The subjects of the study consisted of 120 male and 22 female university students. They were divided into two groups: the natural field group (NFG n=49) and the competitive sports group (CSG n=93). The NFG consisted of students who belong to outdoor activity groups like a climbing club. And the CSG was made up of students who belong to competitive sports clubs like baseball or tennis clubs. The tendency toward spirituality was measured using The Japanese Youth Spirituality Rating Scale (JYS) and The Purpose In Life Test (PIL). The tendency toward spirituality was then compared between these two groups. **Results** The NFG showed higher scores of JYS than those of the CSG. However, there was no significant difference in PIL. There was no significant difference in the results between male and female. This might mean that the NFG has higher tendency of spirituality than the CSG. **Discussion** Our previous study suggested that there was a relationship between habits of daily exercise and the tendency of spirituality. In this study, it was examined what kind of activities could more efficiently enhance one's tendency of spirituality. As a result, it was revealed that outdoor activities could enhance one's tendency of spirituality more efficiently than ordinary competitive sports. Further investigation is demanded to clear what kind of mechanisms lead to this result.

THE RELATIONSHIP BETWEEN PHYSICAL DISCOMFORT AND COMPELLED WALKING IN JAPANESE CITY MARATHON RACES

MORI, H.1,2, NABEKURA, Y.3, YAMAMOTO, M.1

1)National Institute of Fitness and Sports in Kanoya, 2) Research Fellow of Japan Society for the Promotion of Science, 3)Tsukuba University
Introduction Many city marathoners wish to continue running until the finish line, which they often do by walking after 30 km during a marathon race. The factors influencing this phenomenon include running strategy and training volume (Mori et al. 2014, 2015). Moreover, it is known that this phenomenon may be accounted for by physical difficulties encountered during running, such as muscle and joint discomfort. However, it is unclear whether they relate to city marathoners becoming compelled to walk. The purpose of this study was to determine the relationship of physical discomfort and compelled walking for both men and women separately in Japanese city marathon races. **Methods** This study was undertaken at four popular city marathons held in Japan. A total of 1,410 runners (Men: n=1134, Women: n=276; Mean age, 38 ± 12 years; Height, 169 ± 7 cm; Weight, 61 ± 9 kg; Finish time, 4:18 ± 1:18; Monthly running distance, 154 ± 118km/month) who completed each race were surveyed. The survey questionnaire included queries on the finish time, age, body characteristics, training volume (monthly running distance), total number of marathon races participated in, whether the respondents were compelled to walk (i.e. did not drop out), and if discomfort was encountered during running. The reasons for compelled walking included muscle soreness (calf, anterior thigh and posterior thigh), joint discomfort (knee, low back, foot), as well as blister and foot soreness from wearing shoes during the race. **Results** Runners who were compelled to walk accounted for 46% and 52% of men and women respondents, respectively. Runners who were physically hindered accounted for 65% and 76% of men and women respondents, respectively as well. A higher percentage of female runners experienced joint discomfort (knee, low back, foot) compared to men. Calf soreness, anterior and posterior thigh soreness, knee, low back and foot joint discomfort were strong factors in relation to compelled walking for male runners. Calf soreness, anterior and posterior thigh soreness were significant factors in relation to compelled walking for female runners. **Discussion** Although muscle soreness (i.e. calf, anterior thigh and posterior thigh) was related to compelled walking during marathon races, joint discomfort (i.e. knee, low back, foot) was found to be a significant factor in relation to compelled walking for male runners only. Joint discomfort (in particular, the knee joint) is predominately affected by larger Q-angles. Anatomically, females have wider pelvic girdles, which can result in larger Q-angles compared to men. In fact, in the current study, a higher percentage of female runners experienced joint discomfort relative to their male counterparts. Therefore, regardless of whether female runners were compelled to walk, the majority experienced joint discomfort, which may therefore not have been a strong factor in relation to compelled walking. RESEARCH ON PROMOTION OF WINTER SPORT PARTICIPATION IN CHINA

WANG , Y.
China Sport Information Center

Research on Promotion of Winter Sport Participation in China Introduction In 2015, Beijing won the bid to host the 2022 Winter Olympics united with Zhangjiakou, which leads to massive surge of winter sport participants in China. Currently, Chinese Olympic Committee is implementing the "Encouraging 300 Million People to Participate in Winter Sport" program. Winter sport in China enjoys a long history but its base is relatively weak and the participants are limited to people from northern China. In order to achieve the target of bringing 300 million Chinese to winter sport, some further measures need to be adopted. **Methods** This paper tries to summarize and analyze the status quo of winter sport participation in China. On this basis, a few suggestions for further enhancing the participation level of winter sport in China have been proposed. The methods of literature research, expert interviews and comparative analysis are applied in this paper. **Results** Firstly, the southern and western regions in China should be attached more importance. The northeast region is the traditional base for winter sport in China. However, following the rapid economic and social development of the country, more and more people from the southern China especially the middle class are becoming skiing enthusiasts. Secondly, the construction of ice and snow infrastructure should be accelerated. The organizing committee has promised a frugal plan, with a total budget of slightly over 3 billion US dollars, split between games operation and infrastructure construction. 20 years ago, there were no more than 20 ski facilities in China, but now the number has exceeded 500. Thirdly, all aspects of social sectors should be admitted and guided to invest in the construction of winter sport facilities and operation of winter sport events. Fourthly, the role of various levels of winter sport associations should be given full play. **Discussion** With careful system design and appropriate promoting measures, we believe that the 2022 Winter Olympics will boost participation and involvement in winter sport across China. The fast development of winter sport may also change the

lifestyle of millions of Chinese and help them live a healthier and more enjoyable life. References Liu Xiaojian. DEVELOPMENT OF AN ALTERNATIVE SOLAR COLLECTOR USING PET BOTTLES FOR DRESSING ROOMS WATER HEATING OF THE OLYMPIC CENTRE AT UNB

MARTINS, L.G.1, SANTOS, L.B.2, RUSSOMANNO, T.G.3

Uniceub, UnB

Introduction In sports facilities, water is very important both for sports training and for the maintenance of athletes' personal hygiene. Seeking an alternative and clean energy source, this project aims to use PET (polyethylene terephthalate) bottles as alternative solar collectors utilizing the principle of heat transfer, in order to heat the water of the facilities to better serve their users. **Methods** The model consists of a system with collector grid composed of interconnected pipes and recycled absorption plates, both wrapped in PET bottles; this is aimed by driving the water to the storage container. As water moves through the pipes, the sun light heats the water in the grid that flows through it to the top of the tank, thus creating a convection current. Data collection will be based on periodic measurement, by using specific thermometers, of the incoming and outcome temperatures of the fluid collector grids, together with the water storage container and the environment temperature. It will be measured the time required to acquire the average temperature of the fluid mass in the heat tank, through a digital precision chronometer. **Results** It is expected that the prototype, with a daily intense sunlight of 6 to 8 hours, can achieve an average temperature of the water column in the tank about 45 degrees Celsius. With this result the solar collector using PET bottles can be used as an alternative way to heat water in sports venues. In our case, the prototype will be used in the dressing rooms for shower heating. **Discussion** Heating water with an alternative solar collector using PET bottles can be a cheaper and environment friendly solution for sports facilities and sports venues, depending on the climate conditions. We expected an energy consumption economy of 35% in our showers heating system. The system can also be used for swimming pools with bigger solar grids. **References** CAMILA, R.; DENISE, T.; ROCHA, P. G. Cenários para a Matriz Elétrica 2050. EFFECTS OF COMBINED BALANCE AND STRENGTHENING EXERCISES ON POSTACTIVATION POTENTIATION AND PERFORMANCE IN FEMALE YOUTH ATHLETES

PRIESKE, O.1, MAFFIULETTI, N.A.2, HELM, N.1, GRANACHER, U.1

1: University of Potsdam, 2: Schulthess Clinic Zurich

Introduction It is well-known that different conditioning activities can improve muscle contractile properties possibly inducing acute enhancements in proxies of athletic performance (Sale, 2002). Furthermore, balance training appears to have facilitating effects on subsequent strengthening exercises (Bruhn et al., 2006). Thus, the purpose of the present study was to examine the acute effects of a combined conditioning activity (i.e., balance and strength [B+S] vs. a single conditioning activity (i.e., strength only [S]) on twitch contractile properties, maximal voluntary strength, and jump performance in youth athletes. **Methods** Female elite youth soccer players (N=12, age: 14-15 yrs) were tested for electrically-evoked isometric twitches and maximal voluntary contraction (MVC) torque of the plantar flexor muscles. In addition, they completed countermovement jumps (CMJ) and drop jumps (DJ) in randomized order before and after two conditioning activities (B+S, S) and a resting control period. S included 3 series of 8-10 dynamic leg extensions at 80% of the one repetition maximum whereas B+S comprised 3 series of 40s double-leg stances on a balance board prior to leg extensions (same as S). Twitch peak torque, twitch rate of torque development, MVC torque, CMJ and DJ height as well as DJ contact time were assessed. **Results** Repeated measures ANOVA indicated significant effects of conditioning activities on twitch contractile properties ($p<.05$, $d=1.1$) and performance outputs ($p<.05$, $1.1\leq d\leq 1.2$). Post-hoc tests revealed that postactivation potentiation was larger by trend for twitch peak torque ($p=.07$, $d=1.8$) and significantly larger for twitch rate of torque development ($p<.05$, $d=2.4$) following S (33 and 55%) but not B+S (25 and 45%) when compared to control (21 and 42%). In contrast, CMJ height was significantly higher (3%, $p<.01$, $d=1.9$) and DJ contact time was significantly shorter (10%, $p<.01$, $d=2.0$) following B+S but not S compared to control. **Discussion** This study revealed acute improvements in twitch contractile properties following S and significant increases in jump performance following B+S only. Thus, it appears that postactivation potentiation effects in the triceps surae do not directly translate to improved jump performance in female youth soccer players. Muscle contractile properties appear to be affected by type and/or volume of the conditioning activities. Thus, it can be speculated that gains in jump performance following B+S are related to neuromuscular changes (e.g., intermuscular coordination) rather than improved contractile properties. **References** Sale DG (2002). BIOLOGICAL VARIATION AND DEVICE ERROR IN VERTICAL JUMP HEIGHT WITH TWO TYPES OF MEASUREMENT SYSTEM

LIPINSKA, P., PUERO, B., JIMÉNEZ-OLMEDO, J.M., PENICHET-TOMÁS, A., ŹMIJEWSKI, P., HOPKINS, W.G.

Institute of Sport - National Research Institute

Introduction Vertical-jump tests are used to evaluate lower-body power of athletes and non-athletes. The aim of this study was to compare two methodologies for such tests: the popular and convenient jump mat, and a criterion method, motion capture by video analysis. Methods Thirty-one young adult males (15 rowers and 19 non-athletes) alternated four countermovement jumps (CMJ) with four standing jumps (SJ). Jump height was measured with a commercially available jump mat and simultaneously by video. The modifying effects of foot length on the two measures of jump height were estimated with a mixed model, which also allowed separate estimation of errors arising from the subject and from the device. Effects were evaluated using standardization and non-clinical magnitude-based inference. Results Countermovement jump height was 34.4 ± 6.2 cm and 47.8 ± 6.8 cm for the jump mat and video respectively (mean \pm SD). Foot length had a clearly positive small effect on jump height for the video compared with the jump mat (1.8 ± 0.6 cm per 3 cm of foot length for CMJ, mean \pm 90% confidence limits; similar effect for SJ). Adjustment to zero foot length removed most of the difference in jump height between the methods, although the remaining difference was unclear. Within-subject variability for CMJ and SJ were both 1.5 cm (SD, 90% confidence limits ± 0.2 cm). Device errors with jump mat and video were similar for CMJ (SD 0.7 and 0.8 cm respectively), but less with the jump mat for SJ (SD 0.2 and 0.8 cm respectively). Discussion The substantial difference between jump height with the jump mat and video can be explained by the effect of foot length on the way flight time is recorded on the jump mat. Both methods contributed a similar substantial amount of error for countermovement jumps, but surprisingly, the jump mat had less error for standing jumps. We conclude that a jump mat provides trustworthy measurements for monitoring changes in jump height.

VALIDATION OF THE MICROSOFT KINECT™ FOR EVALUATING KNEE JOINT ANGLE IN SQUAT EXERCISE

DONGHI, F., ROSSI, A., BONFANTI, L., FORMENTI, D., ALBERTI, G.

Università degli Studi di Milano

Introduction Microsoft Kinect™ (MK) is a markerless, cheap and suitable technology that could be used to replace more complex video analysis instruments (Bonnechère et al., 2014). Due to high price and poor transportability of marker-based system, MK can be a useful instrument for sport scientists to analyse athletes' movement. Thus, the aim of this study was to investigate the concurrent validity of the MK compared to a low cost video analysis software such as Kinovea (Ki) in the measure of knee joint angles (KJA) during a slow squat motion. Methods Thirty-seven males took part in this study (28.29 ± 13.56 yrs, 75.05 ± 8.92 kg, and 180.37 ± 8.21 cm). Participants were asked to perform three repetitions of squat exercises at three different KJA (i.e., quarter squat (QS), half squat (HS), and full squat (FS)). The KJA was measured during the three squat exercises by MK using LabVIEW (National Instrument, USA) and Ki (V0.8.15). In order to detect differences and interaction among squat exercises and between MK and Ki, two-way ANOVA RM corrected for Greenhouse-Geisser adjustment was performed. The magnitude of the difference was evaluated by partial eta squared (part η^2). Pearson Correlation Coefficient (r) was computed to evaluate the relationship between MK and Ki in each squat exercise. The agreement of the two methods was assessed using a modified Bland-Altman analysis (B-A) corrected for repeated measurements. The systematic bias (mean absolute difference, calculated as Ki-KN) and limits of agreement [LOA (1.96 SD of the bias)] were calculated. Results The two-way ANOVA RM showed significant interaction among KJA in the squat exercises and between MK and Ki ($F(1.541, 55.528) = 16.053$, $p < 0.001$, part $\eta^2 = 0.308$). A significant correlation between MK and Ki was found in each squat exercise (QS: $r = 0.742$, $p < 0.001$; HS: $r = 0.714$, $p < 0.001$; FS: $r = 0.832$, $p < 0.001$). A systematic bias of 28.24 [8.04 - 48.45] degrees was detected by B-A. Discussion While the MK ability to track a human figure is acceptable for videogame, MK measurement accuracy is not acceptable for athletes' analysis (Pfister et al., 2014). The systematic bias found between KJA may be explained by different anatomical landmarks estimated by MK (i.e., anterior superior iliac crest) and used in Ki (i.e., greater trochanters) as affirmed by Schmitz et al. (2015) that compare the MK to a marker-based system. References Bonnechère B, Jansen B, Salvia P, Bouzahouene H, Omelina L, Moiseev F, ... Van Sint Jan S. (2014). Gait Posture, 39(1), 593–598. THE EVALUATION OF AUTOMATICALLY DETECTED ELECTROMYOGRAPHIC THRESHOLDS

ERTL, P.1, OVERGAARD, K.2, SØRENSEN, H.2, SCHAPPACHER-TILP, G.1, KAZIMIERSKI-HENTSCHEL, K.1, TILP, M.1

University of Graz

1: UG (Graz, Austria), 2: AU (Aarhus, Denmark) Introduction Electromyographic thresholds (EMGT) can provide individual muscle-specific feedback during incremental tests non-invasively. However, the determination of thresholds depends on signal processing methods [1] and often includes active as well as passive phases of movements, which might bias results. Therefore, the aim of this study was to compare visually and mathematically detected EMGT calculated from active movement phases only. Methods Seven trained triathletes performed an incremental test on a cycle-ergometer. The respiratory compensation point (RCP) was determined using the VE versus VCO₂ relationship [2]. EMG signal was measured continuously (3000 Hz) from vastus lat. (VL) and rectus fem. (RF) of both legs. In a computer-aided, semi-automatic step the activity intervals were registered manually and were used to assess the noise level. In a second step, the data were segmented into signal and pure-noise parts, followed by stabilizing the noise-signal-indicator [3]. Subsequently, several EMG parameters (integrated RMS, maxRMS, mean frequency) were calculated and time courses analyzed by 2 blinded peers to detect thresholds visually (EMGTv). Furthermore, EMG parameters were automatically fitted by minimizing the overall mean square error of three regression lines. A break between the second and third line was interpreted as the EMG threshold (EMGta). Comparison of the methods was conducted by a repeated measures ANOVA and Pearson's correlation coefficients. Results Although several parameters showed a similar behavior, the integrated RMS appeared to be the most consistent signal to detect EMGT visually (EMGTv:100%). No significant difference was found between EMGTv, EMGta and RCP ($p > 0.05$) for both RF, and left VL. EMGTv and EMGta did not differ significantly for right VL, but both were significantly different from RCP ($p < 0.05$). Medium to high correlations were found between EMG thresholds and RCP ($r = 0.62$ - 0.98). Discussion The main outcome of this study was that muscular thresholds could be detected visually and automatically from the integrated RMS of active phases of the EMG signal in RF and VL during incremental tests. Comparisons to ventilatory thresholds revealed better agreement in RF than in VL. This could be explained by heterogeneity in muscle recruitment during incremental tests [4]. AN OBSERVATIONAL STUDY OF STROKE SYNCHRONISATION IN CREW-BOAT SPRINT KAYAKING

TAY, C.S., KONG, P.W.

Nanyang Technological University

Introduction The four-seater K4 is the largest crew-boat in Olympic sprint kayaking. Four paddlers work in unison to propel their boat over distances of 200-, 500- or 1000-m in the shortest time. The role of stroke synchronisation in successful crew-boat performance has been debated; some think that perfect synchronisation is essential (e.g. Wing and Woodburn, 1995), while others think a slight asynchronicity in the blade movement is important (de Brouwer et al., 2013). The aim of this study was to identify the extent of stroke synchronisation for a K4 200-m crew. Methods High-speed (120 Hz) video of a men's K4 200-m crew from a national team was recorded from the sagittal view during a selection timetrial. Video analysis was performed to identify the stroke positions (catch, immersion, extraction and release) of each paddler in the K4, based on McDonnell and colleagues' model (2012). An offset variable, defined as the timing difference between a paddler compared to the first-seat paddler, was obtained for each paddler. The offset was interpreted as either negative, zero, or positive e.g. a negative offset occurs when the back paddler catches before the 1st seat paddler. For all offset variables, mean and 95% CI was calculated. Results The performance timing was 31.87 s. A total of 41 strokes (excluding the first 3 acceleration strokes) were analysed. The mean absolute offset was 90 [79, 100] ms. At the specific stroke positions, the values were: catch 89 [79, 94] ms, immersion 71 [65, 78] ms, extraction 104 [90, 119] ms and release 96 [86, 107] ms. By paddler position, the offsets were: 2nd seat 39 [34, 45] ms, 3rd seat 4 [-1, 9] ms and 4th seat 16 [8, 24] ms. Discussion The results show a tendency for positive-offset synchronisation patterns for the crew, where the 2nd, 3rd, and 4th seat paddlers are slower than the 1st seat paddler. The crew was more synchronised at the immersion position, and least synchronised at the release position. This adds a new perspective to the crew-boat stroke synchronisation theories, that perhaps it is important to be synchronised at one part of the stroke but slightly asynchronised at the other positions. Interestingly, it was the 2nd seat paddler that was most out-of-sync to the 1st seat paddler despite being the closest and having the best view to follow the 1st seat paddler's movements. This highlights the need for future studies to uncover the mechanisms of how synchronisation is achieved. Besides Olympic sprint kayaking, such information would also be useful for other similar sports with crew-boat racing like rowing and dragon boat racing. KNEE MUSCLE TENDON COMPLEX FORCES RATIO DURING SQUATTING

DJORDJEVIĆ, S.1, BERDAJS, M.1, MODIC, Z.1, GERBEC CUCEK, M.1, STANCIN, S.2, SODNIK, J.2, TOMAZIC, S.2

1: TMG-BMC Ltd. (Ljubljana, Slovenia), 2: University of Ljubljana, Faculty of Electrical Engineering (Ljubljana, Slovenia)

Introduction Squatting is one of the most frequently used exercise for strength development. Involvement of different knee muscles in force/torque participation depending on movement pattern and knee angle is point of interest of sport scientists and coaches. Two phenomena influence on the knee muscle tension during squatting: knee angle (lengthening and shortening of the vastus medialis (VM) and vastus lateralis (VL)) and muscles contraction. Using MC sensor (TMG-BMC Ltd.) for muscle and tendon tension measurement we try to find relationship between knee torque and VM and VL and knee torque and tension in patellar tendon. The MC sensor [1, 2] is a wearable ($m < 1.5$ g) sensor that measures muscle and tendon tension/force. The aim of our study was to find angle dependent relationship between directly measured muscle tension on vastus lateralis, vastus medialis and knee torque during controlled squatting as well as relationship between directly measured patellar tendon and knee torque. Methods Thirteen international level athletes (eight male and five female, age 20-31) were measured during squatting. Tension forces of VM, VL and patellar tendon were measured with the MC sensor with 1 kHz sampling rate. Athlete's movements were captured with accelerometer for knee angle detection. To standardize motion as much as possible, the Smith machine was used. Results We calculated knee torque divided by each muscle tension – knee torque divided by MC(VM), knee torque divided by MC(VL) and knee torque divided by summation of MC (VM) and MC (VL). The maximum of ratio between torque and MC (VL) was when the movement was upward – at the angle 20 degrees. The maximum of torque divided by MC (VL) was at 20 degrees also, but when the movement was downward. The ratio between patellar tendon tension and knee torque was linear. The coefficient of determination (R squared) was 0.98. Discussion The basic idea was to try to determine the tension of individual muscles and tendons at different knee torque during defined squatting movement. We found very different tension relationship comparing tension of VL and VM with knee torque and patellar tendon tension- especially comparing eccentric and concentric part of muscle contraction (down and up phase of squatting). The peak of the quotient between knee torque and VM or VL tension have different knee angle dependencies as well. Additional research on knee muscle/tendon mechanics will be necessary for understanding load distribution during different squatting movement. References [1] S. OFFICIAL MATCH BALL DIFFERENCES: WHAT PLAYERS RECOGNIZE

SCHAEFKE, H.1, KRATZENSTEIN, S.1, KOERGER, H.2

1. Christian-Albrechts-University of Kiel, 2. adidas AG

Introduction Football equipment has increasingly become a subject of scientific research. While official match balls (OMB) are evaluated intensely through mechanical testing, less new findings consider the actual football players' perception. This comparative benchmark study investigated subjective player perception of three OMBs by examining ratings of specific ball criteria and its correlation with playing surfaces and player positions. Methods Three certified FIFA match balls (Nike Ordem 2 Hi-Vis, adidas torfabrik & Derbystar Brillant APS) have been tested. Prior to testing, crucial ball criteria were identified through guideline-based interviews with eight experienced players. Consecutively, 82 players (23.4 ± 3.0 years; 3rd - 5th German league) took part in the core study. Balls were tested in randomized order. Participants performed a supervised, standardized test trial and three respective team training sessions. Perception was quantified by completing a questionnaire, which aimed at player-ball interface and general influence factors, likewise. Ranking was conducted according to a 10-point Likert scale. Reproducibility of test design was assessed through repeated measures. Results The preceding interview yielded 8 major characteristics such as flight behavior, energy transmission and grip. Players perceived significant differences between the balls for energy return, grip, design, roundness, visibility and size. Intra class correlation coefficient of repeated measures confirmed excellent reproducibility ($r > 0.9$). The players' position correlated with most perception criteria. No statistical evidence was

found between natural and artificial ground conditions concerning overall ball ratings. Discussion Identified perception criteria confirmed and expanded findings by Roberts et al. (2009). While mechanical tests can explain the interrelationships of e.g. panel number and ball aerodynamics (Asai and Seo, 2013), these test fail to quantify the desirability of ball characteristics (i.e. grip and flight behavior) in relation to players' position. In this study, participants were able to differentiate between individual characteristics of OMBs. Thus, this work presents a reliable approach to quantify players' perceptions. It is suggested that the quantification of subjective player perception can highly contribute to the understanding and evaluation of specific design criteria and the process of development. ACCURACY OF NINE ACTIVITY TRACKERS FOR THE MEASUREMENT OF STEPS, ENERGY EXPENDITURE AND DISTANCE

KILIAN, Y., DROSZEZ, A., MESTER, J.

German Sport University Cologne

Introduction In the last ten years there was an increasing development of wearables and activity trackers. Besides the use by the general population for activity tracking, wearables might also be beneficial for (elite) athletes to monitor their training load and their physical activity during leisure time. Currently, the training load even in elite sports is often not determined or only assessed by the measurement of heart rate or by asking the perceived physical strain after training sessions (Düking et al. 2016). Physical activity during leisure time is usually not determined. For the general use, but especially for the use in elite sports, these activity trackers need to measure accurate and valid. Especially for elite athletes accuracy needs to be given for a broad spectrum of velocities or even fast changes in velocities. Therefore, the aim was to evaluate the validity of eleven activity trackers for measuring step counts, energy expenditure and distance under laboratory conditions with different constant and varying velocities. Method Twenty healthy sport students (10 men, 10 women; mean age: 25.2 ± 2.7 years; height: 175.3 ± 9.4 cm; weight: 70.6 ± 13.3 kg) performed a running protocol consisting of four 5 min stages of different constant velocities (4.3; 7.2; 10.1; 13.0 kmh⁻¹) and a 10 min period of intermittent velocity while wearing nine different activity trackers (Beurer AS 80, Fitbit Charge, Fitbit Charge HR, Garmin Vivoactive, Garmin Vivofit, Garmin Vivosmart, Polar Loop, Sensewear Bodymedia, Withings Puls Ox). Energy expenditure, steps and distance were evaluated by comparing each activity tracker with a reference method (indirect calorimetry, Optogait system, treadmill). Results Steps differed significantly for the Sensewear, Polar and Beurer for all velocities, and for the Fitbit Charge for 4.3 and 13.0 km/h and for Withings for 13.0 km/h and the intermittent protocol. All trackers showed significantly different distances at 4.3 km/h, 7.2 km/h and 10.1 km/h. At 13.0 km/h only Withings and for the intermittent protocol Garmin Vivofit showed good agreement. Although not for every single velocity the Garmin devices (-Vivofit, -Vivosmart, - Vivoactive) and the Fitbit charge showed the best agreements. Conclusion Of all three determined parameters, the number of steps is the most valid measure over all velocities. Three devices measured steps accurately over all velocities. Furthermore, only three devices showed an accurate measure of energy expenditure in 3 of 5 velocities. The measurement of distance is inaccurate for all devices over all velocities. Due to these limitations, activity trackers cannot be used for the quantification of training load in elite sports. References Düking P et al. (2016). Front Physiol. Contact: Y.Kilian@dshs-koeln.de

MO-BN08 Balance & Posture

THE LEVEL OF BODY BALANCE IN A HANDSTAND AND THE EFFECTIVENESS OF SPORTS TRAINING IN GYMNASTICS

KOCHANOWICZ, A.1, KOCHANOWICZ, K.1, NIESPODZIŃSKI, B.2, MIESZKOWSKI, J.2, BISKUP, L.3

1: Gdańsk University of Physical Education and Sport (Gdańsk, Poland), 2: Kazimierz Wielki University (Bydgoszcz, Poland), 3: University of Physical Education in Krakow, (Krakow, Poland)

Introduction The aim of the study was to determine the level of maintaining body balance in a handstand among gymnasts at the stage of directed and championship training and to prove a relationship with the sports result, taking into account the difficulty and the quality of exercises. Methods The study involved boys aged 11-12 years systematically training gymnastics ($n = 20$) and 12 experienced gymnasts aged 18-26 years with an accomplished international class ($n = 12$). The study was conducted prior to the apparatus trial, on the day preceding competition in an official sports tournament. The 10-sec measurements of the body balance in a handstand was performed on an AccuGait force plate. The assessment of the effectiveness of sports training was made on the basis of judges' scores protocols from official sports competitions. Results An analysis of the tests showed significant differences in the level of maintaining the body balance in a handstand. The largest one was reported in mean values of Area 95, whose field in experienced athletes was less than half the size (8.16 ± 8.06 cm²) of the younger group (19.81 ± 8.74 cm²). In both groups, Area 95 showed to be significantly ($p < 0.05$) correlated with sport results, although younger group had higher correlation with the quality ($r = -0.538$) while the adults with the difficulty ($r = -0.755$) of the exercises. Discussion In contrast with other authors' analyses, the present research on body balance in a inverted stance has shown significant differences between experienced and inexperienced gymnasts (Vuillerme et al., 2001; Asseman et al., 2005; Gautier et al., 2009). Attention is also drawn to much higher results of body balance in the medio-lateral axis rather than the antero-posterior one in both groups. This data may confirm the importance of the mobility of wrist and shoulder joints in the sagittal plane in a strategy to maintain body balance in a handstand (Kerwin et al., 2001). Conclusion Analysis of correlations of body balance in a handstand with the level of sports preparation has helped demonstrate that the level of this skill specific to artistic gymnastics improves throughout sport experience and has great significance in developing elite athletes. ADJUSTED CUSHION SHOE CAN CORRECT FOOT POSTURE BUT NOT ALTER POSTURAL CONTROL OF UPRIGHT STANDING IN PEOPLE WITH FLEXIBLE FLATFOOT

YANG, C.H., CHANG, Y.A., HUANG, J.S., CHUANG, Y., CHENG, I.C.

College of Medicine, Tzu-Chi University

Clinically, flat foot is characteristic of lower medial longitudinal arch and heel pronated, which consists of flexible and congenital flat foot. Adjusted cushion shoe can provide an additional support for medial arch with inserted plates to improve the alignment of bone structure in medial side of the foot. We hypothesized that this intervention may significantly improve the alignment of foot to improve postural control of upright standing in recreational athletes with flexible flatfoot. A total of 24 subjects (12 with flexible flat foot and 12 health controls with age- and gender-match) were participated in this study based on the inclusion and exclusion criteria. A motion analysis system and forceplate was used to collect forceplate data during upright quiet standing. The findings have shown that significant improvement in the alignment of foot bone at all plates inserted on the medial side. However, no significant change was found in the variables of center of pressure (CoP) trajectory, indicating no increase in postural control in people with flexible flat foot with adjusted cushion shoe. Changes in foot posture with foot orthotics (for example, adjusted cushion shoe) may not immediately lead to improved postural control of quiet upright standing in people with flexible flatfoot.

EYE MOVEMENTS AFFECT POSTURAL CONTROL IN YOUNG AND OLDER FEMALES

THOMAS, N.M., BAMPOURAS, T.M., DONOVAN, T., DEWHURST, S.

University of Cumbria

Introduction: Eye movements have been shown to affect postural control in young adults (Laurens et al., 2010). However, this has received little attention in older individuals, which is surprising given the prevalence of eye movements in everyday life, the link to postural control, and the high incidence of falls in the elderly. Here we assessed the effects of eye movements on postural control in young and older females. **Methods:** 12 young (mean \pm SD: 26.1 \pm 4.9 years) and 12 older (72.8 \pm 6.9 years) females without visual, vestibular or balance deficits, were presented with 10 visual scenes containing combinations of a) stimuli to initiate stationary gaze fixations, smooth pursuits and saccadic eye movements, and b) absent, fixed and oscillating large-field visual backgrounds to diminish or generate retinal flow. Postural sway and gaze errors were simultaneously assessed with a force platform (AMTI AccuPower) and eye tracking equipment (Tobii Glasses 2), and compared within scenes and between age groups. Hedges g effect sizes were calculated for significant differences. **Results:** Within scene comparisons showed fixed backgrounds and stationary gaze fixations attenuated postural sway ($p<0.001$, $gav=0.96$, 27.18%; $p=0.032$, $gav=0.40$, 12.75%, respectively). In contrast, smooth pursuits and oscillating backgrounds increased postural sway ($p<0.001$, $gav=0.95$, 30.36%; $p<0.001$, $gav=1.46$, 48.20%, respectively). There were no differences regarding saccades. Between age group comparisons showed no differences in postural sway or gaze errors in any visual condition. **Discussion:** The stabilising effect of the fixed visual stimuli show how retinal flow and extraocular factors guide postural adjustments (Guerraz and Bronstein, 2008). The destabilising effect of oscillating backgrounds and smooth pursuits may be related to challenging conditions for sensing body shifts from retinal flow, and more complex extraocular signals, respectively. Because extraocular factors are used for postural control, discerning the contribution of retinal and extraocular components in elders at high fall risk might be an important step in understanding postural stabilisation strategies and developing fall prevention interventions. Moreover, since smooth pursuits increased postural sway, stability whilst tracking moving targets may also be affected during locomotion, which could place older individuals, typically less able to correct postural disturbances, at a greater risk of falls. However, the present results suggest declines in posture and gaze control, during quiet stance, may not be a direct consequence of healthy ageing. **References:** Guerraz M, and Bronstein A. THE EFFECT OF FORWARD-BENT POSTURE OF UPPER BODY IN ACCELERATION PHASE ON 100M SPRINT PERFORMANCE

ADACHI, T., YASUE, M., FUKUDA, T., UEDA, T.

Hiroshima University

Introduction The technique called forward-bent posture is used in the acceleration phase of the 100m sprint running. The performance was influenced because of maintaining forward-bent posture of different distances (Ito, 2010). In this study, there were two purposes. First, to determine whether subjects can carry out accelerating with longer and shorter distance. Second, to reveal the influence of the running velocity (RV), the stride length (SL) and the stride frequency (SF) from the point of view of motion and electromyogram (EMG) of the lower extremities. **Methods** Nine collegiate sprinters run 100m sprint by using three patterns of acceleration patterns. First acceleration pattern was the usual method of raising forward-bent posture which was used in the daily training. Second and third acceleration pattern was the longer and shorter method than the usual method of raising forward-bent posture, respectively. The forward angle of every 10m in 0-40m interval were calculated. Subsequently, six collegiate sprinters run 100m sprint by using three types of acceleration patterns. RV, SL and SF were calculated. In addition, the hip, knee and ankle joints angle of 0-40m interval and EMG of gluteus maximus, rectus femoris, biceps femoris and gastrocnemius of 0-100m interval were measured. **Results** It was thought that subjects could carry out accelerating by longer and shorter. In the RV of 0-100m, the value of the longer raising method was significantly higher than that of the shorter raising one. In the SL of 0-30m, 0-40m, 0-50m, 0-60m, 0-70m and 0-90m, the value of the longer raising method was significantly higher than that of the shorter one. **Discussion** It was estimated that what the knee and ankle angle increased was caused to the reduction of the force to kick the ground because of the kick the ground with a higher center of gravity in the contact phase (Iwai, 1997). In the angle of the knee and ankle joints at the 15m and the 35m points in this phase, the value of the shorter raising method was significantly higher than the other two methods. This was likely to be shorter the stride during running. It was reported that there were the changes, and no changes in relation to muscle activity with the different joint angle of the lower limb (Ema, 2010). By comparing this, the differences in running velocity could not be explained from the amount of muscle discharge of lower limb. However, in this study, the ratio of each muscle activity might be changed among three different methods during accelerating. **References** Ito H, Ito A. (2010). THE EFFECT OF START POSTURE AND STEPPING RATE ON THE PULLING PERFORMANCE OF INDOOR TUG OF WAR

SYU, J.Y.1, CHEN, H.H.2, LIU, Y.T.1

1: NTNU (Taipei, Taiwan), 2: NTTU (Taitung, Taiwan)

Introduction Maintaining a high, steady pulling force while stepping backward is an important technique in indoor tug of war. Literature shows that a low start posture for stepping backward produces a higher pulling force (Guo, 2001). Furthermore, step rate and step size also play important roles in producing high pulling force (Lin, 2000). However, there has been little information about the performance variability of the backward stepping technique in indoor tug of war research. The purpose of the study was to examine the effect of starting posture and the stepping rate on the overall pulling performance of backward stepping in indoor tug of war. Methods 8 elite high school male indoor tug of war athletes volunteered for the study. The MLP-300 (Transducer Techniques) load cell, BIOPAC MP150, and AcqKnowledge 3.9 data processing systems were used for collecting force data, and a JVC camera and the Kwon3D 3.1 system were used for capturing kinematics of left shoulder, hip, knee, and ankle. All the participants performed 3 (low, middle, high posture) x 3 (2 Hz, 1 Hz, 0.5 Hz step rate) trials of pulling with stepping backward. Each trial took 30s, and 3min rests between trials. 2 way repeated measure ANOVAs were performed on the means and SDs of peak pulling force (PPF), step duration, and step length. Results Both main effects were significant on PPF. PPF increased from the high starting posture to the low one, and the 2 Hz rate had the lowest PPF. For the variability of the PPF within a trial, the low starting posture was also higher than the other 2 postures. There was a significant effect of the stepping rate for the step duration, which was a direct consequence from the experimental manipulation. In addition, the significant interaction effect between the starting posture and the stepping rate showed that under the high start posture, the variability of the step duration increased along the decreasing stepping rate, and the high start posture had a higher variability of the step duration than the low posture only at the low stepping rate condition. Discussion The findings of the study, the low starting posture had the highest PPF and the high stepping rate produced low PPF, were consistent with the literature. However, the high variability of the PPF observed in the low starting posture has not been previously reported. Moreover, the analysis of the variability of the step duration indicated that the low step rate tends to have increased variability. The variable step duration may disrupt the in-sync rhythm of the backward step in the team, and the variable PPF may provide an opportunity for the opponent to attack. We suggest that the low starting posture along with the medium (1 Hz) step rate may be the optimal combination for executing backward steps; however, additional training should be focused on reducing the peak force variability when taking the low posture. BIOMECHANICAL ANALYSIS OF A WEARABLE SUPPORT DEVICE FOR OVERHEAD WORK

BERGER, C.1, ARGUBI-WOLLESEN, A.1, WEIDNER, R.1

Helmut-Schmidt-Universität Hamburg

Introduction There is a broad agreement that e.g. in aircraft assembly overhead work with forceful movements is one risk factor for musculoskeletal disorders (MSD) of the upper extremity (Rhode, 2015). At the HSU two wearable support devices were engineered specifically to support overhead work. The aim of this study is to assess the systems effects on reducing exposure on movement-involved muscles for the upper extremity and the lower back while working. Methods 24 participants completed an overhead task using a power drill (load 1,5kg) without (baseline) and with the two exoskeletons A and B. 3D motion-analysis (Vicon) examined full body movements. EMG signals were obtained from eight muscles (e.g. biceps brachii, trapezius, deltoid). Statistical analysis for curve data of the shoulder angles was performed using confidence bands for the difference between the means based on the bootstrap method (Duhamel et al. 2004) using matlab. Repeated measures ANOVAs using SPSS were used to examine the differences in EMG parameters and elevation angle of the shoulder girdle. Results Both exoskeletons decreased muscle activity significantly. For exoskeleton A: biceps 1,6%MVC*sec ($F=14.2$; $p<.001$; $\eta^2=.381$), forearm extensors 8,6%MVC*sec ($F=12.4$; $p<.001$; $\eta^2=.350$) and infraspinatus 9,7%MVC*sec ($F=5.5$; $p=.037$; $\eta^2=.152$), for exoskeleton B: trapezius 12%MVC*sec ($F=4.1$; $p=.022$; $\eta^2=.153$), deltoid 6,3%MVC*sec ($F=20.7$; $p<.001$; $\eta^2=.474$) and triceps 3,8%MVC*sec ($F=5.8$; $p=.006$; $\eta^2=.202$). No significant differences were found for lower back muscle. Both exoskeletons (A/B) showed significant differences for shoulder mobility compared to baseline for the following parameters: abduction: 0-18%/0-15% and 82-100%/85-100%, internal rotation 0-10%/0-5% and 91-100%/96-100%, flexion 0-13% and 79-100% for A and 14-26% of the movement cycle for B. Exoskeleton B showed an increased elevation angle of the shoulder girdle of 4,9° ($F=5.9$; $p=.005$; $\eta^2=.204$). Conclusion Although both support systems restrict shoulder mobility, positive effects of reducing muscle activity were found for overhead work. Especially system B relieved muscles close to the shoulder joint. Therefore, we conclude that wearing the support systems can minimize risk factors for MSD. However, with regard to multifactorial pathways of MSD additional parameters e.g. EMG frequency analysis of muscle fatigue or additional body segments should be further examined. Moreover, ongoing evaluation and adaptions of the systems for the practical use are necessary. Reference Rhode, B. A. (2015). MOJ Orthopedics & Rheumatology, 3(4), 4-11 Duhamel, A., Bourriez, J. UPPER BODY ACCELERATIONS DURING GAIT TERMINATION IN YOUNG AND OLDER WOMEN

RUM, L., LAUDANI, L., MACALUSO, A., VANNOZZI, G.

University of Rome Foro Italico

INTRODUCTION Transitory tasks, such as gait termination, involve interactions between neural and biomechanical factors that can challenge postural stability and head stabilisation patterns in older adults (Tirosh et al., 2005). The aim of the study was to compare upper body patterns of acceleration during planned gait termination at different speeds between young and older women. **METHODS** Ten young and 10 older women were asked to carry out three gait termination trials at slow, comfortable and fast speed. A stereophotogrammetric system (VICON, UK) was used to measure whole body 3D kinematics. RMS of head, trunk and pelvis acceleration were calculated in antero-posterior (AP), medio-lateral (ML) and vertical (VT) directions. AP and ML RMS were normalised by VT RMS to remove the influence of gait speed. Transmission of acceleration was expressed as a percentage difference in RMS from lower to upper body segments (Mazzà et al., 2008). Differences between groups were tested using independent t-test and Mann-Whitney U test ($\alpha=0.05$). **RESULTS** Older women walked slower at each speed and approached the stopping position with lower AP and ML RMS than young women. After removing the influence of gait speed, however, older women showed higher AP and ML normalised RMS than young women. During the last step, pelvis-to-trunk attenuation of RMS accelerations was lower in older compared to young women along AP direction (-2% and 14% at slow speed, 0% and 10% at comfortable speed, respectively; $p<0.05$) and ML direction (0% and 38% at com-

fortable speed, 0% and 41% at fast speed, respectively; $p<0.05$). No significant between-group differences were observed in trunk-to-head attenuation coefficients. DISCUSSION Older women adopted the so called "slowness strategy" likely to improve their stability and reduce the risk of falling. However, when the influence of gait speed was removed, older women showed higher accelerations of upper body segments, which reflect a greater instability with respect to young women. The lower attenuation of acceleration from pelvis to trunk may be ascribed to the fact that: i) older women do not have to reduce acceleration as young women; ii) trunk rigidity in older women reduces their ability of attenuating these accelerations. Therefore, trunk appears to play a major role in the head stabilisation process, which should be taken into account in designing training interventions aimed at preventing falls in older individuals. MO-PM17 Fatigue

SIDE-TO-SIDE DIFFERENCES IN KNEE EXTENSOR STRENGTH AND FATIGUE

AHTIAINEN, J.P., PELTONEN, H.

University of Jyväskylä

Introduction Differential loading patterns during sports training may exacerbate strength imbalances between the lower limbs that may predispose to lower extremity injuries (Rosene et al. 2010). The aim of the present study was to compare maximal power and isometric strength tests in determination of asymmetry in knee extensors; secondly, to study whether the strength differences can be explained by muscle size or neural activity; and third, to study the effects of acute loading on knee extensors strength balance. Methods Team sport athletes (men, n=11, women, n=4; 24 ± 2 yrs.) volunteers for the study. Subjects had no history of lower extremity injuries during the past two years. The maximal power (POW) of knee extensors was determined unilaterally by pneumatic loading device (Hur 3350, Hur Ltd, Finland). Maximal isometric torque (ISO) was measured by dynamometer. EMG activity of m.vastus lateralis (VL) was determined during the strength tests. Thickness of VL was determined by ultrasound. Strength tests were performed before and after acute loading protocol of a 10 repetition maximum set in Hur device followed by approximately 5 min circuit exercise of bench stepping, lunge squats, and vertical jumps. Results Side-to-side knee extensor strength differences did not correlate between POW and ISO tests, and laterality were not related to EMG activity or muscle size. The loading led to decreases bilaterally in POW (-5 ± 20 %, ns.) and ISO (-19 ± 9 %, $p < 0.001$). Acute loading decreased difference between stronger and weaker limb from 8.7 ± 7.7 % to 0.8 ± 14.2 % ($p < 0.05$) in POW but similar change was not observed in ISO. The loading-induced changes in EMG activity were not associated with changes in muscle strength. Discussion Athlete's performance detriments (Hart et al. 2014) and risks for lower extremity injuries (Keeley et al. 2011) can be evaluated by testing of strength imbalance between the lower limbs. However, determination of side difference in knee extensor strength depends on the analyzing method. In the present study, the POW and ISO showed divergent results in 6 out of 15 subjects. Neither EMG activity during the muscle actions nor muscle size of knee extensors explained the present strength differences by side. Fatiguing loading induced decreases strength more in stronger compared to weaker limb in POW but not in ISO. Changes in symmetry of limb strength by fatigue may ultimately decrease athlete's efficiency in sport activities. The present findings suggest that maximal power tests in fatiguing conditions could be promising diagnostic tool in determination of functional asymmetry in the lower limb strength. FATIGUE LEVEL DURING HANDGRIP TEST: COMPARISON BETWEEN YOUNG JUDO ATHLETES AND NON ATHLETES.

MORTATTI, A., HONORATO, R.C., LARA, J.P.R.

Federal University of Rio Grande do Norte

Introduction: The training of young judo athletes involves a lot of intermittent maximal and submaximal isometric handgrip actions, mainly while fighting. However, it is still unclear if this process could generate significant outcomes on strength in adolescents. Therefore, the aim of this study was to analyse the level of fatigue in young judo athletes and untrained young people on a handgrip test. Methods: 40 judo athletes [JA] (13.5 years old ± 1.13) and 40 untrained young people [UN] 13.5 years old ± 1.15 weight, height and maturational status (Mirwald, 2002) were evaluated. The individuals performed, in both hands, a handgrip strength test consisting of 10 all-out repetitions in 10 seconds with 20 seconds of rest between the repetitions. A digital manual dynamometer was used to assess the mean and the peak of handgrip strength of each repetition. The fatigue index ([maximum - minimum] *100/maximum) was used for mean and peak values to determine percentage of loss in strength during the test. The normality of data was assessed by Shapiro-Wilk test, and, after this, all variables were compared between the groups using T student test. The effect size (cohen's d) for the fatigue index of mean and peak was calculated. A p-value less than 0.05 was adopted as criteria of statistical significance. Results: JA and UN presented no differences in weight, height and maturational status. The mean of training age in JA was 5.42 years. The fatigue index mean values in the dominant hand were JA: 33.2 ± 6.8 % and UN: 38.3 ± 8.7 % ($p: 0.004$; ES: 0.65) while the values in the non-dominant hand were JA: 35.3 ± 7.61 % and UN: 38.3 ± 8.3 % ($p: 0.09$; ES: 0.38). For the peak values of strength, the fatigue index was JA: 31.6 ± 7.44 % and UN: 34.8 ± 8.7 ($p: 0.08$; ES: 0.38) for the dominant hand, and JA: 34.5 ± 8.3 % and UN: 35.1 ± 7.1 ($p: 0.76$; ES: 0.06) in the non-dominant hand. Discussion: Despite the equality in the decreasing peak values indicate that both groups could have had same capacity to reach similar values in all repetitions, the significant difference in the mean values showed that JA group had a greater capacity to sustain the isometric contractions at a higher level of strength in comparison to the UN, at least in the dominant hand. Dias et al. (2012) reported similar result in judo athletes when compared with sedentary adult men, indicating that the greatest strength endurance can emerge since the beginning of adolescence and persists until adult age, when judo is practiced. EFFECTS OF TRUNK FATIGUE ON DOUBLE POLING PERFORMANCE AND PACING STRATEGY IN JUNIOR CROSS-COUNTRY SKIERS

BUCHER, E.1, ROTH, R.1, DONATH, L.1, SANDBAKK, Ø.2, FAUDE, O.1

1 University of Basel 2 Norwegian University of Science and Technology

Introduction: The trunk plays a crucial role in the power production during double poling (Hegge et al., 2015), one of the main sub-techniques in classical cross-country skiing. While intense whole-body exercise has been shown to result in general fatigue and reduced performance, the effect of fatigue in more isolated components of the relevant muscle chains is less understood. Therefore, the aim of this study was to investigate acute effects of a fatigued trunk on double poling performance and pacing strategy in junior cross-country skiers. Methods: 16 well-trained male junior cross-country skiers completed two identical pre- and post-tests on separate days in a randomized, controlled cross-over design. In between pre- and post-test, either a 25-min fatiguing exercise sequence targeting the core musculature (FAT) or a 25-min resting control condition (CON) were applied. Performance tests consisted of a maximal isometric trunk strength tests (flexion and extension; IsoMed 2000 backmodule; D&R Ferstl, Hemau, Germany), followed by a 3-min self-paced double poling test (SkiErg; Concept2, Morrisville, VT, USA). Power output, cycle characteristics and cardiorespiratory variables were continuously measured during the double poling test. Results: Isometric peak torque during trunk flexion (-63%) and extension (-11%) decreased in FAT (both $p < 0.001$) and was unchanged in CON ($p = 0.39$ and $p = 0.42$). Trunk fatigue led to a 13% decrease in mean power output (mean pre-post change: -32 (95% CI -41,-23) W; $p < 0.001$), whereas power did not change in CON (+2%; $p = 0.21$). Cycle rate decreased by 10% in FAT (-0.11 (-0.14,-0.08) Hz; $p = 0.001$) and by 5% in CON (-0.06 (-0.09,-0.02) Hz; $p = 0.005$). Peak heart rate did not differ between FAT and CON (-1%; $p = 0.10$ and +1%; $p < 0.001$). Peak oxygen uptake decreased by 4% in FAT ($p = 0.004$) and increased by 3% in CON ($p = 0.027$). Peak ventilation decreased by 7% in FAT ($p < 0.001$) and did not differ in CON (0%; $p = 0.59$). Pacing analysis showed the greatest power reduction during the first 60 s in FAT (-64 W; $p < 0.001$), with less reductions in the second 60 s (-31 W; $p < 0.001$) and no difference in the third 60 s (-3 W; $p = 0.524$). Discussion: Acute fatigue of core muscles in junior cross-country skiers resulted in substantial decreases in power output and altered pacing profiles during double poling. The accompanied reduction in respiratory capacity after fatigue indicates a close tie between trunk control, respiration and performance in double poling. References: Hegge, A. EFFECTS OF ACTIVE RECOVERY AFTER INTENSIVE TRAINING ON PERFORMANCE AND MARKERS OF FATIGUE IN ELITE GERMAN WEIGHTLIFTERS

RAEDER, C., WIEWELHOVE, T., SCHNEIDER, C., DÖWELING, A., FERRAUTI, A.

Ruhr-University Bochum

Introduction The aim of the present study was to investigate the effect of a repeated use of active recovery (ACT) compared with passive recovery (PAS) during a two-day heavy weightlifting training block with two training sessions per day on sport-specific performance and selected markers of fatigue. Methods Eight competitive male ($n=7$) and female ($n=1$) German weightlifters from the Olympic national team participated in this study. In a crossover design, separated by a two-week wash-out period, the subjects performed either supervised ACT (submaximal rowing ergometer exercise; 1 Watt per kg body mass) or PAS (resting in a seated position) for 15 minutes after each training session. Sport-specific performance comprising maximal barbell velocity during the clean pull (CP) at 85% (CP85), 90% (CP90) and 95% (CP95) of the maximum load, as well as markers of fatigue including jump performance (countermovement jump, CMJ), skeletal muscle contractile properties (maximal displacement of the muscle belly, Dm; muscle contraction velocity, V90) using tensiomyography, muscle damage (serum creatine kinase activity, CK), muscle soreness (delayed onset muscle soreness, DOMS), and perceived overall stress and overall recovery levels (short recovery stress scale, SRSS) were measured one day before (Pre) and one day after (Post) completing the training programs. Results There were neither significant recovery type x time interactions nor meaningful differences in pre-post changes between ACT and PAS in all analyzed variables. However, the training block induced small decreases between Pre and Post over all relative intensities in CP (CP85, ACT: Effect size (ES)=-0.20, PAS: ES=-0.50; CP90, ACT: ES=-0.29, PAS: ES=-0.35; CP95, ACT: ES=-0.41, PAS: ES=-0.20; $P>0.05$). There were trivial pre-post changes in CMJ as well as in Dm and V90 in both interventions ($ES<\pm 0.20$; $P>0.05$). Large to very large increases between Pre and Post could be found in CK (ACT: ES=2.11, PAS: ES=1.41; $P=0.001$) and DOMS (ACT: ES=1.65, PAS: ES=2.33; $P=0.052$) as well as moderate to large effects in perceived overall stress (ACT: ES=1.35, PAS: ES=1.01; $P>0.05$) and overall recovery levels (ACT: ES=-1.35, PAS: ES=-1.33; $P>0.05$). Discussion The repeated use of individualized ACT seems not to promote recovery more effectively than PAS. However, ACT has also no detrimental effect on the recovery process compared with PAS. Therefore, the use of ACT should be considered at the individual level in the applied field.

DIFFERENCES OF ACUTE PHYSIOLOGICAL RESPONSES BETWEEN TWO HIGH-INTENSITY INTERVAL EXERCISE MODES IN ENDURANCE AND SPRINT TYPE ATHLETES

CIPRYAN, L., TSCHAKERT, G., HOFMANN, P.

Ostrava University; University of Graz

INTRODUCTION A number of variables prescribe high-intensity interval exercise (HIE) but the principle of individuality has to be respected also. Regarding HIE, the effect of training mode has received limited scientific interest so far. Therefore, the aim was to compare the acute cardiorespiratory and metabolic response to short and long HIE in endurance and sprint trained athletes. METHODS Sixteen highly-trained males (8 endurance (E) and 8 sprint (S) athletes, age 22.5 ± 3.0 years, $\text{VO}_{2\text{max}}$: E: $66.2\pm 5.0 \text{ ml.kg}^{-1}\text{min}^{-1}$; S: $56.8\pm 5.0 \text{ ml.kg}^{-1}\text{min}^{-1}$) volunteered in this study. The participants firstly performed a maximal incremental treadmill test. Then they performed a short (30s) and a long HIE (180s), matched to one constant load exercise (CE) (50 % of $\text{vV'VO}_{2\text{max}}$; total duration 32 min). Long and short intervals were identical for work/relief ratio (1:1) as well as for the relative work ($\text{vV'VO}_{2\text{max}} = 100\%$) and relief intensity (passive). Ventilatory parameters, heart rate (HR) and lactate (La) were monitored during the exercise. A magnitude based inferences were employed within the statistical analysis (Batterham & Hopkins, 2005). RESULTS The HR and V'VO_2 peaks during the long HIE clearly crossed the second ventilatory threshold (VT) while this peak cardiorespiratory response remained at the level of the first VT during the short HIE. The differences between E and S athletes in mean HR response (bpm or % HRmax) were unclear in all trials. Endurance athletes performed the exercise interventions with moderately (CE) or largely (both HIE modes) higher mean V'VO_2 . These differences were unclear or trivial when V'VO_2 was expressed as a function of $\text{V'VO}_{2\text{max}}$. Moderately lower RER values were found in endurance athletes. The E vs. S differences in mean La were unclear (both HIE modes) or nearly perfect in CE, with higher values in sprint athletes. DISCUSSION All exercise tests produced similar values in E and S athletes for mean HR and mean V'VO_2 (% $\text{V'VO}_{2\text{max}}$). However, E athletes performed the exercise trials with

lower RER even if the running speed was individually adjusted at the same relative level. This indicates the greater reliance of E athletes on oxidative metabolism pathway even during high-intensity exercise. Second, the short HIIE was performed fully aerobically. Third, unlike E athletes, S athletes performed the long HIIE mostly anaerobically. Therefore, one needs to be cautious if the development of the glycolytic metabolic pathway is the main aim of such a training program. References: Batterham, A.M., & Hopkins, W.G. (2005). Making meaningful inferences about magnitudes. *Sportscience*, 9, 6-13.

DON'T BE AFRAID OF LACTATE! PARADOX EFFECTS OF Elevated BLOOD LACTATE CONCENTRATION ON HIGH-INTENSITY EXERCISE PERFORMANCE

HOFMANN, P., MÜLLER, A., TSCHAKERT, G.

University of Graz

Introduction Lactate (La) has been termed a waste product, and still many believe this myth although La has been shown to be an energy source, a gluconeogenetic precursor and a regulator (Brooks 2009). The Lactate Shuttle Theory (LST) describes the balance of La production and local and/or systemic La oxidation described for exercising muscles (Brooks 2009), for the healthy (Figley 2011) and injured brain (Dienel 2014), different tissues (Brooks 2009) and solid tumours (Draoui et al. 2011). This review addresses a theoretical position on the influence of high-intensity pre-load lactate elevation on subsequent high-intensity glycolytic exercise of non-pre-loaded muscles. Somehow paradox effects (Almer 2016) can be explained by the LST (Brooks 2009). Athletes usually perform an intense warm-up program elevating La substantially (Bishop 2003), but for the main workout they try to start at low La. It is generally suggested that elevated La always impairs subsequent performance by reducing the anaerobic energy contribution and/or interfering with muscle contractile processes (Bishop 2001, 2003; Mujika et al. 2012). Several studies showed that an elevated systemic La concentration inhibits the rate of glycolysis in subsequent anaerobic work bouts (Bishop et al. 2001), also shown for a La increase by arm exercise that decreased the rate of blood La accumulation in a subsequent cycle ergometer sprint by 50% (Bogdanis et al. 1994), and supported by own results (Müller et al. 2015). The inhibition of La production is due to an inverted gradient from an elevated systemic to the muscular La concentration consequently favouring oxidative energy production at the same workload which may be beneficial for high-intensity workouts of 1-8 min duration. The shift to an enforced oxidative metabolism may maintain better coordinated muscle recruitment due to the reduced local muscle anaerobic energy contribution. We applied this theoretical approach in various comparable situations in the laboratory and under field conditions which will be shown in detail (see also Almer 2016; Bierbaumer 2016). Conclusion Pre-elevated La levels by non-dominant muscle groups uniformly showed a markedly decreased net blood La increase of 30-50% in all experiments. This inhibition of La production did not reduce but instead enhanced high-intensity exercise performance in all dynamic workloads longer than 60 s and shifted metabolism to a more dominant oxidative one. We therefore suggest that this application of the La induction by non-dominant muscles may be used to enhance performance in several high-intensity sports if applied properly. ORDER OF COMBINED STRENGTH AND ENDURANCE TRAINING MAY INFLUENCE NEUROMUSCULAR ADAPTATIONS

KÜÜSMAA, M.1, AVELA, J.1, NEWTON, R.2, RYTKÖNEN, T.1, EKLUND, D.1, IZQUIERDO, M.3, HÄKKINEN, K.1

University of Jyväskylä

1:JYU (Jyväskylä, Finland), 2:ECU (Perth, Australia), 3:UPNA (Navarra, Spain) Introduction Previous studies have shown that combined strength (S) and endurance (E) training order (Cadore et al., 2013) and time-of-day of S (Sedliak et al., 2008) and E training (Hill et al., 1998) may influence the magnitude of training adaptations. The aim of this study was to examine the effects of 24 weeks of morning vs. evening single-session combined SE vs. ES training on neuromuscular performance. Methods 41 men (32.3 ± 5.6 years) trained for 24 (2x12) weeks (2-3 combined sessions per week) in the morning (m) or evening (e) using either SE or ES order (mSE n=9, mES n=9, eSE n=12 and eES n=11). 10 control subjects (C) continued their normal daily activities. Unilateral isometric knee extension force (KE), muscle activity of vastus lateralis (VL) by electromyography (EMG), maximal voluntary activation % by electrical stimulation (VA%) and maximal power during cycling (Wmax) were measured both in the morning and evening. Results Time of day when the training was performed did not influence the results and thus, the groups were combined into the SE (mSE+eSE) and ES (mES+eES) groups. KE force increased only in SE in the morning ($10.9 \pm 18.0\%$; $p < 0.05$) and evening ($15.9 \pm 16.7\%$; $p < 0.01$) by week 24. Evening force changes in SE were larger than in ES ($p < 0.05$) or C ($p < 0.05$). VL EMG activity increased in the morning by week 24 in SE ($28.5 \pm 30.6\%$; $p < 0.001$) and ES ($29.3 \pm 36.4\%$; $p < 0.05$). In the evening VL EMG increased only in SE during weeks 0-24 ($38.3 \pm 31.7\%$; $p < 0.001$), and this change was larger than in ES ($p < 0.05$) or C ($p < 0.05$). VA% increased in SE ($3.2 \pm 5.9\%$) more than C ($p < 0.05$) in the evening by week 24. Wmax increased in SE and ES throughout the training period in the morning ($p < 0.05$) and evening ($p < 0.05$). However, the changes were larger in ES compared to SE in the morning during weeks 0-24 ($p < 0.05$) and in the evening during weeks 13-24 ($p < 0.05$). Discussion These results suggest that changes in neural activation recorded by EMG and VA% may contribute to the magnitude of strength gains especially in SE in the evening during prolonged combined S and E training. ES order, however, may produce greater adaptations than SE in endurance performance both in the morning and evening. It is possible that the residual fatigue produced repeatedly from the first training mode may have compromised the adaptations to the second training mode (Chtara et al., 2005; Cadore et al., 2013). Therefore, the order of S and E in a training session could be selected according to the personal training goal. MO-PM19 Stretching

ACUTE EFFECT OF SINGLE WATSU THERAPY ON THE FLEXIBILITY OF YOUNG MALE SWIMMERS

TUFEKCIOLLU, E., HASSANAIN, M.B.M.

King Fahd University of Petroleum and Mineral

Watsu is a truly contemporary aquatic bodywork therapy. Watsu utilizes both static rotational stretches for the trunk and rhythmical, repeated trunk rotation by Rotating Accordion, Near and Far Leg Rotation. Objective: To find out the impact of Watsu therapy on flexibility. To compare the changes in upper and lower body flexibility after Watsu therapy. Tools and Methods: A group of twelve volunteer male subjects aged between 18 and 22 years studying at KFUPM, S.A. participated to our study. They underwent regular swimming workout more than a year. Only one watsu session was performed on the subjects. Trunk-neck and hip-trunk static flexibility tests were used to measure the flexibility values. The measurements were initially taken before the watsu session and within 5 minutes after the watsu session. Mean, S.D. and t-test were computed using Statistica Software for analyzing the data. Findings: Sit&Reach test score was found to be statistically significant. Trunk&Neck test result was found not to be statistically significant. Mean and S.D from pre to post test were 28.83, 8.31 and 30.08, 8.55, 54.75, 12.65 and 55.33, 12.82 respectively. Conclusions and Assessments: The results of this preliminary study suggest that one watsu session can help improve flexibility. This findings support the effects including increased flexibility and relaxation noted by Watsu therapy receivers. Further studies using true experimental designs with larger sample sizes, and more sessions should be conducted in order to confirm these results.

LOCAL VIBRATION STRETCHING: A NOVEL MODALITY ENHANCING MUSCULOTENDINOUS STIFFNESS WHILE MAINTAINING MUSCLE STRENGTH

IKEDA, N., YONEZU, T., INAMI, T., KAWAKAMI, Y.

Waseda University

Introduction: Static stretching (SS) and dynamic stretching (DS) are the typical modalities to improve joint range of motion (flexibility). SS is known to lower the stiffness and hardness of the musculotendinous tissues [1, 2]. Even though SS is superior to DS in improvement of flexibility, it also induces a decrease in muscle function [3] unlike DS [4, 5]. In this study, we developed a novel stretching method 'local vibration stretching (LVS)', which provides tiny length changes to the muscle-tendon unit being stretched passively. The purpose of this study was to investigate the effect of LVS on the muscle strength and elastic properties of the ankle plantar flexors and Achilles tendon (AT). Methods: Ten healthy young males (25.0 ± 2.8 years) participated in this study. The maximal voluntary isometric plantar flexion strength, AT stiffness, and muscle hardness were measured before (pre) and immediately after (post) five trials of either of three types of stretching: SS, LVS with a frequency of 15Hz, and no intervention (CON). AT stiffness was calculated from the plantar flexion torque increasing gradually to the maximum over 5s and while elongation of AT (the displacement of the distal end of muscle belly of the medial gastrocnemius) was measured with ultrasonography. Muscle hardness (shear modulus – ankle joint angle relationship) was determined for the medial gastrocnemius at three angles (0° (anatomical position) and dorsiflexion 10° & 20°) by using shear wave elastography. Results: The maximal voluntary isometric plantar flexion strength significantly decreased in SS ($p < 0.05$), but not in LVS. The AT stiffness significantly decreased both in SS and LVS ($p < 0.05$), however there were no significant differences in the relative changes of AT stiffness between SS and LVS. The muscle hardness significantly decreased both in SS and LVS ($p < 0.05$) with not significant differences between SS and LVS. All variables remained unchanged in the repeated measurements in CON. Conclusions: The present findings indicate that LVS improves flexibility by changing the muscle-tendon compliant while inducing no muscle function loss, unlike SS. It is suggested that LVS is suitable for a warm-up modality. References: [1] Kubo et al. (2001). J Appl Physiol, 90(2), 520-527. [2] Nakamura et al. (2014). Ultrasound Med Biol, 40(9), 1991-1997. SIMILAR CHANGES IN MUSCLE HARDNESS AT THE MEDIAL AND LATERAL HEAD OF THE GASTROCNEMIUS DURING STATIC STRETCHING

OKAMURA, N., TSUKUNE, M., KOBAYASHI, Y., SUGANO S., FUJIE, M.G.

Waseda University

INTRODUCTION Static stretching is widely used to adjust muscle tone. However, the effect of stretching depends on the individual condition of each muscle. Several muscles are stretched at the same time to maintain a single posture and the effect of stretching varies with each muscle. We have continuously measured muscle hardness using a wearable indentation tester to evaluate muscle tone during static stretching, and found that muscle hardness changes during static stretching [1] [2]. Using this method, we can evaluate muscle tone at several points simultaneously. In this study, we have investigated the similarities in muscle hardness changes at the medial and lateral head of the gastrocnemius while the triceps surae muscles were stretched. METHODS Five healthy university students with no lower limb injuries participated in this study. To measure muscle hardness, wearable indentation testers were fixed to the skin over the medial and lateral head of the gastrocnemius. Each subject stretched both triceps surae muscles for 1 min on a stretching board, using arbitrary strength with no ankle joint rotation. Stretching was repeated three times with 1 min breaks between each trial. We calculated the correlation coefficient of the time series variation between the muscle hardness at the medial head and lateral head. RESULTS Muscle hardness at the medial head correlated highly with muscle hardness at the lateral head in 75% of trials (correlation coefficient $R > 0.7$). In some trials, only one leg showed high correlation coefficient ($R > 0.7$) and the other leg showed relatively low correlation coefficient ($R < 0.5$ or negative value). DISCUSSION High correlation between muscle hardness at the medial and lateral head of the gastrocnemius means the time to decrease or increase muscle tone by stretching is similar at the medial and lateral head. Since muscle length is almost the same in both biceps, the changes in muscle tone are considered similar. In some trials, only one leg showed a high correlation coefficient; this may be explained by a bias in the center of gravity, meaning the other leg was not well stretched. In the future, we will investigate the effect of ankle joint rotation [3] and find the optimal conditions for adjusting the tone of specific muscles by static stretching. REFERENCES [1]

PRE-STRETCH AUGMENTATION AND ECCENTRIC UTILIZATION RATIO IN 15 TO 18 YEARS OLD ATHLETES OF DIFFERENT SPORT EVENTS

PETRIDIS, L., PÁLINKÁS, G.

University of Physical Education

Introduction Eccentric utilization ratio (EUR) is used as an indicator of power performance, and pre-stretch augmentation (PSA) is used to measure the ability to utilize pre-stretch of the muscles. The purpose of this study is to examine any differences in EUR and PSA in young male athletes between the ages of 15 and 18 years and between different sport events. Methods A total of 183 male athletes were measured representing five different sport events, specifically soccer (n=137), basketball (n=18), handball (n=6), rowing (n=15) and modern pentathlon (n=7). Four age groups were formed, 15 (n=27), 16 (n=49), 17 (n=55) and 18 years old (n=52). The athletes performed three squat jumps (SJ) and three counter movement jumps (CMJ) on a force platform, the best value for each jump type was recorded and used for analysis. Jump height was measured based on the flight time method. EUR was calculated by dividing CMJ height to SJ height, while PSA was calculated by subtracting the SJ height from CMJ height, dividing by SJ height and multiplying by 100. Results Results didn't reveal differences between the age groups in EUR or PSA, except the 17 years old athletes, who showed higher values especially compared to the 16 years old athletes. Neither were found differences between the sport events, basketball and handball players showed higher values in EUR and PSA, however these differences statistically were not significant. Discussion Power and explosive force production is critical in many sports, the ability to utilize the stretch shortening cycle of the muscle can be of great importance in athletic performance. Based on the results power performance as measured by EUR and PSA does not change with age in the examined age period and does not differ between the examined sport events, indicating perhaps that other factors (e.g. muscle fibres type, neuromuscular activation) have a more definitive role. The training regime of the athletes should be also considered, however, lack of detailed information didn't allow for such an analysis.

EFFECT OF STRETCHING ON REDUCING THE INCIDENCE OF MUSCULOSKELETAL DISORDERS AMONG TEACHERS

LEUNG, E., SUM, R., LEE, S.

1,2The Chinese University of Hong Kong, 3The Hong Kong Chinese Christian Churches Union Logos Academy

Purpose: Musculoskeletal disorders (MSD) are common occupational health problems around the world. The adverse impact of MSD on the teaching profession has been reported to be high with the prevalence rate of 39% to 95% (Erick & Smith, 2011). Stretching is a potential way to reduce work-related MSD (da Costa & Vieira, 2008). The purpose of study was to evaluate the effectiveness of stretching on reducing the incidence of musculoskeletal disorders among teachers in Hong Kong. Methods: A total of 21 teachers from a primary school were recruited and participated in the project. Participants received the stretching program which were adapted from the "Stretching Exercises to Prevent Musculoskeletal Injury Manual" of the Occupational Safety and Health Council of Hong Kong (2013). The stretching exercises were reviewed by a physiotherapist and a physical fitness specialist. The participants were advised to perform a set of 15 stretching exercises for around 15 minutes per day. Log books were provided to record their compliance rates. Nordic Musculoskeletal Questionnaire (Kuorinka, et al., 1987) was used. The assessments of the prevalence rates of MSD were conducted at baseline and third month of the intervention. Results: There was no difference (*McNemar X₂, p>0.05) in prevalence rates between baseline (95%) and posttest (100%) for the Intervention sample. There was no difference ($F_{1,17}=0.46$, p>0.05) in total number of trouble/pain areas between baseline and posttest after controlling for exercise days (frequent vs less). Participants with exercise frequency more than 22 days were doing better than that of less or equal to 22 days but not significant ($F_{1,17}=0.89$, p>0.05) statistically. Conclusion: The lack of intervention effects might be attributed to the lack of programme contents engagement and small sample size. Future studies should be on strategies to increase the compliance rate. Supervised preventive stretching exercise programmes for reducing occupationally related MSD should be further investigated. MO-PM20 Training & Testing: Mixed Session**THE EFFECT OF A MATCH ON PSYCHOMOTOR VIGILANCE IN FUTSAL REFEREES**

AHMED, H.S.1, DAVISON, G.1, MARCORA, S.M.1, DIXON, D.2

University of Kent

Futsal is characterized as an intermittent sport played between two competing teams of five players per team and it is officiated by two referees whom implement the Futsal laws of the game. Some previous studies have investigated referees' physiological demands but there is little research on cognitive performance, yet it is important to consider such perceptual-cognitive factors that may influence referees' performance (Weston, et al., 2012). The aim of the present study was to assess referees' performance on the psychomotor vigilance task (PVT) before and after a competitive Futsal match. Methods: After University Ethics Committee approval, Eleven Futsal referees (mean \pm SD: age, 33.5 ± 9.8 years; height, 180.6 ± 7.5 cm; weight 82.9 ± 15.3 kg) from the FA National Futsal Group, FA Futsal Super League, London, UK, were studied in matches during the 2015/16 season. The referees had between 5 and 15 years of refereeing experience at the top level. Referees were required to undertake the 10-min PVT at 60 min before the match kick-off time (pre) and immediately after matches. They also completed the Brunel Mood Scale (BRUMS) questionnaire before the pre-match PVT and after the post-match PVT. Result: Data were analysed by paired t-tests comparing pre- to post-match results. There was no significant different in PVT pre- and

post-match, Lapses ($RT > 500$ ms), Slowest 10% and Fastest 10% PVT scores (all $P > 0.05$). However, there was significant difference in BRUMS in tension (0.8 ± 1.0 pre- vs 0.1 ± 0.3 post-match, $P < 0.05$), vigour (9.3 ± 2.6 pre- vs 6.3 ± 2.7 post-match, $P < 0.05$) and fatigue (1.3 ± 1.5 pre- vs 4.8 ± 2.6 post-match, $P < 0.05$). In conclusion, the present finding found that performance on the 10-min PVT did not decrease after a match, which was in opposition to our hypothesis. We had anticipated a decrease due to mental and physical fatigue induced by the match. However, the present results suggest that referees were able to maintain their cognitive performance over the course of a match, which could suggest resilience to negative effects of physical and mental fatigue. These findings were in response to a single match, however, and many referees are required to officiate multiple games on the same day (e.g. at tournaments) sometimes with minimal recovery between matches. In addition, there was a tendency for less experienced (less than 10 years) referees to have greater post-match decreases, so future research should compare referees of varying experience and also assess the effects after multiple matches in a single day. COMPARISON OF THE DIFFERENTIAL LEARNING APPROACH IN THE FORM OF GAMES AND TRADITIONAL TENNIS TRAINING

HEGEN, P., RIZZI, N., SCHÖLLHORN, W.I.

University of Mainz

Introduction According to the curriculum of the German Tennis Association (DTB, 1996) a tennis specific movement should be learned correctly under stable conditions and regularly repeated with sufficient number. Deviations from the prescribed standards during the learning process are considered as destructive. A constructive influence of errors on learning is suggested by the differential learning approach (Schöllhorn, 2000). Positive effects of DL training were shown for the tennis serve (Humpert et al., 2006). The aim of this study is to investigate the effect of DL in form of games and classical tennis training on longline and diagonal forehand stroke. Methods 20 subjects (14 male, 6 female; 11.6 ± 1.5 years of age) were randomly assigned to two intervention groups. Each subject completed over six weeks twelve training sessions (TS) with 40 forehand trials. The classical group (CL) followed a standardized training protocol according to the curriculum. The differential learning group (DL) trained in form of games accompanied by a big amount of additional noise in the forehand executions. Precision data of pre-, post-, and retention-tests were analyzed by means of a repeated measurement ANOVA with additional post hoc paired t-tests and Bonferroni correction. Results Both groups started from the same initial level and improved their performance of the longline and diagonal task during the acquisition phase. In the retention-test the performance of the CL group decreased in both tasks back to its initial level. No statistically significant change in the DL group was identified. The repeated measurement ANOVA of the longline task showed significant results ($p=.000$) with a high effect size ($\eta^2=.355$) for the factor time. The interaction of the factor group and time ($p=.455$) and the between-subject effect ($p=.658$) was not significant. The paired t-tests indicated an improvement from pre- to post-test for both groups (CL: $p=.024$; DL: $p=.009$). However the CL-Group decreased their performance from post- to retention-test ($p=.017$). The DL-Group stabilized their performance on a higher level compared to pre-test. For the diagonal task a statistical trend was observed. All factors were not significant (time: $p=.077$; time x group: $p=.329$; group: $p=.876$). Discussion Both groups were able to increase their performance from pre- to post-test. The development of the DL group differs in comparison to the CL group mainly during the learning phase. While the CL group dropped back to the initial level, the DL group remained nearly on the post-test level. At least evidence for advantage during the learning phase is provided by the DL group. PREDICTING ELITE TRIATHLON PERFORMANCE BY A TRIATHLON COACH SURVEY AND ARTIFICIAL NEURAL NETWORKS

HOFFMANN, M.1, MOELLER, T.2, SEIDEL, I.1,2, STEIN, T.1

1: Karlsruhe Institute of Technology (KIT, Karlsruhe, Germany), 2: Institute of Applied Training Science (IAT, Leipzig, Germany)

Introduction: Performance prediction in triathlon could be useful for talent diagnostics and to develop individual race tactics (Landers et al., 2000). Thereby, anthropometric and physiological parameters measured in laboratory tests provide an important basis for race time predictions (Schabert et al., 2000). We conducted a survey with professional triathlon coaches followed by the development of artificial neural networks (ANNs) to identify performance relevant parameters and to predict overall race times of German male elite triathletes. **Methods:** Anthropometric and physiological parameters of 25 laboratory tests of eleven male elite triathletes (20-32 yrs) were collected at the IAT between 2008 and 2012. A dominance paired comparison with three German professional triathlon coaches was used to identify relevant parameters based on their professional expertise. Afterwards, two-layer feedforward ANNs (Levenberg-Marquardt algorithm) were computed to highlight appropriate parameters of elite Olympic distance triathlon performance and to predict overall race time. **Results:** The dominance paired comparison concerning anthropometric parameters led to BMI [kg/m²], Rohrer-Index [kg/m³], Quetelet-Index [g/cm²] and body fat [% and kg]. The dominance paired comparison concerning physiological parameters led to maximum running pace [m/s], running pace at 3-mmol/l blood lactate [m/s], relative VO_{2max} [ml/min/kg], maximum running pace in mobilisation test [m/s] and absolute VO_{2max} [ml/min] as most important for Olympic distance triathlon performance. The ANN using anthropometric variables explained 58% of the variance in overall race time ($R^2 = 0.58$; RMSE = 124.25 [s]). The ANN using physiological variables explained 90% of the variance in overall race time ($R^2 = 0.90$; RMSE = 58.80 [s]). **Discussion:** The combination of a professional triathlon coach survey and ANNs provided two performance prediction models with high percentages of variance explained (anthropometric: $R^2 = 0.58$; physiological: $R^2 = 0.90$). These predictions outperformed a purely statistical approach comprising factor analysis and multiple regressions (Hoffmann et al., 2015). Furthermore, the RMSE was lower than the performance variation of elite athletes. Therefore, the trained ANN considering professional expertise can be used to predict individual race time based on the values of an actual performance diagnostic. GRADUAL SPECIFICITY DURING ACTUAL AND IMAGINED ISOMETRIC CONTRACTIONS

TRAVERSE, E., PAPAXANTHIS, C., LEBON, F.

INSERM U 1093 Université Bourgogne Franche-Comté

Introduction Mental training with motor imagery (MI) has been shown to increase muscle strength (Ranganathan et al. 2004). During such training, maximal imagined contractions are generally instructed as the motor cortex being more activated in high imagined contractions

(Helm et al. 2015). However, the gradual specificity of MI, i.e., the parallel between neurophysiological processes and increasing imagined contractions, is not clearly demonstrated. The aim of this study was to better understand the neural correlates of this specificity. Methods Two experiments were performed, using transcranial magnetic stimulation (TMS) and electrical peripheral nerve stimulation (ES) on Flexor Carpo Radialis. In the first experiment, participants (n=11) were instructed to rest or to actually perform grip strength of the right hand with a dynamometer from 25% to 75% of maximal voluntary contractions (MVC). In the second experiment, participants (n=10) were instructed to rest or to imagine squeezing the hand from 25% to 100%MVC. In both experiments, TMS was applied during actual and imagined contractions with intensity set at 120% of rest or active motor threshold. The same protocol was realized with ES of median nerve, with the intensity set to induce Mmax. Results Motor Evoked Potential (MEP) amplitude, for all intensities and conditions was greater than that at rest ($\text{Chi}^2=12.88$ and 19.56 , $p<0.01$ respectively). During actual contraction, MEP amplitude at 25%MVC was lower than that at 50%MVC ($p=0.05$). During MI, MEP amplitude at 75%MVC was significantly greater than that at 25%MVC ($p=0.03$). Discussion According to previous findings, we demonstrate a gradual specificity with strength increase during MI and actual movement (Helm et al. 2015; Pearcy et al. 2014). The same pattern for corticospinal excitability was observed: we found an increase up to 50%MVC during actual contractions and up to 75%MVC during imagined contractions, followed by a plateau. For highest levels of strength, cortical inhibitory and facilitatory processes may be modulated to change the modality, spatial and temporal, of motor units' recruitment (Oya, Riek, and Cresswell 2009). MI training has been showed to improve strength; it may be of importance to pay attention at imagined contraction intensities. It seems more effective to imagine a high intensity submaximal contraction whereas low or maximal intensity. References Helm F, Marinovic W, Krüger B, Munzert J, and Riek S. (2015). ELECTROPHYSIOLOGICAL CORRELATES OF SKILL-SPECIFIC MODULATIONS OF COGNITIVE CONTROL IN BADMINTON PLAYERS

SUN, J., TU, K.C., WANG, C.H., TSAI, C.L.

National Cheng Kung University

Introduction Recently there have been increasing researches suggest that sports training involving cognitive skills (i.e., open-skilled sports) may be associated with enhanced cognitions. However, sports training has been associated with enhanced aerobic fitness, which is also beneficial for cognitive functions. Thus, it is unclear whether the skill-specific effect of sports training on cognitions can still be observed after accounting for the fitness effect. Accordingly, this study compared neurocognitive performance with those of athletes in other sports requiring less complex cognitive skills (i.e., track and field) to further address this issue. Method We examined the differences in behavioural and event-related potential (ERP) measures during a flanker task involving different levels of cognitive control between badminton players (n = 16; aged 20.68 ± 1.9 years; $\text{VO2max} = 55.69 \pm 0.9 \text{ mL/kg-min}$) and fitness-matched athletic controls (n = 16; aged 20.94 ± 1.1 years; $\text{VO2max} = 55.20 \pm 2.1 \text{ mL/kg-min}$). Result Behaviour data showed that badminton players responded faster than non-players selectively in the condition involving higher level of cognitive control (i.e., response conflict in the incongruent condition). In addition, the ERP data showed that, as compared to the athletic controls, badminton players exhibited smaller N2 amplitudes but greater P3 amplitudes at electrodes around fronto-central areas (i.e., Fz, FCz, CPz). Discussion These combined analysis of behaviour and ERP data suggested that long-term participation in a sport requiring intense cognitive skills (i.e., badminton) may be related to a reduction in task-relevant response conflict, with a concomitant increased top-down attentional control during task execution, thus better task performance. Based on these findings, we conclude that the sport-skill-specific changes in cognitive function might be independent of aerobic fitness, further supporting the claim that mental training in sports may be a medium for cognitive enhancement.

COMPARISON OF BRJ AND WINGATE ANAEROBIC POWER TESTS ASSAYED BY LACTATE RECOVERY LEVELS IN ALPINE SKIERS

HOSHINO, H., TSUNODA, K., MAUNE, J., SASAKI, T.

Hokusei gakuen University

Introduction Alpine skiers require enhanced anaerobic power capacity as well as explosive power and muscle strength. Therefore, two tests are widely used to elucidate such power values: the rebound squat jump (BRJ) test, pioneered by Bosco (Bosco. C, 1997), and Wingate tests (Petelin von Duvillard. S and Knowles. W. J. 1997). It is generally assumed that the two tests are interchangeable and the choice of which one to use is just a matter of preference. However, whether or not the two tests are indeed interchangeable has not been examined in detail. The purpose of this study is to compare at the physiological level, via lactate levels, the BRJ and Wingate tests, each of 90-s duration. Methods Ten competitive male alpine skiers were the subjects in this study. Subjects performed a 90-s BRJ test immediately after which subjects sat in a resting position and lactate levels were measured at one minute intervals over 30 minutes using a Lactate Pro 2 (Arkray Co., Ltd.) testing blood taken from their fingertips. A resting lactate level was obtained by measuring lactate levels of each subject following 30 minutes of resting in a sitting position prior to the start of a training session. BRJ tests were conducted on force platform equipment. The jump height and power were calculated based on the flight time using Bosco's equation. Subjects performed continuous vertical jumping from the squat position with counter movement. Subjects also did a 90-s Wingate test at 7.5% load of body weight performed at maximal effort on a different day in order to exclude the effects of fatigue and lactate levels were determined as above. Tests were performed using a Powermax II (Konami Co., Ltd.), which is a bicycle type ergometer of infinitely adjustable mechanical resistance in an automated system. Result and Discussion As expected lactate levels decreased over the 30 minute test periods, but there were significant differences between the two profiles. Data for the two methods were fit using linear regression yielding exponential functions for each test type. Maximum lactate values obtained immediately upon finishing each anaerobic power test were significantly different ($p < 0.01$). The Wingate test average max lactate level was $20.6 \pm 3.1 \text{ mmol/L}$, while for the BRJ test the max lactate level was $13.9 \pm 3.1 \text{ mmol/L}$. Lactate values at the end of the monitoring period, 30 minutes, were also significantly different ($p < 0.01$) between the two anaerobic test types: BRJ $4.4 \pm 1.5 \text{ mmol/L}$, and Wingate $9.7 \pm 3.7 \text{ mmol/L}$. The higher lactate levels at the 30 minute point in the Wingate test, indicates that cycling makes more anaerobic demands on the body than BRJ. The Wingate test thus appears better suited for analyzing overall anaerobic capacity, but the BRJ contains motions pertinent for alpine skiers. Thus, these current results do not favor one method over another, at least for alpine skiers. Reference Bosco. C, (1997) SCIENCE AND SKIING, 229-250. Petelin von Duvillard. S and Knowles. W. J. (1997) SCIENCE AND SKIING, 229-250.

COMPARISON OF CHARACTERISTIC OF ANAEROBIC POWERS BETWEEN WORLD RANKED, NATIONAL RANKED SENIOR AND NATIONAL RANKED JUNIOR ALPINE RACERS.

NAKAZATO, K., ISHIGE, Y., HIRANO, Y.

Japan Institute of Sports Sciences

[Introduction] For alpine skiing, anaerobic power is used for producing the turn and dealing with bumps of surface (Kröll J et al., 2010). Aerobic power is used for continuing turns in entire runs, recovery between runs and competitions and keeping physical condition for a competition season (Neumayr G et al., 2003). To achieve success, alpine racers train both anaerobic and aerobic energy systems. However, the target values are required for the training. The aims of this study were to compare the anaerobic powers within world ranked, national ranked senior and junior alpine racers. [Method] All subjects (world ranked (WR); n=2, national ranked senior (NS); n=10 and national ranked junior (NJ); n=9) were members of the Japanese national team in the tested year. Measured parameters were the following: height (cm), weight (kg), % body fat (%BF: %), fat free mass (FFM: kg), isokinetic knee joint torque (IKKT: Nm/BW), vertical jump height (VJ: cm), counter movement jump height (CMJ: cm), squat jump height (SJ: cm), rebound jump height (RJ: cm) and repeated squat jump height (RSJ: cm). Furthermore, FIS point of slalom (SL) and giant slalom (GS) were obtained from the official FIS website. One-way ANOVA was used for comparisons between the results of senior and junior anaerobic power ($p < .05$) performed by SPSS Statistics 19. Due to the small number of subject from world ranked races, no statistical calculation was used for comparison. [Result] All results of mean values from each group were following : IKKT of right leg extensor (Nm/BW); WR : 4.3, NS : 3.6 and NJ : 3.4, IKKT of right leg flexor (Nm/BW); WR : 2.0, NS : 1.9 and NJ : 1.8, VJ (cm); WR : 55.6, NS : 53.3 and NJ : 52.7, CMJ (cm); WR : 52.0, NS : 47.2, NJ : 45.4, SJ (cm); WR : 46.2, NS : 42.9, NJ : 41.3, RJ (cm); WR : 35.9, NS : 34.0 and NJ : 33.5 and RSJ (cm); WR : 45.6, NS : 44.0 and NJ : 41.2. There were no significant differences between anaerobic powers from the NS and NJ. Although not statistically different, all results of the WR were greater than NS and NJ races, and FIS point of SL from WR was smaller than NS and NJ. [Discussion] Junior races have had already same anaerobic power to senior racers. Greater anaerobic power from the world ranked racers was observed compared to national ranked senior and junior races. Remarkably, fat free mass from world ranked racers was greater than the other skiers (WR : 71.3kg, NS : 65.9kg, NJ : 65.8kg). This difference would influence the relative anaerobic power tests results. Conclusions of this study were to achieve success in the world, senior and junior alpine racers should train anaerobic powers and on snow training. SPRINT PERFORMANCE AND MAXIMAL STRENGTH: FOURTY YEARS AFTER... AN ANALYSIS OF MASTER SPRINTERS

PAOLI, A.1, MORO, T.1, MARCOLIN, G.1, ROSSATO, E.2, BIANCO, A.3

University of Padova, Padova, Italy, University of Palermo, Palermo, Italy

Introduction The age-related loss of strength and power is a well known phenomenon but the relationship between this loss and sprint performance has been not, still now, directly investigated. Therefore, the aim of our study was to analyse the decline in sprint and maximal strength performance in master sprinters. Methods We studied 7 master males sprinter aged 57 ± 6.1 yrs who recorded their 1RM on bench press and squat at the age of twenty. We used Italian Track and Field Federation historical data to get athletes' better performance on 100 mt at the age of twenty. We compared those data with the actual time on 100 mt, moreover we measured 1RM on squat and bench press to compare with 1RM recorded at twenty. We measured also squat jump (SJ) and counter movement jump (CMJ) performance. Results As expected there was a significant decreases in all measured performance: bench press from 89.28 ± 7.87 to 54 ± 14.45 ($p < 0.0001$), squat form 177.14 ± 50.57 to 84 ± 17.11 ($p < 0.0001$) and 100 mt time from 11.13 ± 0.11 to 13.76 ± 1.66 ($p < 0.005$). There was no significant correlation between 100 mt performance and bench press or squat 1RM at twenty (no data are available about SJ or CMJ at that time), moreover no significant correlation was found between current 100 mt performance and SJ, CMJ or bench press 1RM. A significant correlation was found instead between squat 1RM and current 100 mt performance ($r^2 = 0.74$, $p = 0.013$) Discussion Our data suggest that whilst there is no correlation between lower limb strength performance (squat) and 100 mt performance at the age of twenty a correlation could be found at the age of 55-60. Interestingly no correlation was found between lower limb power index (SJ and CMJ) and current 100 mt performance. Our data suggest that in older sprint athletes lower limb strength could be related with sprint performance. Contact antonio.paoli@unipd.it

EFFECTS OF RECREATIONAL FOOTBALL PERFORMED ONCE A WEEK ON CARDIOVASCULAR RISK FACTORS IN MIDDLE-AGED MEN. A RANDOMISED CONTROLLED TRIAL DESIGN.

BEATO, M.1, IMPELLIZZERI, F.M.2, CORATELLA, G.1, SCHENA, F.1

1:University of Verona (Verona, Italy); 2:Schulthess Clinic (Zurich, Switzerland)

Introduction It is well established that there is a strong relationship among physical activity, cardiovascular diseases and mortality. International guidelines recommend at least 150 minutes per week of moderate intensity aerobic training in order to achieve health benefits. Considering the lack of time the major barrier to active life style, the same benefits could be achieved also with lower amount of the recommended training volume. Regular recreational football training induces lowering blood pressure, heart rate at rest, fat percentage, maximal aerobic power (VO_{2max}) and LDL cholesterol (Bangsbo et al., 2014; Krstrup et al., 2013). Despite the popularity and wide diffusion of this sport, no one has investigated the effect of one session per week on cardiovascular risk factors. This study analysed the effect of 1-hour football session per week on middle-aged men. Methods This study used a randomised controlled trial design. Participants were randomized between Football Group (FG) and Control Group (CG). FG performed supervised recreational football training (5-a-side futsal match) on 36 x 18.5 meters synthetic indoor once per week (1 hour) over 3 months. Results After 12 training weeks, VO_{2max} and maximal aerobic speed (MAS) improved in FG respectively of 4.4% ($p = 0.002$) and 5.95% ($p = 0.01$). SBP and MBP improved respectively of 2.5% ($p = 0.04$) and 2.2% ($p = 0.044$) in FG, while DBP didn't change during protocol period ($p > 0.05$). CG didn't show any meaningful variation over the training period. Anthropometric and blood parameters did not change in both FG and CG during the study. Discussion This study is the first examining the effect of 1-hour recreational football session per week on cardiovascular risk factors. Recreational football activity produces health benefits improving VO_{2max} and blood pressure parameters in middle-aged men. This study may have important implications on the prevention of cardiovascular disease and for designing health programs. References Bangsbo J, Junge A, Dvorak J, et al. (2014). RUGBY: WHY SANZAR NATIONS WIN SO CONSISTENTLY ?

ALPUIM, J.

Instituto Federal de Brasília

Introduction In International Sporting Success, there are several areas of research trying to determinate the critical. And, in spite of paying much bigger salaries, and having much more players, evidence shows that England and France national rugby teams underperform, compared to South Africa, New Zealand and Australia (SANZAR nations). Therefore, the aim of this PhD research was to find some indications on why SANZAR nations win so consistently. Methods The methodology used in this research was a bibliographic review, exploratory interviews to SANZAR players and coaches, in Portugal and Brasil. Then five Dimensions were drawn: Balanced Competitions, Resources, Public Policies, Branding and International Strategy. Three hypothesis were raised. We tried to figure out which indicators would best suit this research, to build the Questionnaire, which was applied in 87 interviews on local stakeholders (CEOs and Presidents), in a four months field research. Some semi-structured interviews took place, to understand and connect the data researched. The data was then analyzed through SPSS. Results Three countries handled the entire process of professionalization, from 1995, in a completely different pathway from european rugby. Club rugby remains mainly amateur, with representative rugby having an important significance to all three countries researched, and it's only semi-professional. All clubs' competitions are city-based, with compulsory grade teams. Super Rugby and International Teams are fully professional, with a Calendar built to promote sporting success, in all four-tier competition levels. There is no National Governments money in all three countries' rugby, although there are significant public policies that help rugby. The percentage of Pacific Islanders in New Zealand and Australian rugby is above 35% of professional players, most of them raised from local immigrants. There are still racial issues on South African rugby. Travelling so much is believed for some important stakeholders as a major reason for success. Discussion Whether this results can or will be replicated, either in Portugal or Brasil, we'll have to wait. In both cases, there are enough data to replicate. Although this research was geographically limited, the sample was a very strong one. In future researches, we would try to reproduce this study at High Schools, Women, 7s, and in under represented regions. Mini-Orals**MO-PM37 Training & Testing: Children****THE EFFECT OF TASK-SPECIFIC PHYSICAL THERAPY ON THE MABC2 IN CHILDREN WITH DCD**

WOLFGRAM, J.1,2, BERGER, M.A.M.1, VAN DER KAMP, J.2, DE KLOET, A.J.1,3, BEEK, P.J.2

1 The Hague University of Applied Sciences; 2 Vrije Universiteit Amsterdam; 3 Sophia Revalidatie

Introduction Children with DCD have difficulties with fine and/or gross motor skills, resulting in slower and less accurate motor performance than their peers (APA, 2013). They participate less often in physical and group activities, making them vulnerable to social isolation and prone to health issues later in life. It has been shown that, on average, they have lower self-esteem and self-worth, higher BMI and lower muscle strength (Rivilis, et al., 2011; Zwicker et al., 2012). To date, however, there has been limited research on interventions designed to improve motor skills in children with DCD. The aim of the present study is to evaluate the effect of task-specific physical therapy on the motor skills of children with DCD measured on the MABC2 by scrutinizing the patient files of DCD-children. Method Clinical files of 75 children (4-14 years), diagnosed with DCD, will be used to acquire data on motor skill performance. MABC2 scores will be registered at base-line and at the end of rehabilitation. Descriptive statistics will be presented as mean and standard deviations. Paired sample t-tests will be used to compare pre- and posttests on the MABC2 scores. Results Preliminary findings based on the data of three clinical patients show that all three children (mean age 8.7 yrs., base-line MABC2 1st or 2nd percentile) score well over the 15th percentile (ranging from 16 up to 75) after physical therapy (average of 2 times pw, 30-50 min, 25 weeks). The therapy sessions focused on improving balancing skills and aiming and catching skills. Discussion The preliminary findings suggest that dedicated motor skill training might be effective in improving the motor skills of children with DCD. After physical therapy, the children's scores on the MABC2 are within the normal range instead of being clinical. Further analyses will be conducted to determine the relationships between age, gender, comorbidity, duration and nature of the training given, and improvements in the outcome scores on the MABC2. 1Sports Medicine Unit, Umeå University, Sweden 2Faculty of P.E. & Sports Science, National & Kapodistrian University of Athens, Greece 3Medical School, National & Kapodistrian University of Athens, Greece Introduction Performance in gymnastics is the result of the optimal combination of muscle strength, speed and flexibility (Bassa et al., 2002). The purpose of the present study was to investigate differences in physiological characteristics between prepubescent female artistic and rhythmic gymnasts. Methods Fourteen prepubescent female rhythmic gymnasts (RG) (age: 10.8 ± 1.0 yrs, body weight: 31.6 ± 4.1 kg, body height: 139.2 ± 7.4 cm) and eleven prepubescent female artistic gymnasts (AG) (age: 10.0 ± 1.4 yrs, body weight: 29.7 ± 5.2 kg, body height: 136.0 ± 9.1 cm) participated in this study. All subjects participated regularly (≥ 4 days/week) in sport specific training and had a training experience of 4.6 ± 1.5 yrs. Anthropometric characteristics as well as aerobic capacity (20m beep test), flexibility (sit and reach test), lower limbs strength and explosiveness (squat and countermovement jumps respectively), speed (20m sprint) and agility (agility T-Test) were measured. Differences between groups were ana-

lyzed using student's t-test. Results are presented as mean \pm SD. Results There were no statistical differences between groups in age ($p=0.16$), body weight ($p=0.31$), body height ($p=0.35$), flexibility ($RG=15.4 \pm 3.8$ vs. AG= 16.2 ± 5.1 cm, $p=0.65$) and agility ($RG=14.8 \pm 1.1$ vs. AG= 14.9 ± 1.3 cm, $p=0.81$). Artistic gymnasts performed significantly better than rhythmic gymnasts in speed ($RG=4.1 \pm 0.2$ vs. AG= 3.8 ± 0.1 sec, $p<0.01$), lower limbs strength ($RG=21.5 \pm 3.0$ vs. AG= 26.4 ± 4.2 cm, $p<0.01$) and explosiveness ($RG=26.1 \pm 4.1$ vs. AG= 30.8 ± 5.5 cm, $p<0.05$), while rhythmic gymnasts performed better in aerobic capacity ($RG=1234.3 \pm 288.2$ vs. AG= 968.9 ± 172.4 m, $p<0.05$). Discussion The results of the present study indicate that sport specific training in prepubescent female athletes seems to affect their physiological characteristics according to sports' demands. Both sports demand stability and control of body movement, but since artistic gymnastics is characterized by short and explosive efforts (Mello et al., 2014), artistic gymnasts seem to perform better in sprint and strength tests, while rhythmic gymnasts seem to be more aerobically trained. ACUTE METABOLIC, HAEMATOLOGICAL AND BODY COMPOSITION CHANGES IN AN 120 KM ENDURANCE CYCLE RACE

HEAZLEWOOD, I.

Charles Darwin University

Introduction Acute responses to endurance events such as triathlon and cycle races have focused on haematological changes, hydration status and physiological factors limiting endurance exercise capacity such as oxygen consumption, exercise economy, lactate threshold, available carbohydrates and fats/lipids and genetics. The research aim was to determine acute responses of metabolic, haematological, pulmonary and body composition changes to a 120km cycle race. Methods The research design, and approved by CDU ethics committee, was a pretest to posttest repeated measures design and data were collected before/after 120km race and participants were predominantly masters level cyclists (male n=8, mean age=50.6yrs, sd=+/-6.6; female n=9, mean age=47.8yrs, sd=+/-12.8). Data included age, sex, height, weight, waist circumference, hip circumference to calculate body mass index (BMI) and waist/hip ratio. Body composition and mass were evaluated by bioelectric impedance/analogue scale for body mass, percentage body fat, fat mass in kg, fat free mass (FFM) in kg, total muscle mass in kg, total body water (TBW) in percent and mass in kg, body muscle mass (BMM), bioelectrical impedance in ohms. Haematological factors were packed cell volume (PCV), triglycerides, blood lactate, haemoglobin and glucose. Basal metabolic rate (BMR in kJ/day) was assessed via the bioelectric impedance system with BMR estimation recursion formula multiple regressive analysis using FFM scores. Data were pooled to increase sample size for statistical analysis and a paired t-tests with Bonferroni multiple-significance-test correction was applied. Results Mean finish time was 178.95 and s.d. +/- 43.27 mins. Significant changes occurred in body mass (pre 75.79 vs. 74.33kg , $p<0.001$), BMI (24.00 vs. 23.55, $p<0.001$), PVC (45.43 vs. 44.11, $p<0.001$), blood lactate (3.02 vs. 5.18 mM, $p=0.008$), BMR (7516 vs. 7632kJ, $p=0.015$), % fat (19.52 vs. 16.11%, $p<0.01$), fat mass (14.72 vs. 11.93kg, $p<0.001$), total muscle mass (58.29 vs. 59.46kg, $p=0.008$), bioelectric impedance (577 vs. 542 ohms, $p<0.001$), and trunk fat mass (8.14 vs. 5.97kg, $p<0.001$). Discussion As expected acute changes occurred as significant decreases in total body mass, BMI, PVC, fat mass and bioelectric impedance attributed to water/fluid loss and utilisation of fat/lipid substrates. Significant increases as expected occurred in BMR and blood lactate. All changes indicated a reasonable physical work tolerance in the athletes reflecting positive training adaptations. ADOLESCENT AWKWARDNESS ON THE SPRINT MOTION IN JAPANESE ELEMENTARY SCHOOL CHILDREN

KOKUDO, S.

Kobe University

The adolescent awkwardness of sprint was investigated from the speed decline; however, the awkwardness of the motion is unclear. PURPOSE: To determine the adolescent awkwardness on the sprint motion in elementary school children. METHODS: Observational sprint motion causal model, which includes 36 checkpoints, was developed based on the biomechanical findings and the descriptive checkpoints of previous studies. All of the observation point was evaluated in the 2-3 category. Intermediate 50m sprint speed (SS) and sprint motion (SM) of 533 children, 1st - 6th grade of elementary school, were recorded by sensor timer and digital video cameras. Their forms were played in slow motion or frame-by-frame, and 4 investigator evaluated the checkpoints. Based on the categorical factor analysis, 25 checkpoints belonged one dimensional scale. These item characteristics, item difficulty and discriminant power, and sprint motion score (SMS) of each subject were calculated applying item response theory. RESULTS: The correlation coefficients between SS and SMS were $r=0.608$, $p<0.01$ for boys and $r=0.599$, $p<0.01$ for girls. The SS of both boys and girls were developing linearly. Although the SMS increased linearly until grade 4, the score was not improved at grade 5 (G5) and grade 6 (G6). Focusing on G5 and G6 children, the children was separated into 2 groups; short group (SG) (<140cm for G5, <147cm for G6, the criteria was based on the growth index) and Tall group(TG). The SMS of TG was less than that of SG (TG: -0.17+1.10 vs. SG: 0.23+0.84 for G5 boys, TG: 0.07+1.02 vs. SG: 0.24+0.69 for G5 girls, TG: -0.10+0.63 vs. SG: 0.06+0.61 for G6 girls) except G6 boys (TG 0.58+0.95 vs. SG 0.57+0.58). The correlation coefficient between SS and SMS is significant ($p<0.05$) for both TG and SG of G5 (TG: $r=.763$ and SG: $r=.560$ for boys, TG: $r=.635$ and SG: $r=.595$ for girls) and for only SG of G6 (SG boys: $r=.550$, SG girls: $r=.589$ vs. TG boys: $r=-.160$, TG girls: $r=.170$). The uncorrelated results on TG of G6 is presumed to be due to adolescent awkwardness. CONCLUSIONS: The sprint speed and sprint motion do not develop linearly during growth spurt age. The relationship between sprint speed and sprint motion becomes very low during growth spurt phase on G6 children because of adolescent awkwardness. COMPELLING OVERUSE INJURY INCIDENCE IN YOUTH MULTISPORT ATHLETES

REJEB, A.

ASPETAR

Do not insert authors here Introduction Injury epidemiology is imperative for the development of prevention strategies. Apart from football, little is known about injury epidemiology among young elite athletes. The aim of the present study is to examine the incidence of injuries sustained by adolescent highly trained multisport athletes and to compare injury-related variables to exposure data. Methods The injury data were prospectively collected from 152 male adolescent athletes using an injury surveillance system and training exposure data

during 5 consecutive seasons according to injury type, body part, severity and mechanism. An injury was recorded as a physical complaint requiring the attention of the medical staff. Overuse injuries were defined as injuries resulting from the repetition of micro-trauma without a recognizable mechanism and with insidious onset. The severity of an injury was based on time-loss criteria: minor (1–7 days), moderately serious (8–28 days), serious (>28 days–6 months) or long-term (>6 months) (Timpka et al 2014). The training season was from September to the end of June. Results The mean age of the athletes was 15.1 ± 1.85 years. Altogether 643 injuries were documented in 152 athletes. Of these injuries, 87% were time loss (TL) injuries with an incidence of 4.8 per 1000 hours; (95% confidence interval [CI], 4.4–5.2.0). The prevalence of growth related injuries accounted for 22 %. Exposure to training was associated with an increase of overuse injuries (relative risk [1.03]). The most commonly diagnosed type of injury was muscle and tendon injuries (30.1%). Most injuries were located at the lower extremities (67%), with the majority affecting the foot and ankle (22%). There were 53% minor injuries, 34% moderately serious injuries, and 13% serious injuries. TL overuse injuries amounted to 44% with an incidence of 2.4 (95% confidence interval [CI], 2.1–2.7) per 1000 hours exposure. Injury occurrence followed a seasonal fluctuation trend peaking in March. Discussion This study revealed high rates of overuse injuries resulting in time loss, although most injuries were minor. Even though many injuries were rated as minor which does not cause immediate impairment, these injuries in adolescents may have long-term consequences. A higher prevalence of growth injuries compared to previously reported studies. Comparing our findings on time-loss injuries are consistent with other studies of similar methodology in youth soccer athletes. Overuse injuries of the knee and traumatic injuries for the ankle were commonly reported in our study, suggesting a need for the implementation of specific injury prevention strategies. THE IMPACT OF LONG-TERM ATHLETIC TRAINING ON MOTOR, COGNITIVE, AND ACADEMIC PERFORMANCE IN YOUTH ATHLETES

BORDE, R., GRANACHER, U.

University of Potsdam

Introduction: Several sports (e.g., gymnastics) demand an early start into long-term athlete development because peak performances are achieved at a relatively young age (Myer et al., 2015). The challenging combination of extensive training loads and academic demands may impede youth athletes' cognitive and academic performance (Myer et al., 2015, Brettschneider, 1999). The aims of this study were to examine how long-term athletic training (AT) affects youth athletes' motor, cognitive, and academic performances. Methods: The study was conducted at a German primary school with a specific program for youth athletes. Overall, 45 prepuberal fourth graders from a youth athlete class (YC) and a regular class (RC) participated in this study. Twenty students were enrolled in YC (age 9.5 ± 0.5 years, Tanner I+II) and 25 students in RC (age 9.6 ± 0.6 years, Tanner I+II). Over one school year YC performed AT that consisted of physical education (PE) and sport-specific training (i.e., gymnastics, swimming, athletics, football, BMX) while RC conducted PE only. All students were tested for their motor (i.e., 20-m sprint, star-agility run, 1-kg ball push, standing long jump, stand-and-reach test, single leg stand, 6-min run), cognitive (i.e., d2-test), and academic performance (i.e., reading [ELFE], writing [Hamburger Schreibprobel], calculating [Deutscher Mathe-matiktest]). In addition, we obtained German, English, Mathematics, and PE marks from the school report. Analyses were conducted using an ANCOVA model. Further, Cohen's d was calculated. Results: At baseline, YC performed significantly better than RC in 4 out of 7 motor performance tests ($p < 0.01$; $d = 0.61$ – 2.29), but not in cognitive and academic achievements. The AT volume amounted to 585 min/week for the YC and PE volume was 156 min/week for the RC. After the one-year intervention, significant differences were found in 6 out of 7 motor performance tests ($p < 0.05$; $d = 0.75$ – 1.40) as well as in German and PE marks ($p < 0.05$; $d = 0.75$ – 1.56) in favor of YC. Yet, AT did not produce any significant differences between YC and RC in the d2-test, in writing, reading, calculating, and in Mathematics and English marks ($p > 0.05$; $d = 0.20$ – 0.43). Discussion: Our results revealed that a one-year AT in addition to PE improved motor and selected academic performances in YC compared to RC. It can be concluded that intensive training in combination with regular school demands does not impede youth athletes' cognitive and academic performances. References: 1. Myer, G.D., N. MO-PM44 Molecular Responses to Exercise

EFFECTS OF SPRINT AND ECCENTRIC TRAINING ON APOPTOSIS AND MHC mRNA IN RAT SKELETAL MUSCLES

KHALEDI, N., AZAD, M., HEDAYATI, M.

kharazmi university, Shahid Beheshti University of Medical Sciences

Introduction Apoptosis or cell programmed death plays important roles in retain of tissue and cellular homeostasis. Many transcription factors regulate it that one of them is FOXO1. Also, it has been shown that FOXO1 induces fiber type transition (Sanchez et al., 2014). We aimed to see the effects of sprint interval exercise and eccentric exercise on FOXO1 as an apoptosis factor and fiber type transition in rat skeletal muscles Methods Forty young male Sprague-Dawley rats (190–235 g) divided into 5 groups of 8; chronic and acute sprint interval (CSI and ASI), chronic and acute eccentric (CE and AE) and control (C). ASI was running with 10 m/min to 85 m/min which gradually increased in 3 consecutive days that included 7 sets of 1 min with rest interval of 3 min in between. CSI was sprinting 1 min and 2–5 min rest between sets (6–10 sets/days, 5–6 days/weeks) on treadmill for 9 weeks (Ogura et al., 2005). CE was running on treadmill in 3 days of week for 9 weeks, that slope and duration gradually managed from -4° to -16° and 15 min to 90 min, respectively. AE group was running with 16 m/min on -16° slope for 3 consecutive day that included 18 sets of 5 min with rest interval of 2 min in between (Chiang et al., 2009). Soleus and SVL muscles mRNA were analyzed by real-time PCR. Results FOXO1 mRNA did not change significantly in both muscles of sprint interval groups and in soleus of eccentric groups, but SVL FOXO1 mRNA levels increased by 3.92-fold in AE and decreased 0.56-fold in CE group. In soleus muscle of AE and CE groups, fast MHC isoforms mRNA expression decreased significantly and in CSI group slow MHC decreased. In SVL muscle, MHC I increased in ASI and MHC IIb decreased in CSI, MHC I, IIa and IIx increased in AE group and MHC IIa and IIx increased in CE group. Discussion AE increases and CE decreases FOXO1 mRNA in SVL muscle. Eccentric exercise produces more muscle damage that accompanies to more oxidative stress in skeletal muscles (Silva et al., 2013), that stimulates FOXO1 activation . If exercise bout repeated, adaptations stimulated such as decreased in muscle damage ,that leads to a decrease in FOXO1

activation. Changes in transcriptional activation and/or in MHC mRNA stability could be alter MHC isoforms in mRNA level (Caiozzo et al., 1996), that can represent a more important factor in fiber type transition (Yuan et al., 2011). MUSCLE DAMAGE OF BODYBUILDERS AFTER AN UNACUSTOMED STRENUOUS RESISTANCE TRAINING SESSION

BLOWFIELD, K., HAFF, G.G., NOSAKA, K.

Edith Cowan University

Introduction Muscle damage is induced by unaccustomed exercise consisting of eccentric contractions, and is best indicated by a prolonged loss of muscle function [1]. Delayed onset muscle soreness (DOMS) is considered to be a symptom of muscle damage, but its magnitude does not necessarily correspond with the magnitude of muscle damage [2]. Anecdotally, bodybuilders experience DOMS after resistance training, however no previous studies have reported muscle damage of bodybuilders. Newton et al. [3] reported faster recovery of muscle function after unaccustomed elbow flexor eccentric exercise for resistance-trained than untrained men, but found similar magnitudes of DOMS between groups. Thus, the present study tested the hypothesis that reductions in muscle function and increases in plasma creatine kinase (CK) activity following an unaccustomed training session would be small, but DOMS would still be developed in bodybuilders. Methods Ten male bodybuilders (age: 23 ± 2 y, height: 176 ± 4 cm, body mass: 85 ± 8 kg) with a minimum of 3-y resistance training experience were recruited for the study. They performed a large volume of exercises targeting the pectoral muscles, consisting of 5 exercises at 8-12 repetitions with a moderate load followed by 12 exercises to volitional failure. Muscle function measures in barbell bench throw (e.g. peak force, peak velocity), isokinetic maximal elbow extension torque and muscle pain during palpation of the clavicular and sternal portion of the chest using a visual analogue scale (VAS: 100-mm) were taken before, immediately after, and 1-3 days after exercise. Results Significant changes in all variables were observed after exercise ($P < 0.05$). For example, peak force in barbell bench throw decreased immediately ($23 \pm 20\%$) and 1 day after exercise ($9 \pm 15\%$) but returned to baseline (930 ± 129 N) by 2 days post-exercise. Additionally, other muscle function measures showed similar changes. DOMS developed after exercise and peaked 1-day post-exercise (e.g. 57 ± 22 mm for the clavicular portion of the chest). No significant changes in plasma CK activity were observed after exercise. Discussion These results were similar to that shown by the previous study of resistance-trained men [3]. Despite small decreases in muscle function 1-day post-exercise, DOMS showed higher values than the levels that the participants usually experienced after their regular training sessions. It appears that regular resistance training had conferred a protective effect against muscle fibre damage, but bodybuilders are still susceptible to DOMS, which may be associated with connective tissue damage and inflammation [2].

DYNAMICS OF SKELETAL MUSCLE DAMAGE MARKERS IN THE BLOOD AND CHARACTERISTICS ASSOCIATED WITH FULL MARATHON-INDUCED IMMEDIATE ONSET MUSCLE SORENESS

TOKINOYA, K., ISHIKURA, K., EBINA, K., KAWAGUCHI, Y., MIZUSHIMA, T., MIYAKAWA, S., NABEKURA, Y., OHMORI, H.

University of Tsukuba

Introduction It has been reported that muscle soreness occurs during or immediately after prolonged exercise, such as after running a full marathon. Our group has termed this form of muscle soreness, immediate onset muscle soreness (IOMS)[1]. It was estimated that muscle damage due to extensive mechanical stress and metabolic stress occurred with the onset of IOMS. Primary skeletal muscle damage markers with delayed onset muscle soreness after excessive exercise were as follows: creatine kinase (CK) activity, lactate dehydrogenase (LDH) level, aspartate aminotransferase (AST) level and aldolase (ALD) level in blood. These markers all displayed similar dynamics[2,3]. However, it was unclear whether these markers exhibited the same dynamics for both DOMS and IOMS. This study aimed to elucidate the dynamics of each skeletal muscle damage marker following IOMS. Methods A total of 20 subjects (males: 18; females: 2) participated in a full marathon race. Muscle soreness was evaluated using a numeric rating scale (NRS) at before (pre) and immediately after (post) exercise, at 1-4 days (Day 1-Day 4), and 7 days (Day 7) after exercise. Skeletal muscle damage markers in the blood were measured, including serum CK activity, LDH level, AST level and ALD level at each time point. Results Peak muscle soreness was immediately observed after the full marathon-induced appearance of IOMS. With regards to the skeletal muscle damage markers in blood, CK significantly increased postexercise and peaked on Day 1, with AST exhibiting a similar trend. LDH demonstrated a peak value postexercise and maintained significantly elevated levels until Day 4 compared with the pre-exercise values. However, levels began to decrease after Day 1. ALD significantly increased from postexercise and peaked on Day 3. Discussion The appearance of IOMS was confirmed because muscle soreness peaked postexercise in each body part. Blood levels of LDH, CK and AST peaked at postexercise or Day 1 after the full-marathon involving IOMS, which was clearly different from DOMS dynamics, which peaked at 3 or 4 days after extensive exercise. However, ALD peaked on Day 3 in IOMS, which was different from the other makers. These were different from similarly peaked appearances after 3 or 4 days for DOMS in these markers. Future research should investigate the characteristics of these skeletal muscle damage markers in the blood following IOMS to determine the mechanisms by which this condition occurs. References 1.) MCP-1, TNF-ALPHA AND NGF CHANGES AFTER PROLONGED RUNNING

NOVAK, J.1, TOPOLCAN, O.2, RACEK, J.3, ZEMAN, V.1

1: Institute of Sports Medicine, Medical Faculty /Plzen, Czech Republic; 2: Dept. of Immunoanalysis, Faculty Hospital /Plzen, Czech Republic; 3: Dept of Biochemistry, Faculty Hospital /Plzen, Czech R

Marathon and untra-marathon running evokes significant changes in numerous body functions. Several biomarkers prove microtraumatic damage of skeletal muscles, connected to inflammatory reaction during prolonged continuous running performance. The changes of monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor alpha (TNF alpha) and nerve growth factor (NGF) were rarely studied. PURPOSE: To determine changes of MCP-1, TNF alpha and NGF after endurance running (duration 3 to 24 hours). METHODS: 35 volun-

teeres participated in 3 different runs covering 42.2 km, 100km and/or 24-hour run. Blood samples taken prior to the run and after the finish were studied with the help of immunoanalysis. RESULTS: Significant increase after the run was observed in MCP-1 (423 ± 163 rose to 909 ± 327 pg/ml), TNF-alpha (4.08 ± 1.56 rose to 5.29 ± 2.09 pg/ml) and NGF (1.48 ± 0.66 rose to 1.95 ± 0.76 pg/ml). From the personalized medicine point of view marked differences in the reaction of individual runners were found. However, no correlations between the running duration and MCP-1, TNF alpha and NGF were observed. CONCLUSION: Changes in MCP 1 and TNF alpha after the running race of long duration may be partly explained by inflammatory overstrain reaction of athletes' muscle tissue. The mechanism of increased NGF after the race is not clear and should deserve further investigations.

IMPACT OF HFE GENE MUTATION ON EXERCISE PERFORMANCE IN MICE

DJEMAI, H., THOMASSON, R.1,2, DAMIEN, V.1,2, DESGORCES, F.1,2, DENIS, R.3, TOUSSAINT, J.F.1,2, NOIREZ, P.1,2

1 IRMES, INSEP, France, 2 EA 7329, Paris Descartes University Sorbonne Paris Cité, France, 3 BFA, Paris Diderot University, Sorbonne Paris Cité, Paris, France

Introduction Iron is essential in erythropoiesis and other metabolic and physiological functions. Hepcidin is the central protein implicated in the regulation of iron metabolism. In elite athletes, its level appears to be increased. Hemochromatosis, caused by a homozygous mutation of the HFE gene, is characterized by a low level of hepcidin and iron overload in different organs of the body. A close relationship between heterozygosity for the HFE gene and physical performance has recently been demonstrated. Indeed, athletes who access the international podiums have a high frequency of heterozygous mutation of the HFE gene (80%) (Hermine and al., 2015). The objective of the study is to evaluate the effects of the HFE gene mutation on exercise performance in HFE - / - knock-out (KO), HFE + / + wild-type (WT) and heterozygote (HT) mice. Methods Twenty four (8 KO 8 HETE 8 WT) male were used in this study. Mice were followed from the age of 7 months to 24 months. Their body composition was measured by magnetic resonance (Bruker, Germany). Rest parameters (i.e. energy expenditure (EE), VO₂, respiratory exchange ratio (RER = VCO₂ / VO₂), feeding behavior and motor activity) were analyzed over a 72 h period in 7 months old mice. All the animals performed running exercises on a motorized treadmill equipped with an indirect calorimetry system (Phenomaster, TSE, Germany) to evaluate their maximal oxygen consumption (VO₂ peak) and the maximal running speed at 75% of VO₂ peak (Vmax). Their heart function was monitored by echocardiography. Results KO mice at 7 months had a significantly higher body mass and lean mass until the age of 14 months ($p < 0.05$, $p < 0.001$). The 7 months old KO mice had a significantly lower energy expenditure than WT mice during daytime phase ($p < 0.01$). In nocturnal phase, KO mice (7 months) had a significantly greater ambulatory activity. VO₂ were significantly lower in KO mice during daytime phase ($p < 0.01$). These first results showed no significant difference of VO₂ peak (ml.kg⁻¹.h⁻¹) between the different groups. The distance (m) and the trip time (sec) observed for HT and KO mice at 7 months was significantly greater than WT mice ($p < 0.01$). RER peak is lower in KO mice after exercise than in WT mice at 7 months. These differences disappear with aging. The study of cardiac function by echocardiography showed systolic dysfunction in young and old KO mice compared to HT and WT mice. Discussion Our results show that muscle mass seems to confer selective advantage in KO mice for exercise performance. After exercise, the RER of 7 months old KO mice was lower than WT mice suggesting that their higher lean mass could improve their recovery capabilities after exercise. Finally, the systolic dysfunction might be one of the causes that could explain the higher decline in exercise performance of KO mice with age. Reference Hermine, O. et al 2015. Eighty percent of French sport winners in Olympic, World and Europeans competitions have mutations in the hemochromatosis HFE gene. Biochimie, 119, 1-5.

ASSOCIATION BETWEEN THE WEIGHT CLASS OF JUDO ATHLETES AND GENETIC POLYMORPHISMS RELATED TO THE PHENOTYPE OF SKELETAL MUSCLE

ITAKA, T.1, AGEMIZU, K.2, ARUGA, S.3, MACHIDA, S.1

1: Juntendo University, 2: Tokai University, 3: Tokai University

Introduction Genetic polymorphisms influence sports performance, physical fitness, and body size (including skeletal muscle mass, fat mass), suggesting that the weight class of judo athletes can be affected by genetic factors. However, to date, there has been no research regarding the influence of genetic polymorphisms on weight class in sports. The purpose of this study was to investigate the association between the weight class of judo athletes and genetic polymorphisms related to the phenotype of skeletal muscle. Methods The study subjects included 156 male judo athletes from top-level universities in Japan. They were divided into three groups based on weight class. "Light class" was defined as -60 kg and -66 kg; "Middle class" as -73 kg, -81 kg, and -90 kg; and "Heavy class" as -100 kg and +100 kg. DNA was extracted from their saliva and genotyped for alpha actinin 3 (ACTN3) [rs1815739], angiotensin I-converting enzyme (ACE) [rs1799752], insulin-like growth factor 2 (IGF2) [rs680], interleukin 15 receptor subunit alpha (IL15Ra) [rs2296135, rs2228059], myostatin (MSTN) [rs1805086], ciliary neurotrophic factor (CNTF) [rs1800169], CNTF receptor (CNTFR) [rs41274853], and cyclin-dependent kinase inhibitor 1A (CDKN1A) [rs1801270] gene polymorphisms. Controls were individuals from the general Japanese population with known genotyping as reported in previous studies. Genotype distribution among the weight class of the judo athletes and controls were compared using chi-square tests. Results There was a significant difference in the genotype frequency of CDKN1A gene among the Light class but not the Middle and Heavy classes, compared with the controls (Light class: 42.9% for CC, 42.9% for CA and 14.3% for AA vs. Controls: 23.9% for CC, 53.7% for CA and 22.4% for AA). However, there were no significant differences in the genotype frequency of ACTN3, ACE, IGF2, IL15Ra, MSTN, CNTF, and CNTFR genes among all the weight classes of those judo athletes. Discussion and Conclusion CDKN1A gene (p21) is essential for myogenic stem cell function, such as cell cycle and differentiation. Hence, the CDKN1A gene polymorphism may be associated with the weight class of judo athletes, although further studies are needed. STATISTICAL METHODS FOR THE ESTIMATION OF BODY SHAPE BY FITTING 3D WHOLE-BODY SCANNING DATE TO HOMOLOGOUS BODY MODEL IN JAPANESE ELITE FEMALE ATHLETES

FUNATO, K.1, KASHIWAGI, Y.1, SOMA, M.1, HAKAMADA, N.2

1: Nippon Sport Science University, Tokyo, Japan 2:Japan Institute of Sports Sciences, Tokyo, Japan

Introduction In anthropometry for the athletes such as to talent identification and development, characteristics in body shape are one of the most important parameters as the results of specific physical training and /or routine workout performed. Until now, these parameters were typically measured under manually skilled techniques in anthropometry. In recent years, high sensing techniques in whole body measurement system for humans (that is called "Bodyline Scanner", Hamamatsu Photonics K.K., Japan) was developed [1], which shape data converts to Homologous Body Model (HBM) and identify the characteristic of its shape using statistical methods [2]. The purposes of present study were to obtain 3D whole body laser scan date and by fitting HBM, statistical characteristics in body shape were to develop especially for Japanese female sedentary and athletes in different athletic levels. Methods Newly developed Bodyline scanner (BLS) was capable of digitizing whole body shape as three dimensional coordinates in the order of 2.5mm intervals in space (normal adult body shape put in ~500,000 points). The principle of the measuring method was optical triangle measurement, in which light source was using a laser diode. The color information was used to detect the position of land mark seals which was pasted on the skin according to the anatomical basis in human anthropometry. HBM was constructed by fitting the whole body laser scan date to standardized template (generic) model. Template model was used as Dhaiba model which was developed from Japanese in large populations by Digital human research group of National Institute of Advance Industrial Science and Technology (AIST). A statistical body shape model (SBSM) was developed by using principal component (PC) analysis in specific HBM group. Fifty females including athletes and sedentary persons aged from 15 to 21yrs were served as subjects. Results and Discussion Using this newly developed methods, characteristic in body shape for female athletes were evident. Softball female athletes, for example, statistically characterized body shape was as follows; 1st PC: body size such as height and limb length, 2nd PC: circumference in lower trunk and hip, 3rd PC: thickness of upper trunk. PC scores were associated with anthropometric variables and specific body shape for elite athletes could be evaluated by plotting the PC scores in x-y coordinates. Conclusion The methods for evaluating body shape statistically by fitting the whole body scan date to homologous boy model is useful for reliable prediction of specific body shape of female elite athletes. INFLUENCE OF INCREASED TRAINING VOLUME ON IRON STATUS IN WELL-TRAINED FEMALE LONG DISTANCE RUNNERS

ISHIBASHI, A.1,2, MAEDA, N.2, SUMI, D.2, GOTO, K.2

1:Japan Institute of Sports Sciences,2:Graduate School of Sport and Health Science, Ritsumeikan University

Introduction Since iron is essential for providing oxygen into working muscles during exercise, iron deficiency leads to decrement of endurance capacity in endurance events. However, mechanism for iron deficiency among endurance athletes remains unclear. The purpose of the present study was to compare iron status among three periods with different training volume in well-trained female long distance runners. Methods Sixteen female long distance runners participated in the present study. During 8 months of intervention period, fasting blood samples were collected at the onset the intervention period with lower training volume (LOW), general training period with moderate training volume (MOD) and intensified training period with high training volume (INT) to determine blood hematological parameters, iron parameters, inflammatory parameters. Psychological parameters and 3 day of food diary were also assessed. Results Body weight did not differ significantly among three periods, while lean body mass was significantly higher in the MOD and INT compared with LOW ($P < 0.05$). Hemoglobin concentration was not significantly different among three periods, but transferrin saturation (TSAT) was significant higher in INT than in LOW ($P < 0.05$). Energy intake and iron intake from daily diet was significantly higher in INT than in LOW ($P < 0.05$). However, 44% (LOW), 25% (MOD) and 25% (INT) of total subjects were evaluated as iron deficiency. Discussion The iron status was improved during intensified training period, with concomitant increase in iron intake. However, in spite of increase in iron intake during intervention period, 25% of the subjects remained iron deficient during intensified training period. Therefore, increased iron intake was not fully successful to overcome iron deficiency among female long distance runners. A potential mechanism may be augmented hepcidin (iron regulating hormone), which plays a role in inhibiting iron metabolism (Ziemann et al. 2013). COMBINED ORAL CONTRACEPTIVES INCREASE OXIDATIVE STRESS INCREASE IN FEMALE ATHLETES

CAUCI, S., MIGLIOZZI, F., VENUTI, I., LINUSSIO, M., BULIGAN, C., FRANCESCATO, M.P.

University of Udine

INTRODUCTION In athletes oxidative stress is a recognized causative agent of muscle redox imbalance that can promote muscle fatigue and injury, thus impairing the exercise performance (Jackson et al. 2011). However, so far, few studies focused on female athletes. Some evidence suggested that female athletes were more susceptible to oxidative stress than male athletes (Sackeck et al, 2000), but the use of contraception was not addressed. We aimed to investigate oxidative stress in sportswomen of different disciplines according to oral combined contraceptive (OC) use and lifestyle/alimentary habits. **METHODS** Italian sportswomen, regularly performing 5 or more hours weekly of sport activity, including training and competitions ($n=144$; mean age 23.4 ± 4.2 years; body-mass-index 21.2 ± 2.2 kg/m 2 ; sport activity 9.2 ± 4.1 hours/week) were analyzed, 48% were volleyball players, followed by soccer players (12.5%), track-and-field sports (10.4%), and other disciplines. Oxidative stress was evaluated by blood lipid peroxidation and free oxygen radical defense levels (according to Francescato et al, 2014) (FORT and FORD Units, respectively, Callegari, Italy) in OC-users ($n=42$) compared to non-OC-users. Stratification of lipid peroxidation was performed by the threshold of 310 FORT Units as high level (Kamhieh-Milz and Salama 2014). **RESULTS** Elevated oxidative stress levels (≥ 310 FORT Units) were found in 92.9% of OC-users and in 23.5% of non-OC-users (OR=42, 95%CI, 12-149).

Continuous values of oxidative stress FORT Units were 2-fold higher in OC-users versus non-OC-users ($p<0.001$), and were inversely related to free radicals defense FORD Units in OC-users ($p=0.01$). Hours of exercise/week, age, coffee consumption, and smoke had no association with continuous values of oxidative stress. In non-OC-users only, oxidative stress was positively correlated with weight ($p=0.009$), BMI ($p=0.002$), and inversely correlated with chocolate ($p=0.009$), and fish consumption ($p=0.029$). CONCLUSIONS Oxidative stress in competitive athletes is a matter of study and debate, because markedly elevated oxidative stress in athletes could be detrimental to physical activity and elevate cardiovascular risk (as effort thromboembolism). Further research is needed to extend our results, to clarify the biochemical pathways leading to increased lipid peroxidation and reduced anti-oxidant defense, and to elucidate the potential effects on athletic performance according to gender. OC use should be considered by clinicians, coaches, sport trainers and athletes themselves when developing strategies to reduce oxidative stress in female athletes. THE ROLE OF ORAL CONTRACEPTION IN THE EFFECT OF BODY TEMPERATURE ON SKIN BLOOD FLOW DURING EXERCISE IN THE HEAT

MINAHAN, C., MELNIKOFF, M., QUINN, K.

Griffith University

Introduction Progestogen-related elevation in core body temperature (T_c; Rogers and Baker 1997) is observed in normally-menstruating women (WomenNM) during the luteal phase of the menstrual cycle and in women taking a combined oral contraceptive (WomenOC) when compared to WomenNM during the follicular phase (Kolka et al. 1997; Grucza et al. 1993). Consequently, there is an increasing requirement for skin blood flow (BFsk) to mediate T_c in WomenNM in the luteal compared to the follicular phase during heavy-intensity exercise in the heat (Kolka et al. 1997). The purpose of this study was to compare T_c and BFs_k responses to exercise in the heat between WomenNM (follicular) and WomenOC. Methods Eight WomenOC and eight WomenNM performed two i. 22 (TEMP), and ii. 35 (HEAT) degrees Celsius, 3-stage cycling trials comprising T_c and BFs_k measurements at laboratory arrival (i.e., baseline; BL), and after 60 min of seated rest in the prescribed environment (i.e., REST), 30 min of cycling at 90% of lactate threshold 1 (LT1; Stage 1), 15 min at 135% LT1 (Stage 2), and 7.5 min at 180% LT1 (Stage 3). Fully-factorial ANOVA with LSD pairwise comparisons was used to determine statistically significant differences at $p < 0.05$. Results WomenOC had higher T_c compared to WomenNM from BL until 22.5 min of Stage 1 in both conditions ($p < 0.05$). There were no further differences in T_c between the two groups in either trial ($p > 0.05$). The relative (%) increase in BFs_k from REST to 7.5 min of exercise at LT1 was greater in the HEAT compared to the TEMP trial for both groups ($p < 0.01$). BFs_k was stable during Stage 1 of the TEMP trial ($p > 0.05$) and increased similarly in both groups at Stage 2. After the sharp increase in BFs_k from REST to 7.5 min of Stage 1 during the HEAT trial, no further change in BFs_k was observed for WomenNM ($p > 0.05$), whereas BFs_k increased to 15 min of Stage 1 in WomenOC ($p < 0.01$) and remained elevated. Discussion The findings of the present study demonstrate that women taking a combined monophasic oral contraceptive pill exhibit greater BFs_k compared to normally-menstruating women (follicular) that is only evidenced beyond a certain requirement for heat loss i.e., during exercise in a hot, but not temperate, environment. This redistribution of blood flow during exercise would require increased cardiac output to maintain muscle perfusion during high-intensity exercise. 1. Rogers, S., Baker, M. (1997). CHANGES IN ESTROGEN AND PROGESTERONE LEVELS DO NOT RELATE WITH VO₂ DURING MENSTRUAL CYCLE IN FEMALE ATHLETES

BARBA MORENO, L., CUPEIRO, R., SANTIAGO ROMERO, E., CARBONERO, J., PEINADO, A.B.

Technical University of Madrid

INTRODUCTION The most relevant hormones during menstrual cycle are estrogen and progesterone. These hormones levels change during the different phases of the menstrual cycle and may improved or decreased performance at different times throughout menstrual cycle (1). For this reason, those hormonal variations have been related with the difference VO₂ values in woman athletes (1-3). Thus, the aim of this study is to investigate the relationship between hormone levels along menstrual cycle and VO₂ during a constant endurance exercise. METHODS Six endurance-trained women (58.7 ± 5.07 kg, $163, 2 \pm 4.9$ cm and 37.1 ± 4.3 yrs) performed a maximal graded test and three continuous running sessions of 40 min at 75% of the VO_{2max} velocity (VO_{2max}) on each phase of their menstrual cycle (early follicular phase, midfollicular phase and luteal phase). VO₂ values of the two intermediate min of each 10 min period were averaged and considered for the analysis. A blood sample was obtained on each phase to measure estrogen, progesterone, FSH and LH levels. RESULTS There was not significant correlation between VO₂ and estrogen, progesterone, FSH or LH levels ($p > 0.05$) on early and midfollicular phases. However we found a borderline significant correlation in luteal phase between VO₂ and progesterone ($r = 0.771$; $p = 0.072$), and between VO₂ and FSH ($r = 0.771$; $p = 0.072$). DISCUSSION We found an increase on VO₂ as progesterone and FSH levels rise, but only during luteal phase. These relations have not been previously reported, maybe because most of the studies compare VO_{2max} instead of VO₂ at a submaximal and constant intensity (1-3). These data suggest that from the two most relevant hormones of the menstrual cycle, the variations of progesterone during the luteal phase can affect VO₂ levels, which could finally influence in athlete performance. INFLUENCE OF MENSTRUAL CYCLE ON RESPIRATORY AND PERCEIVED EXERTION VARIABLES: A PILOT STUDY

ALFARO, V.M., BARBA-MORENO, L., CASTRO, E.A., PEINADO, A.B., ESTÉVES, N.K., GALINDO, M., CARRERA, A., CUPEIRO, R.

Polytechnic University of Madrid

Introduction Respiratory variables and Rating of Perceived Exertion (RPE) can vary depending on the menstrual cycle phase (Smekal et al., 2007; Janse de Jonge, 2003). Though many researches compare the luteal (LP) and follicular phase, there are few studies which split the latter into early follicular phase (EFP) and mid follicular phase (MFP), although hormone levels are different between both phases (Smekal et al., 2007; Janse de Jonge, 2003). Therefore, the main objective of this study is to compare the three phases of the menstrual cycle heading to respiratory variables as well as the RPE. Methods Seven endurance trained females (37.1 ± 4.3 yrs; 58.7 ± 5.1 kg; 163.2 ± 4.9 cm; 50.17 ± 2.83 VO_{2max}) performed a maximal graded test and three continuous running sessions of 40 min at 75% of the VO_{2max} velocity

at each phase of their menstrual cycle (EFP, MFP and LP). Ventilation (VE), VO₂ and Respiratory Exchange Ratio (RER) were measured; values of the two intermediate min of each 10 min period were averaged and considered for the analysis. RPE was measured by Borg 6-20 Scale every 10 min. Results Friedman ANOVA showed no significant differences in RER and RPE among menstrual cycle phases. However, a trend to significance was found in the 20-30 period ($p=0.06$) and 30-40 period ($p=0.06$) for VE, presenting higher VE during these periods on LP session (20-30 period=84.5±9.6 l/min; 30-40 period=86.2±9.8 l/min) than VE on EFP session (20-30 period=79.2±10.12 l/min; 30-40 period=81.56±11.8). Another borderline significance appears for VO₂ measured within 20-30 period ($p=0.084$), being higher for the value of LP session (44.18±6.09 ml/kg/min) than the one of MFP (43.46±3.17 ml/kg/min). Discussion Some studies reported higher VE and VO_{2max} levels on LP compared to the follicular phase for athletes exercising at 80% and 100% VO_{2max} (Williams et al., 1997; Janse de Jonge, 2003). Our results suggest a higher VE and VO₂ from min 20 of exercise during LP, being in accordance to other studies (Smekal et al., 2007; Janse de Jonge, 2003). Thus, indicating that during LP women seem to have a poorer running economy, though they are not large variations. References Janse de Jonge XAK. (2003). Sports Med, 33 (11): 833-851. Smekal G et al. RELATIONSHIP BETWEEN HOFFMANN REFLEX AND VERTICAL JUMP DURING MENSTRUAL CYCLE PHASES IN YOUNG JAPANESE WOMEN

MURATA, M.1, YAMAGUCHI, H.2, SEKI, K.3, TAKAHARA, T.4, SAITO, T.5, ONODERA, S.5

1Graduate School, Kawasaki University of Medical Welfare, 2Kibi International University, 3University of Marketing and Distribution Sciences, 4University of Human Arts and Sciences, 5Kawasaki Universi

Background Menstrual cycle reflects the reproductive function in women, and the menstrual cycle phase (MCP) affects physiological functions. MCP may impact the physical performance and athletic capability. The spinal cord is the final common pathway for all motor behavior, and the Hoffman reflex (H-reflex) can be used to evaluate activity in the spinal cord. Previous studies have investigated the H-reflex differences between men and women and have found that the modulation of spinal excitability is stronger in women than in men. The present study investigated the relationship between spinal α-motoneuron excitability and vertical jumps during MCP in young Japanese women. Methods Five healthy women volunteered to participate in this study. Three MCPs were defined: the menstrual phase, follicular phase, and luteal phase. The H-reflex was measured twice during each phase with the subject in the prone position. The H-reflex of soleus muscle was evoked by electrical stimulation at the tibialis nerve in the popliteal fossa with a single square pulse of 1-ms duration. The maximal M-wave (Mmax) amplitude was defined as the peak amplitude of the M-wave in response to increases in stimulus intensity. The H-wave was evoked by electrical stimulation intensity recorded in 20% of the Mmax amplitude. The vertical jump was used as the performance measure. Results and Discussion The ratio of the maximum amplitude of the H-wave to the Mmax amplitude of varied according to MCP. The change in spinal α-motoneuron excitability associated with MCP was probably related to changes in the reproductive hormone levels; therefore, the response was likely to be different in each phase. H-waves of the subjects were as follows: menstrual phase, 32.1 ± 14.8% (mean ± standard deviation); follicular phase, 32.4 ± 15.1%; and luteal phase, 32.4 ± 16.2%. The vertical jumps of the subjects were as follows: menstrual phase, 41.7 ± 3.5 cm; follicular phase, 43.7 ± 3.5 cm; and luteal phase, 43.4 ± 2.3 cm. When we assumed a standard menstrual-phase, each phase was lower or higher than the H-wave in the follicular phase for decreased spinal excitability. The relationship between spinal α-motoneuron excitability and performance conforms to MCP. The change in spinal α-motoneuron excitability related to MCP suggests the presence of differences in the excitability between each phase, as measured using the H-reflex. Conclusion When we assumed a standard menstrual-phase, each phase was lower than the H-wave and the vertical jump during the follicular phase for increased spinal excitability. PHYSICAL ACTIVITY AND NUTRITION INTAKE DURING PREGNANCY AND THEIR ASSOCIATED FACTORS IN CHINESE WOMEN

MI, X., MASAYUKI, K., MIO, N., KARINA, A., HYEON-KI, K., HIROKI, T., HISAO, S., SHIZUO, S.

Sport Sciences

Introduction Excessive gestational weight gain (GWG) is emerging as an important predictor of maternal and offspring future obesity (Rooney et al, 2005). More than 50% of women experienced excessive GWG in China (Jiang et al, 2012). The physical activity (PA) and nutrition intake are key modifiable factors associated with weight related outcomes in pregnancy. There is only one study evaluated PA level during pregnancy among women living in urban of eastern China (Zhang et al, 2014). It is not generalizable and there is much differences in lifestyle by regions in china. Therefore, there is a need to measure PA and nutrition intake and associated factors among Chinese pregnant women in other regions including rural and urban regions. Methods This cross-sectional study enrolled 1224 pregnant women in Chengdu, west of China. The pregnancy physical activity questionnaire (PPAQ) and food frequency questionnaire (FFQ) were used to assess their PA and nutrition intake during pregnancy, respectively. These data were also analyzed by multiple binary logistic regression to determine associated factors on PA and nutrition intake during pregnancy. Results Time expenditure of physical activities classified by type and nutrition intake was varied significantly through the three trimesters ($p < 0.01$). More than 50% Chinese pregnant women met the international guideline for PA (≥ 150 mins moderate and above intensity activities per week), but they expended little time on exercises. Most pregnant women had imbalanced nutrition intake with excessive energy derived from fat. The age, household income, habitual exercise before pregnancy and previous live births are associated with PA and nutrition during pregnancy. Discussion More than 50% Chinese pregnant women met the guideline for PA, but most Chinese pregnant women expended little time on exercises and had imbalanced nutrition intake. The primary reason maybe was the high proportion of habitual exercise before pregnancy, which related to PA during Pregnancy. Because of traditional Chinese culture which defines pregnancy as a vulnerable period, most women had not done exercise during pregnancy. This may also partly explain why the pregnant Chinese women reported that their most common form of exercise was slow walking. References Rooney, B. L., Schaubberger, C. W., & Mathiason, M. A. THE EFFECTS OF SELF-REPORTED MENSTRUAL CYCLE PHASE ON PHYSICAL FOOTBALL PERFORMANCE

JULIAN, R., HECKSTEDEN, A., MEYER, T.

Saarland University

Introduction Despite the increasing scientific interest surrounding female football, gender-specific aspects of physiology, e.g. the menstrual cycle, remain largely unexplored (Datson, 2014). This is despite the known influence of the involved hormones on relevant aspects of exercise physiology and energy metabolism (De Jonge 2003). Therefore, the aim of the study was to investigate the effects of menstrual cycle phase on football specific performance. **Method** Sixteen sub elite female football players (19.4 ± 3.0 y, 164.8 ± 6.8 cm) participated in the current study. Prior to testing all participants completed a menstruation diary for a minimum of 6 months. Females who had a cycle phase < 25 days or > 30 days were excluded. The phases of the menstrual cycle were determined by counting backwards from subsequent menses, and were then controlled using the onset of the following menses. Testing time-points were established as Follicular Phase (FP) day 5-7 and Luteal Phase (LP) day 21-22, where greatest hormonal variations are known to occur (Reilly, 2010). A battery of football specific performance tests was implemented (endurance capacity (Yo-Yo IE1), sprinting performance (3 x 30m) and explosive lower limb power (CMJ)). Data was collected in the early evening and training load was kept consistent for the 48 hours prior to testing. All measures were conducted outside on artificial turf under similar weather conditions. Results Magnitude based inferences indicated a possibly harmful effect in the LP for Yo-Yo performance. For all other performance variables, a most likely negligible effect was suggested. Standard null hypothesis testing indicated a tendency towards significance in Yo-Yo IE1 performance ($p=0.065$) between phases. No significant differences in CMJ ($p=0.544$) or 3x30m sprint at any distance splits (0-5m, $p=0.787$; 0-10m, $p=0.786$; 0-30m, $p=0.772$) were found. **Discussion** The results suggest a possible reduction in endurance capability for female footballers, indicated by a decline in Yo-Yo IE1 performance. Further investigation is needed to corroborate this influence of menstrual cycle on performance and to establish the underlying mechanisms. Furthermore, although lab based performance appears to be reduced, the effects of menstrual cycle phase on game specific scenarios is warranted within future research on this topic. 16:20 - 17:50**Invited symposia****IS-PM11 Strategies to combat sarcopenia****IT'S NEVER TOO LATE – EXERCISE INTERVENTIONS TO ATTENUATE AGE-RELATED MUSCLE LOSS**

WEISSNER, B.

University of Vienna

Sarcopenia as defined by the European Working Group on Sarcopenia in Older People is characterized by the age-related loss of muscle mass, strength and function [1]. In order to stay physically (and mentally) fit and healthy, exercise training (aerobic, muscle strengthening, balance and flexibility training) is suggested for older adults [2]. Especially, resistance training has been proven to effectively increase muscle mass, strength and function even at a higher age, whereby an intensity progression from about 40% to 80% of the individual one repetition maximum is suggested when starting an exercise program [3] indicating that high intensities would be needed to induce substantial gains in muscle strength and mass. However, a previous meta-analysis has shown that resistance training at lower than traditionally recommended intensities is also effective, when a sufficient number of repetitions is performed [4]. Besides the classical resistance training other training modalities (vibration training, elastic-band resistance training, concurrent training ...) will be discussed with respect to their effectiveness to prevent or combat sarcopenia. 1. PHARMACOLOGICAL AND DIETARY APPROACHES TO COMBAT AGE-RELATED SARCOPENIA.

KADI, F.

School of Health and Medical Sciences

There are several challenges facing the management of age-related sarcopenia, defined as both low muscle mass and muscle function. A major challenge is to identify major factors and underlying mechanisms contributing to the degradation of muscle function with increasing age in order to develop targeted interventions. The present talk focuses on the use of non-pharmacological tools with special emphasis on the different dietary approaches combined to exercise. Given the fact that it is currently acknowledged that sarcopenia is driven by multiple mechanisms, the use of combined non-pharmacological interventions might prove useful. Pharmacological approaches for elderly unable to engage in exercise and based on the use of hormones or new agents with putative myotrophic effects are discussed both in term of efficiency and side effects.

IMMUNESENESCENCE, INFLAMMATION AND SARCOPAENIA

LORD, J.

University of Birmingham

Ageing is associated with an increase in systemic inflammation and this is in turn correlated with sarcopenia and frailty. The drivers for this age-related increase in inflammation are varied and include: increased adiposity, reduced physical activity, but also reduced anti-inflammatory and increased pro-inflammatory functioning of the immune system, which form part of the age-related decline in immune function known as immunosenescence. These include production of pro-inflammatory cytokines by monocytes in the basal state, reduced production of anti-inflammatory cytokines (IL-10) by regulatory cells and reduced migration efficiency by neutrophils leading to excess release of proteases and damage to healthy tissue. Chronic conditions which include increased systemic inflammation, such as COPD, liver cirrhosis and Rheumatoid Arthritis, are also accompanied by loss of muscle mass and strength. There is thus a wealth of data suggesting a connection between systemic inflammation, immune dysregulation and sarcopenia. What is less clear is whether inflammation occurs in skeletal muscle itself and the mechanisms that might link inflammation with sarcopenia. In relation to immunosenescence, our work has shown that neutrophil dysfunction is due to constitutive activation of the PI3 kinase pathway, moreover that inhibition of the pathway corrects the defect. We have also recently found an association between physical activity levels and neutrophil function in older adults which suggest that neutrophil migration can also be affected by exercise.

Invited symposia**IS-PM12 Statins, physical activity and muscle dysfunction****STATINS, MITOCHONDRIAL FUNCTION AND PHYSICAL ACTIVITY**

DELA, F.

University of Copenhagen

Statin induced myalgia has been hypothesized to be linked to a dysfunction of the skeletal muscle mitochondria. In rat muscle it has been demonstrated that atorvastatin treatment leads to an increased ROS production following exercise, as well as a decrease in maximal mitochondrial respiration. In human studies, using PCr recovery following exercise, an impaired mitochondrial function is found in hypercholesterolemic patients receiving statin therapy. Furthermore, by high resolution respirometry of skinned muscle fibers it have been shown that converged electron flux through complex I+II elicit a decrease in state 3 respiration in statin treated patients. This may be due to a decrease of Q10 content, but studies using Q10 supplementation along with statin treatment are not conclusive. Along with other candidates for statin induced myalgia (genetic susceptibility, mitochondrial calcium handling, skeletal muscle protein turnover, Vitamin D insufficiency) altered oxygen flux in the mitochondrial respiratory chain may be culprit in statin induced myalgia.

INTERACTION BETWEEN STATINS, EXERCISE AND MUSCLE SYMPTOMS

TAYLOR, B.A.

University of Connecticut

Hydroxy-methylglutaryl (HMG) CoA reductase inhibitors or statins are the most effective medications for reducing low-density lipoprotein cholesterol concentrations and cardiac events. Statins can produce statin-associated muscle symptoms (SAMS) consisting of myalgia or pain, cramps and weakness. SAMS may compromise medication compliance and quality of life, and may reduce physical activity, which is prescribed as lifestyle therapy for hyperlipidemia. The majority of statin muscle side effects have been documented by patient self-report in the resting state. Consequently, the true frequency of statin-related muscle complaints is not known, as 30-50% may be non-specific (i.e., non-statin-related), and SAMS may also be exacerbated by exercise. Indeed, physically active individuals are less likely to tolerate statins because of SAMS (1,2). In addition, several studies have reported that exercise with a statin produces greater CK elevations than does exercise alone. For example, in one study, post-exercise CK levels were 62% and 77% higher in patients treated with lovastatin vs. placebo 24 and 48 hours after downhill treadmill walking (3). These findings were confirmed with a report of higher CK levels after the 2011 Boston marathon in statin-using athletes (4). Both human and animal studies indicate that increased exercise-associated muscle damage with statin myopathy may be attributable to alterations in pathways associated with protein degradation, apoptosis, carbohydrate oxidation, oxidative stress and inflammation (5-7). Similarly, recent studies looking at concentrations of muscle-specific microRNAs following exercise demonstrated that statin-using athletes exhibited higher extracellular concentrations of miR-499-5p relative to non-statin-using athletes (8). SAMS may also be influenced by genetic variants, Vitamin D exposure, diet and other medications/supplements. The interaction between statins, exercise and muscle symptoms will be more effectively diagnosed and treated as rigorous scientific studies accumulate. The purpose of this presentation is to detail the effects of statins on skeletal muscle, particularly following exercise, explore mechanisms underlying SAMS, and present emerging evidence supporting environmental and genetic modifiers that may influence the relationship between statin therapy, physical activity, and muscle side effects. THE IMPACT OF STATINS ON MUSCLE PROTEIN AND CARBOHYDRATE METABOLISM

MALLINSON, J.E.

University of Nottingham

Statins are used clinically for cholesterol reduction and their use has been associated with a 30% reduction in cardiovascular events. Statins are generally well tolerated, but can have muscle specific side-effects (through poorly defined mechanisms), ranging from myalgia (muscle aches or weaknesses with and without elevated serum CK concentration), myopathy (muscle necrosis and elevated CK

respectively), and in the severest case, rhabdomyolysis (typically >10 times the upper limit of normal serum CK). Meta-analysis of randomised controlled trials suggests rhabdomyolysis is rare, however increased incidence of myalgia is seen in patients receiving statins compared to placebo. Current treatment for statin myalgia is the discontinuation of statin use, in which symptoms are most often reversible, and therefore it is important to identify the mechanism of statin induced muscle dysfunction, not least because older people are sarcopenic and also at greatest risk from statin mediated musculoskeletal side effects. This presentation will provide novel pre-clinical insight pertaining to the molecular aetiology of statin induced myopathy, and will highlight a pharmacological approach to counteract statin induced myopathy. Focus will also be given to providing mechanistic insight of the association between statin myalgia and the dysregulation of muscle carbohydrate and protein metabolism in older volunteers.

Invited symposia

VIDEO ANALYSIS OF ACL INJURIES IN FOOTBALL

KROSSHAUG, T.

Norwegian School of Sport Sciences

A precise description of the injury mechanism is critical for the development of effective preventive measures for ACL injuries. Video analysis is the only way to systematically collect kinematic information from real injury situations. We have therefore analyzed 39 cases of ACL injuries in professional football where the injury mechanism was assessed through a description of the match situation and player-opponent behavior. However, a detailed biomechanical assessment is not possible using a visual assessment. For this reason, we developed a Model-Based Image-Matching technique to reconstruct the kinematics of the injured person. In this method, 3D models of the surroundings as well as a customized skeleton model are manually matched to the background video footage. With this technique, it is possible to produce estimate temporal joint angle histories, velocities and accelerations, which are necessary for detailed biomechanical analyses of the injury mechanism. After a 10-year effort to collect and analyze videos of 10 ACL injury situations that were filmed with at least two cameras, we found surprisingly consistent knee kinematics in the impact phase of the injury situation. All the 10 players showed immediate valgus motion within 40 ms after initial contact. Moreover, the tibia rotated internally during the first 40 ms. These results, in combination with other important findings in the literature, led us to propose a new hypothesis for the mechanism of ACL injuries.

FOOTBALL SHOES – ARE THEY A RISK FACTOR FOR INJURIES?

GEHRING, D.

University of Freiburg

The shoe of the football player is specifically discussed to be an external risk factor of injuries as the athlete wears a cleated football shoe that penetrates an uneven turf. Based on a systematic literature review this talk summarizes the current knowledge about the shoe-ground interaction in football and its relevance with respect to injuries. This talk will show how different surface conditions like dry vs. wet grass or different kinds of natural grass influence injury occurrences. Moreover, we will answer the question if newest generations of artificial turf increase the injury risk compared to natural grass (Williams et al. 2011). We will then describe the concept of traction, which is closely related to this question and which describes the resistance of the shoe against sliding and rotational motion on the ground. Literature reveals that there is a clear effect of traction properties on the athlete's performance (e.g. Sterzing et al. 2010) but as well on the injury risk. We will demonstrate that it is important to differentiate the traction properties of a shoe carefully; as for instance a higher rotational traction is associated with an increased injury risk but a higher translational traction with a reduced injury rate (Wannop et al. 2013). Finally, we will make conclusions about the 'ideal' shoe in order to prevent football injuries. References: Williams et al. (2011) Sports Med, 903-23 Sterzing et al. (2010) Footwear Sci, 37-49. Wannop et al. (2013) MSSE, 2137-43.

INJURY PREVENTION PROGRAMMES: WHAT HELPS?

BIZZINI, M.

Schulthess Clinic, Zürich, Switzerland

Most football injuries are caused by foul play: Fair Play and stricter application of the Laws of the Game are crucial in the prevention of contact injuries (few publications at today). However, non-contact injuries can be reduced with multi-modal programmes, as originally published by Ekstrand in the 80's. Further, two exercise-based prevention programmes, the PEP (Gilchrist 2008) and moreover „The 11+“ (Soligard et al 2008), were able to significantly reduce the incidence of lower extremity injuries in female college players. Similar results in term of injury reduction (ca. 50%) have been recently found in a large RCT in male US soccer teams adopting the FIFA 11+ as a standard warm up (Silvers et al 2015). Research has further reinforced the importance of neuromuscular control in sports injury prevention (Herman et al 2012). Specific eccentric exercises have shown to significantly reduce the incidence of new and recurrent hamstring injuries in male players (Petersen et al 2011). Countrywide prevention campaigns in amateur football (Junge et al 2011) showed both an overall reduction of injuries and of health-care related costs. Despite these findings, the dissemination and implementation of injury prevention programmes in the real world of sport, and moreover at community level, remains a major challenge.

Oral presentations

OP-PM37 Hydration Status

IMPACT OF EXERCISE-INDUCED DEHYDRATION ON SMALL AIRWAY FUNCTION IN THE HEALTHY ACTIVE HUMAN

LOWMAN, A., GONZÁLEZ-ALONSO, J., KIPPELEN, P.

Brunel University London

Introduction: Whole-body dehydration can impair cardiovascular and metabolic function during exercise, but its effects on lung function are still unclear. Preliminary results from our group suggest that exercise-induced mild dehydration causes gas trapping and small airway collapse in symptomatic individuals with a history of asthma (Simpson et al., 2015). Whether the impact of dehydration on small airway function is population-specific (i.e., only observed in susceptible individuals with a history of asthma) or present even in healthy individuals remains to be established. The primary aim of our research was to establish the impact of exercise-induced dehydration on small airway function in healthy, active humans. The secondary aim was to determine whether reduced endogenous production of nitric oxide (NO, a regulator of bronchial tone) mediates dehydration-induced lung function alterations in humans. **Methods:** Eight, healthy male athletes (aged 19 to 33 yr) cycled for 2 h in the heat at 55% of maximal oxygen uptake ($\dot{V}O_{2\text{max}}$) while not ingesting fluid and becoming dehydrated (dehydration trial), or ingesting fluid to minimize fluid loss (control trial). Hydration status was monitored through changes in nude body mass between pre- and post-exercise. Spirometry and full body plethysmography were conducted before and at several time points after exercise (up to 2 h). Exhaled NO was recorded before, immediately after, and at 30 and 95 min post-exercise. Data were analysed using repeated measures ANOVAs. **Results:** The dehydration protocol caused a $3.8 \pm 0.7\%$ (range 3.3–5.3%) reduction in nude body mass (vs $1.1 \pm 0.3\%$ in the control protocol, $P < 0.001$). Dehydration caused a statistically significant ($P = 0.039$), and clinically relevant decline in forced vital capacity ($FVC = 221 \pm 248$ mL), as well as significant increases in residual volume ($RV = 439 \pm 126$ mL, $P = 0.003$) and in functional residual capacity ($FRC = 336 \pm 190$ mL, $P = 0.005$). No statistically significant changes in these lung function parameters were observed in the control condition. Dehydration did not alter post-exercise exhaled NO levels ($FeNO = 1.4 \pm 4.6$ vs -2.1 ± 5.0 ppb in control, $P > 0.05$). **Conclusions:** Our results suggest that moderate-to-severe exercise-induced whole body dehydration impedes small airway function in the healthy, active human. Those changes are unlikely to be mediated by alterations in NO production within the airways. References Simpson A, Romer L, Kippelen P. (2015) Respirology, 20, 121. Contact: 1113349@my.brunel.ac.uk

BODY POSITION & WATER ABSORPTION ~AN INVESTIGATION WITH ISOTOPIC LABELED WATER~

MORIKAWA, A.1, SUZUKI, M.1, TANAKA, U.1, YAMADA, Y.3, NAKAE, S.3,4, HOJO, T.1, HIGAKI, Y.2, TANAKA, H.2, EBINE, N.1

1:Doshisha University, 2:Fukuoka University, 3:National Institutes of Biomedical Innovation, Health and Nutrition, 4:Tokyo Gakugei University

Introduction Previous studies that observe the relationship between body position and gastric emptying, have mostly focused on solid food and little is known about liquid in the gut. The bottom part of the stomach in an average human body resides below the pylorus when in the upright position, due to gravity. This phenomenon requires extra work for the stomach, as gastric components need to push up in order for gastric emptying to occur. The purpose of the present study was to verify the speed of water absorption in different body positions. A promoting position (PP), where the subjects were placed with the head and trunk slanted 20 degrees upwards parallel from the ground, was designed, to investigate whether water absorption will occur faster. Method Absorption was assessed by following the change in the enrichment of deuterium oxide in urine samples, after the intake of labeled water in seven healthy male students. Two trials were conducted: one remaining sitting in the standard position (SP) throughout the trial, and the other, being in the PP for the first 10 mins of the trial. After ingestion, subjects were instructed to remain in a rested state in which urine samples were obtained. At each sampling, subjects were required to conduct complete urinary retention in order to prevent contamination of left over urine in the bladder, most likely to affect the next urine sampling. Results Lower values were constantly observed in the PP trial in the enrichment of isotope than the SP trial. In comparison to the SP trial, urine taken after 60 mins of administration in the PP trial showed a significantly lower value in the enrichment of isotope ($P = 0.013$). Although not statistically significant, body fluid in the PP trial reached equilibrium faster than the SP trial. Discussion In the process of rehydration, ingested water must mix with the extracellular and intracellular water to reach equilibrium with the rest of the body water pool. Isotope enrichment in the PP trial stayed near the equilibrium value and settled into equilibrium faster than the SP trial, which shows that the PP promotes water absorption. Meanwhile, in addition to the difference in the enrichment of isotope, a few physiological reactions due to the difference in body position were observed between the two testing occasions. ESTIMATION OF SWEATING PATTERNS DURING CYCLING EXERCISE BY MEANS OF THE CLOSED CHAMBER CONDENSER TECHNOLOGY

CLIJSEN , R., CLARYS , P., BAREL, A.O., SCHOUTEDEN, R., VAN OLST, B., AERENHOUTS, D.

University of Applied Sciences and Arts of Southern Switzerland, SUPSI, Switzerland

Knowledge of sweat loss and local sweating patterns is of importance in occupational and the exercise physiology setting. Techniques evolved from whole body mass measurement before versus after exercise, over absorbancy methodology, to the ventilated capsule methodology. The aim of the present study was to evaluate the applicability of an adapted closed chamber skin evaporimeter methodology (Bio Aquaflux® instrument) to estimate sweat production. Therefore, 14 healthy subjects performed a 20 minutes cycle ergometer trial at fixed heart rates of respectively 55% HR_{reserve} and 75% HR_{reserve}. Sweat production was estimated by measuring body weight before and after exercise, by calculated the amount of sweat collected in a patch placed on the upper back during exercise, and by measuring the water flux (in g.h⁻¹.m⁻²) with the Bio-Aquaflux® instrument on the back contralateral to the patch application site. Sweat rates (all in g.h⁻¹.m⁻²) at 55% of HR reserve as determined with the different methods were respectively 389 ± 206 for the body weight method, 363 ± 280 for the patch method and 206 ± 109 for the Biox Aquaflux® instrument. At 75% of HR_{reserve} these values reached respectively 729 ± 103 , 1054 ± 372 and 446 ± 120 g.h⁻¹.m⁻². Correlations between the measurement methods were all significant at 75% HR_{reserve} trial (with r ranging from .68 to .76) whilst at 55% HR_{reserve} a significant relation was detected between the patch method and

the Bio Aquaflux® only (with r ranging from .41 to .79). The Biox instrument is a practical and direct method for the estimation of local sweat rates under field conditions. The high correlations between the Biox Aquaflux® instrument and the other methods used for sweat production indicates the potential of the closed chamber methodology as an additional field method.

HSP72 mRNA TRANSCRIPTION, AND SWEAT ADAPTATIONS ARE GREATER POST HEAT ACCLIMATION IN TRAINED VS. UNTRAINED INDIVIDUALS

GIBSON, O.R., TAYLOR, L., WATT, P.W., MAXWELL, N.S.

Brunel University London

Introduction Heat shock protein-72 (Hsp72) is a cytoprotective protein with gene transcription (mRNA) proportional to the magnitude of cellular stress, notably elevated temperature. Following transcription, increased basal Hsp72 protein is an important component of thermotolerance, a cellular element of the inducible heat acclimation (HA) phenotype. The aim of this experiment was to determine whether training status influenced the magnitude of Hsp72 mRNA transcription during HA, alongside other typical phenotypic responses. Methods Six trained (T; VO₂peak = 4.58±0.46 L·min⁻¹) and six untrained males (UT; VO₂peak = 3.25±0.53 L·min⁻¹) matched for age (T= 22±3 yrs, UT= 23±4 yrs), body surface area (T= 1.97±0.10 m², UT= 1.91±0.13 m²), mass (T= 75.7±6.0 kg, UT= 74.4±8.6 kg) and fat mass (T= 12.5±1.2%, UT= 13.5±3.5%) performed ten, 90 min sessions of isothermal HA [rectal temperature (Trec) ≥38.5 °C]. Leukocyte Hsp72 mRNA was measured pre and immediately post the first (D1) and last (D10) day of HA, with gene transcription quantified using RT-QPCR. On D1 and D10, resting Trec and heart rate (HR), and sweat rate (SR; %body mass (%BM)) were quantified. Results Hsp72 mRNA increased ($p<0.05$) pre-post HA for both T and UT on D1 (Pre, T= 1.8±0.8, UT= 1.5±0.7; Post, T= 5.7±2.4, UT= 3.3±1.3) and D10 (Pre, T= 2.0±0.7, UT= 1.8±0.9; Post, T= 4.7±1.2, UT= 3.0±1.1), with no difference between D1 and D10. Hsp72 mRNA was significantly greater post HA ($p<0.05$) in T compared to UT. SR demonstrated a greater ($p<0.05$) magnitude of adaptation in T (+1.24±0.55%BM) compared to UT (+0.54±0.39%BM). No difference ($p>0.05$) in the magnitude of adaptation (D1 to D10) occurred for resting Trec (T= -0.53±0.23°C, UT= -0.37±0.17°C) or HR (T= -12±4 b·min⁻¹, UT= -11±12 b·min⁻¹). During the HA, T demonstrated a greater ($p<0.05$) ΔTrec (D1 = 1.95±0.33°C; D10 = 2.48±0.25°C) and mean Trec (D1 = 38.39±0.17°C, D10 = 38.36±0.23°C) than UT (ΔTrec; D1 = 1.51±0.46°C, D10 = 1.71±0.33°C; mean Trec D1 = 38.14±0.34°C, D10 = 38.08±0.31°C). No difference ($p>0.05$) in the Δ or mean Trec occurred between D1 and D10. Discussion Trained individuals demonstrate increased transcription of Hsp72 mRNA in comparison to untrained. It is unknown if this is due to improved gene regulation, or increased thermoregulatory strain during HA. Increased strain may account for the greater sudomotor adaptation. Equality of Trec and HR adaptations demonstrates comparable adaptive capacity for these measures irrespective of training status.

Oral presentations

OP-PM75 Health & Fitness: Exercise & Ageing

EFFECTS ON WHITE BLOOD CELLS IN SENIOR CITIZENS DURING POST EXERCISE RECOVERY IN DIFFERENT ENVIRONMENTS

AHNESJÖ, J., BERGMAN, P.

Department of sport science

Effects on white blood cells in senior citizens during post exercise recovery in different environments (indoors, simulated outdoors and outdoors) Introduction Natural environments are known to promote health and may also provide extraordinary conditions for post exercise recovery (Kuo 2015). In the project Health Effects of Recreation Outdoors (HERO) we explore the hypothesis that post exercise recovery in natural environments may be reflected in white blood cell counts (WBC). In our study 50 seniors (age >65 years) performed moderate physical activity (20 min) followed by passive recovery (2h) in three different environments (indoors, simulated outdoors and "true" outdoors). Method The experimental setup was a randomized cross-over design, thus all test persons did all treatments in a randomized order. We sampled white blood cells (WBC-diff), which were used to detect and quantify inflammatory response. Results Our early findings provide some support for the hypothesis that environment may impose differences in recovery effectiveness. White blood cell count (WBC-diff) appears to differ between the treatments and there is a significant interaction between sampling time and recovery environment in the monocytes, suggesting that the monocyte numbers differ, not only between sampling times but also between environments. In addition, WBC also show that some of the test persons develop leukocytosis during exercise and that white blood cell levels decrease rapidly immediately post exercise to levels significantly lower than base line values. Discussion Our results suggest that moderate physical activity in senior citizens may result in acute leukocytosis (see e.g. Sand et. al. 2013) and that recovery effectiveness (e.g. in monocyte response) may be dependent upon environmental factors. The clinical importance of our results are not fully understood but there has been suggested an "open window" immediately post exercise in which infection risk may be elevated (Pedersen & Toft 2000) and it is possible that recovery out of doors may reduce this risk. References Sand, K., L. Flatebo, K., Andersen, M., B., Maghazachi, A., A. (2013) World J Exp Med 20; 3(1): 11-20 Pedersen, B., K. & Toft, A., D. (2000) Br J Sports Med 34:246-251 Kuo, M. (2015) Frontiers in Psychology 6

EFFECTS OF CREATINE SUPPLEMENTATION AND HIGH-LOW RESISTANCE TRAINING IN AGING ADULTS

CANDOW, D., JOHANNESMEYER, S.

University of Regina

The purpose was to investigate the effects of high-low resistance training (2 sets of leg press, chest press, hack squat and lat pull-down exercises performed to muscle fatigue at 80% baseline 1-repetition maximum [1-RM] immediately followed by repetitions to muscle fatigue at 30% baseline 1-RM) and creatine supplementation in aging adults. Participants were randomized to one of two groups: Creatine (CR: n = 14, 7 females, 7 males; 0.1 g/kg/day of creatine + 0.1 g/kg/day of maltodextrin; age = 58.0 ± 3.0 years) or Placebo (PLA: n = 17, 7 females, 10 males; 0.2 g/kg/day of maltodextrin; age = 57.6 ± 5.0 years) during 12 weeks of high-low resistance training (3 days/week). Prior to and following training and supplementation, assessments were made for body composition (whole-body lean tissue mass, fat mass, bone mineral), strength (1-repetition maximum for the leg press, chest press, hack squat and lat pull-down exercise),

muscle endurance (total number of repetitions performed for 1 set using 70% baseline 1-RM for the chest press exercise and 80% 1-RM for the leg press exercise), tasks of functionality (hand-grip strength, balance, falls, walking speed), muscle protein catabolism (urinary excretion of 3-methylhistidine, 3-MH) and diet. Results showed that high-low resistance training improved lean tissue mass, muscle strength, endurance and tasks of functionality ($p < 0.05$). The addition of creatine to high-low resistance training significantly increased body mass ($p = 0.002$) and lean tissue mass ($p = 0.007$) compared to placebo. Males on creatine increased muscle strength (lat pull-down only) to a greater extent than females on creatine ($p = 0.005$). Creatine enabled males to train at a greater capacity over time compared to males on placebo ($p = 0.049$) and females on creatine ($p = 0.012$). Males on creatine ($p = 0.019$) and females on placebo ($p = 0.014$) decreased 3-MH, while females on creatine showed an increase. In conclusion, high-low resistance training is an effective intervention for improving muscle mass, muscle performance and functionality in aging adults. The addition of creatine to high-low resistance training augments the gains in lean tissue mass from resistance training alone.

LOW INTENSITY RESISTANCE EXERCISE IMPROVES COGNITIVE FUNCTION IN ELDERLY

SARDELI, A.V., RODRIGUES, M.S., FERREIRA, M.L.V., SANTOS, L.C., CAVAGLIERI, C.R., CHACON-MIKAHIL, M.P.T.

University of Campinas

Introduction. Decline in cognitive function (CF) is inherent to the aging process, impairing the performance in daily living activities and the elderly life quality. CF has been improved after endurance exercise sessions of various intensities and volumes (Kashihara et al., 2009). Regarding resistance exercise (RE), the ideal dose of resistance exercise prescription to improve CF need to be elucidated. A couple of RE protocols have been proposed for improve health in elderly, through increase in strength and muscle mass. Thus, our aim was to compare the effect on CF among some of these RE protocols recommended for elderly Health. Methods. In total, 21 healthy elderly (9 men and 12 women; 64.3 ± 5.04 years; and 1RM 161.67 ± 63.01 kg), volunteered for a cross-over design, containing a control session (CON) and three RE protocols performed in 45° leg press machine: HIRE, four sets until failure at 80% of 1RM ; LIRE, four sets until failure at 30% of 1RM ; and BFRRE 30 repetitions plus three sets of 15 repetitions, with 50% of blood flow restriction at 30% of 1RM. CF was measured before and after [5 min] the experimental protocols, through the three sections of Stroop test, which evaluate selective attention and processing speed. Since the data were not normally distributed, we applied non-parametric tests to compare the delta (post minus pre) among the 4 experimental protocols. The Bonferroni correction was applied for Friedman test ($p < 0.0125$) and for Wilcoxon post-hoc test ($p < 0.008$). Data is present in median and interquartile range. Results. For section 2 of Stroop test there was larger reduction of response time for LIRE (-255.6 ± 376.0 to -65.1) compared to HIRE (-39.3 ± 206.1 to 182.5) and CON (-39.0 ± 198.6 to 178.2), without differences in number of hits. There reduction in response time of LIRE was not different from BFRRE (-130.5 ± 237.5 to 16.3). Discussion. Among other mechanisms, the stimulus from optimal sympathetic modulation after endurance exercise has emerged as a strong candidate to improvements in CF (Kashihara, 2009; Murray and Russoniello, 2012). RE do not arouse changes in autonomic control in the same fashion than endurance exercise. Nevertheless, LIRE, the RE likely more similar to the endurance exercise cardiovascular effects (considering its higher volume and low intensity), were the best for CF improvements. Complementary analysis, suggested variations in autonomic modulation also after RE would explain reduction in response time herein. We concluded that LIRE was the best RE for improve CF in healthy elderly, while HIRE and BFRRE showed no significant effects. References Kashihara K, Maruyama T, Murota M, Nakahara Y. (2009). J Physiol Anthropol, 28(4): 155–164. Murray NP, Russoniello C. (2012). Appl Psychophysiol Biofeedback, 37:219–227.

MIDLIFE PHYSICAL ACTIVITY AND COGNITION IN LATE LIFE: A PROSPECTIVE TWIN STUDY

ISO-MARKKU, P., WALLER, K., VUOKSIMAA, E., HEIKKILÄ, K., RINNE, J., KAPRIO, J., KUJALA, U.M.

HUS Medical Imaging Center, Helsinki University Central Hospital and University of Helsinki, Helsinki, Finland

Midlife physical activity and cognition in late life: a prospective twin study Iso-Markku P1, Waller K2, Vuoksimaa E1, Heikkilä K1, Rinne J3, Kaprio J3,4,5, Kujala UM2 1 University of Helsinki, Finland 2 University of Jyväskylä, Finland 3 University of Turku, Finland 4 THL, Finland 5 FIMM, FINLAND Introduction Physical activity has been associated with better cognition both in previous cohort studies and in randomized controlled trials (RCTs). However, the durations in RCTs have been short considering the long preclinical phase of dementia. Cohort studied are liable for selection bias and causality cannot be inferred solely on them. Twin studies, however, give an excellent opportunity to take into account potential confounding from genetic and environment influences. The majority of the earlier twin studies on the subject have studied physical activity roughly mainly with only one crude physical activity indicator as a covariate, in a subgroup of a cohort or with a crude outcome measure; register-based dementia deaths. The aim of this study was to study whether midlife physical activity has effect on late life cognition in an extensive twin population. Methods The study population is a subgroup of the older cohort of the Finnish Twin Study (the twins born in Finland before 1958 and both co-twins alive in 1967) who were at least 65 years old at the follow-up and to whom telephone administered cognition screenings have been done at the follow-up. Physical activity was queried in 1976 and 1981. We studied both the intensity (whether or not the participant engages in physical activity more strenuous than walking) and the volume of physical activity (metabolic equivalent of energy expenditure hours i.e. MET-hours). The risk of cognitive decline was assessed with logistic and linear regression models assessing separately the risk in individual-based analyses comparing individuals and in pairwise analyses comparing twins with their co-twins. Results In individual-based analyses, persistent engagement in vigorous physical activity in midlife was associated with reduced risk of cognitive impairment (covariate-adjusted OR 0.50, 95% CI 0.35- 0.73). The trends in the pairwise analyses were similar but statistically non-significant. In the analyses of the volume of physical activity, the participants who belonged to the more active quintiles at both questionnaire years had reduced risk of cognitive impairment compared with participants in the most inactive quintile (covariate-adjusted OR 0.61, 95% CI 0.43- 0.88). No dose-response was found in linear regression analyses in the individual-base or in the pairwise analyses. Discussion Vigorous physical activity was significantly associated with reduced risk of cognitive impairment in the individual analyses with similar trends in the pairwise analyses. A moderate amount of physical activity seems sufficient to render cognition-protective benefits.

THE CONTRIBUTIONS OF URBAN PARKS TO PHYSICAL ACTIVITY AMONG OLDER ADULTS: THE SYSTEMATIC OBSERVATION WITHIN THE HONG KONG – LEIPZIG STUDY

DUAN, Y.P.1, WAGNER, P.2, ZHANG, R.2, BREHM, W.3

1:Hong Kong Baptist University (Hong Kong, China), 2: University of Leipzig (Leipzig, Germany), 3: University of Bayreuth (Bayreuth, Germany)

Introduction Urban parks have been acknowledged as important places for physical activity (PA) for urban residents, and particularly for senior city residents. There are numerous health benefits and a relatively low cost solution of park-based PA. However, parks are underused, especially for engaging in PA. More than half of park users are sedentary. In addition, only one third of park users engage in some types of PA with intensity during park visits – however, there are more park users in Hong Kong compared to western countries like Germany. This study took Hong Kong in China and Leipzig in Germany as example, to (1) describe and compare the characteristics of PA areas in urban parks in two cities; (2) to describe and compare the PA of the elderly within these areas in two cities. Methods Six parks were selected randomly in each city. Systematic observations were conducted in total twelve parks in the fall of 2014 and in the summer of 2015 by using a modified SOPARC (McKenzie et al., 2006) observation tool. Descriptive analysis and Chi² tests were used. Results The selected result revealed that sports course (50.34%) and fitness stations (20%) ranked the first two PA areas in parks in Hong Kong while grassy areas (34%) and playgrounds (29%) were in Leipzig. Parks in both cities were highly accessible, available and lighted in the evening. Moreover, most Chinese elderly in parks used trails and paths (48.76%) as well as fitness areas (19.92%) while the majority of German elderly (96.28%) only used trails and paths in parks. The most common PA for Chinese elderly was walking and fitness exercise while walking and cycling for German. In addition, more Chinese elderly participated in individual exercise (72.76%) compared with German (48.72%) ($\chi^2 [1, N = 6125] = 370.82; p < .001$). In terms of intensity of PA, more German elderly performed with moderate intensity (50.34%) and less with vigorous intensity (2.75%) compared with Chinese with moderate (30.42%) and vigorous intensities (20.59%) ($\chi^2 [2, N = 4946] = 459.9; p < .001$). Discussion The findings of this study adds empirical knowledge regarding how to optimize park services to promote PA behavior among the elderly under different culture contexts. THE CONTRIBUTIONS OF URBAN PARKS TO PHYSICAL ACTIVITY AMONG OLDER ADULTS: THE QUESTIONNAIRE SURVEY WITHIN THE HONG KONG – LEIPZIG STUDY

WAGNER, P.1, DUAN, Y.2, ZHANG, R.1, BREHM, W.3

1: University of Leipzig (Germany), 2: Hong Kong Baptist University (Hong Kong, China), 3: University of Bayreuth (Germany)

Introduction Regarding population aging as global phenomenon, urban parks have been acknowledged as important places for physical activity (PA) for urban residents, particularly for older adults (Van Dyck et al., 2013). There are numerous health benefits and a relatively low cost solution of park-based PA. However, parks are underused, especially for engaging in PA. More than half of park users are sedentary. In addition, only one third of park users engage in some type of PA with intensity during park visits – however, there are more park users in Hong Kong compared to western countries like Germany (Han et al., 2014). While aiming to promote PA in parks, it is necessary to study the characteristics of PA and PA areas in parks as well as the correlates of park-based PA with a cultural comparison of Eastern and Western older adults. Methods The Hong Kong (HK) – Leipzig (LE) study consists of a systematic observation and a questionnaire survey for each city. For questionnaire survey, in each city 300 elderly park users (60+yr) were randomly recruited from six parks. Participants completed a face-to-face survey measuring socio demographic variables (i.e. age, gender, education, marital status), psychosocial factors (i.e. self-efficacy, enjoyment, perceived barriers, perceived benefits, social support), perception of park environment (safety, attractiveness, features and accessibility) and park-based PA (duration and intensity level). Results The study design and selected results from the questionnaire survey of the Hong Kong - Leipzig study will be presented. The influences of demographics, psychosocial factors and perceptions of park environment on park-based PA among seniors in HK and LE were examined using hierarchical multiple regression analyses. Psychosocial correlates, especially self-efficacy, perceived benefits and perceived barriers, provided stronger effects than perceived park environmental correlates on explaining PA in parks. Discussion Present findings of significant interactions suggest multi-level interventions that target park environment and individual change could be particularly effective. OP-PM63 Taping & Injuries

KINESIOLOGY TAPE COUNTERS BALANCE IMPAIRMENT AFTER ECCENTRIC EXERCISE

HOSP, S., FOLIE, R., CSAPO, R., HASLER, M., NACHBAUER, W.

University of Innsbruck

Introduction Exhaustive exercise has been shown to impair balance ability, thus increasing the risk of knee injury in sports (Changela et al., 2012). Even though the use of Kinesiology tape (KT) has lately gained popularity within the sporting community for injury prevention, there is a paucity of evidence demonstrating its effectiveness (Williams et al., 2012). Therefore, the aim of this study was to investigate the influence of KT on balance ability after eccentric exercise in healthy men. Methods Twelve young men (age: 23.3 ± 2.6 years) with no prior history of lower limb injury took part in this study. All participants were invited to two visits separated by one week, to perform the scheduled tests once without the use of KT and once after application of KT at the knee joint. Upon each visit, the ability to maintain balance was assessed in a single-leg stance test using a computerized balance stability test system (Biodex Balance System®) prior to and

immediately after an eccentric exercise. The exercise protocol consisted of 30-minute downhill walking on a treadmill at an inclination of 20%. A stability index was calculated and statistically analyzed by repeated-measures ANOVA. Results Without KT, the stability index increased from 2.5° to 3.0° after downhill walking, which reflects an exercise-related deterioration of balance. Following application of KT, by contrast, the stability index remained almost unchanged (2.5° to 2.6°). The "time × taping" interaction effect was significant ($p = 0.049$), indicating that the exercise-related change of the stability index differed between the two taping conditions, with the impairment of balance being significantly greater when no KT was used. Discussion Eccentric exercise resulted in a significant deterioration of balance ability which could be attenuated by usage of KT. Thus, KT applied to the knee joint counteracted the exercise-related decline of balance ability observed when no tape was used. As its elastic material pulls and stretches the skin, KT might increase the sensory feedback from various mechanoreceptors located in the skin, muscle, and joint capsule, thereby improving proprioceptive performance and balance ability (Chang et al., 2010). Since the exercise-related impairment of balance ability represents an important risk factor for knee injuries, application of KT may be a clinically useful tool for injury prevention by enhancing the balance ability of athletes in the fatigued state. KINESIO TAPE: WHAT DOES IT ACTUALLY DO MECHANICALLY?

PAMUK, U., YUCESOY, C.A.

Bogazici University

Introduction Kinesio taping (KT) has been increasingly used in the treatment of sports injuries and various neuro-musculoskeletal disorders. It is expected to improve muscle strength and activity, joint range of motion, position sense and proprioception, scar healing and lymph flow. KT effects reported in numerous studies are inconsistent or even too small, obscuring its effectiveness. Assessments are often done in the whole body level; yet, it is implicitly assumed that KT is selectively effective on targeted tissues, determined by the particular KT application. A scientific basis for KT effects and a control over the expected physiological outcomes requires determining what KT really does mechanically on the underlying tissues. Muscular and connective tissues are continuous across the limb (Yucesoy, 2010). Therefore, the loads imposed superficially on the skin can be transmitted to deeper tissues to produce heterogeneous mechanical KT effects. The aim was to characterize those objectively and to test the hypothesis that KT causes local deformations not necessarily aligned with tape adhering direction and limited to the directly targeted tissues. Methods Magnetic resonance image (MRI) sets were acquired in healthy human subjects ($n=5$) before and acutely after KT is applied over the skin along m. tibialis anterior (TA) (Pamuk and Yucesoy, 2015). Joint angles were kept constant. Demons algorithm was used to calculate local tissue deformations within the lower leg (Yaman, et al., 2013). Strain artifacts due to subject repositioning for KT were quantified as well. Deformation maps were analyzed in the following anatomical regions: directly targeted tissues i.e., tissues superficial to TA (KT-to-TA) and TA; and non-targeted tissues i.e., the remainder musculature of the lower leg. Results Wilcoxon rank-sum test yielded significantly higher ($p<0.05$) mean peak tissue strains compared to strain artifacts in all anatomical regions (10.9% vs 3.3% respectively). Directly targeted tissues: deformations only in part of KT-to-TA region agree with tape adhering direction. Skin, the rest of KT-to-TA and TA regions show deformations (up to 51.5%) in other directions. Non-targeted tissues: sizable heterogeneous deformations are found, but in smaller amplitudes. Discussion A specific superficial loading imposed by KT causes a multi directional, heterogeneous deformation of the targeted and non-targeted tissues within the entire limb. This confirms our hypothesis and shows that KT is quite effective. Yet the findings also show that tailoring the expected physiological outcomes according to the tape adhering direction alone is a simplistic approach. TUBITAK grant (111E084) is acknowledged. EFFECTS OF AN ELASTIC TAPING APPLICATION ON ACTIVE CERVICAL R.O.M.

RUSSO, L., PANEZZA, T., BARTOLUCCI, P.

University of L'Aquila

Introduction: Elastic taping is largely used by professionals for sports practitioners and common people. The aim of this study was to measure the effects on perceived pain and active cervical Range of Motion (ACROM) of a classical application of elastic taping (ET). Previous studies (Saavedra-Hernandez et al., 2012; Gong, 2015) investigated the effects of neuromuscular taping or manipulation on cervical function and pain but the results are inconsistent. Methods: Fifty subjects (33.9 ± 4.8 yrs; 174.5 ± 8.2 cm; 73.5 ± 11.2 kg; 38M; 12F) for the study group (SG) and twenty subjects (32.6 ± 3.9 yrs; 174.9 ± 10.9 cm; 71.2 ± 12.9 kg; 11M; 9F) for the control group (CG) were respectively recruited. Each group performed three ACROM measurements with an inertial sensor (Moover, Sensor Medica, Guidonia-RM, Italy) and declared three times the perceived pain on neck basing on a 0-10 VAS scale: at the baseline, after 20' from ET application and after three days dressing the ET application. Between the first and the second ACROM and VAS measurement an ET (Taping Elastico®, ATS, Arezzo, Italy) was applied on the superior trapezius and cervical zone of the SG subjects. The ET was dressed in for three days and it was removed 1 hour before the last evaluation. The measured parameters were: maximum and average left and right rotation and lateral inclination, maximum and average flexion and extension, subjective perception of neck pain on a 0-10 VAS scale. ANOVA analysis was used to find out significant differences between repeated measurements and the level of significance was setting at $p<0.05$. Results: The CG did not show any significant change in any measurement session both for ACROM and VAS parameters. The SG showed higher significant values for all the measured parameters in ACROM test and lower values in VAS scale after three days respect to the baseline. Better values in ACROM and VAS parameters were measured also between the second and the last session of test. Finally, some significant differences were also found between baseline and after 20' from the ET application just for ACROM parameters. Discussion: The results give more information on the usefulness of ET and the results of other authors (Saavedra-Hernandez et al., 2012) are reinforced. Objective effects on ACROM and a reduced subjective perception of pain for ET are well documented in this study. The results underlines the usefulness of ET in terms to enhance ACROM in all directions and to reduce subjective neck pain when it is necessary. References: Saavedra-Hernandez M et al. (2012). THE RELATIONSHIP BETWEEN MUSCULOSKELETAL SCREENINGS AND SUBSEQUENT SHOULDER INJURIES IN JUNIOR AND PROFESSIONALLY RANKED TENNIS PLAYERS

GESCHEIT, D., CORMACK, S., DUFFIELD, R., KEMP, J., OMIZZOLO, M., REID, M.

Tennis Australia

Introduction: The shoulder has been commonly reported as the most prevalent upper limb injury region in sub-elite and elite tennis players^{1,2,3}. Musculoskeletal screenings (MS) are used to determine intrinsic risk factors associated with such injuries. However, the relationship between MS outcomes and subsequent shoulder injuries in sub-elite and elite tennis players remains unclear. Purpose: To determine the relationship between selected MS tools and ensuing shoulder injuries in junior (sub-elite) and professionally (elite) ranked tennis players. Methods: Shoulder injury and MS data (2012-2015) from junior and professionally ranked (ITF junior and/or ATP/WTA ranking) Australian tennis players (n=88 males, 76 females, 10-31 years) were obtained from a security-protected database. In total, 354 unique MS and 124 shoulder injuries resulting in 679 days of interrupted training were identified. MS tests included shoulder internal (IR) & external (ER) range of motion (ROM), Empty Can (EC), shoulder IR & ER maximal contraction, scapular dyskinesis, thoracic ROM and extension, and elbow extension. The relationship of each MS measure to subsequent shoulder injury incidence was assessed. In addition, the association between MS measures was analysed to determine any mediating shoulder injury variables. Injury severity (days interrupted training; moderate ≤7, severe >7) was also analysed in relation to antecedent MS results. Comparisons between injured and non-injured were assessed via one-way ANOVA and Chi-Square tests. Regression analysis determined whether there were any interrelationships between MS measures ($p<0.05$) and odds ratios determined which MS measures increased/decreased injury risk. Results: Athletes incurring a shoulder injury in the 12 months post MS, had significantly less dominant (D) shoulder IR (<40°; $R=-0.11$, $p=0.05$). This reduction in D shoulder IR was also associated with 'subtle' and 'obvious' ratings of D scapular dyskinesis during flexion as compared to normal ratings ($p<0.01$). Greater D elbow extension pain ratings were reported in the post MS injured ($R=-0.13$, $p=0.04$) compared to the non-injured athletes. Pain/abnormal D EC ratings resulted in athletes being 4.4 ($p=0.01$) and 5.2 times ($p=0.001$) more likely to have a severe shoulder injury respectively. No other MS measure was associated with shoulder injury occurrence of any severity. Conclusions: Dominant shoulder IR, elbow extension and EC measures may be intrinsic risk factors for shoulder injuries in sub-elite and elite tennis players. Additionally, D shoulder IR may also be an indicator for scapular dyskinesia. Although a large battery of MS measures are commonly performed, these may be the most appropriate tools for shoulder injury screening in tennis players. References: 1 Hutchinson et al. (1995). THE LONG-TERM EFFECT OF ABDOMINAL STRENGTHENING EXERCISE ON FEMALE DIASTASIS OF RECTUS ABDOMINIS

PASCOAL, A.G.¹, RAJKOWSKA, N.², MOTA, P.¹

¹University of Lisbon

1:University of Lisbon, FMH, LBMF, CIPER-Neuromechanics (Lisboa, Portugal) **2:**Gdansk University of Physical Education and Sport (Gdansk, Poland); INTRODUCTION Diastasis of rectus abdominis or the increased inter-rectus distance (IRD) is a common musculoskeletal condition on postpartum women. Previous studies showed that a single abdominal isometric contraction involved on abdominal crunch exercise has a positive acute effect on reducing the IRD (Pascoal et al. 2014). The aim of this study was to analyze the long-term effect of the abdominal strengthening exercise (e.g. crunch) on IRD magnitude. METHODS A sample of 45 healthy female volunteers was considered in three groups: 1) exercise-nulliparous group (E-N), including competitive bodybuilders (N=15); 2) non-exercise-post-partum group (NE-P), including early postpartum (18-24 weeks) women (N=15); and 3) non-exercise-nulliparous group (NE-N). Ultrasound images were recorded with a 12 MHz scanner in a supine resting position, 2 cm above the umbilicus, and exported in DICOM format for a posterior IRD offline measurement (mm) following previously described procedures (Mota et al. 2012). RESULTS A significant correlation was found between IRD and BMI. An ANCOVA [between-subjects factor: exercise-level; covariate: body mass index (BMI)] revealed a significant main effects of exercise-level, $F(2,41)=30.82, p=.00, \eta^2=.601$, no effect of BMI, $F(1,41)=.10, p=.08, \eta^2=.003$, and no interaction between exercise-level and BMI, $F(2,39)=0.15, p=.86, \eta^2=.008$. The E-N group had significantly lower IRD, controlling for the BMI, than the NE-P group [Mean Difference (MD):13.0;SEM:1.8;Confidence Interval 95% (CI95):16.6-9.4] or the NE-N group (MD:3.9;SEM:1.5;CI95:0.9-7.0). The NE-P group had significantly higher IRD than the NE-N group (MD:9.1;SEM:1.4;CI95:6.3-11.9). DISCUSSION The results on bodybuilders (E-N group) demonstrate the effect of long-term abdominal training (LTAT) on reducing female supraumbilical IRD. This is in agreement with those studies who suggest that an antenatal abdominal strengthening exercises program reduces the presence and width of postpartum DRA (Chiarello et al. 2005). However, further studies are needed to clarify if LTAT is effective to prevent or reduce postpartum DRA. The influence of pregnancy on IRD, revealed by the comparison between NE-N and NE-P groups, was similar in magnitude as reported previously (Pascoal, Dionisio et al. 2014). REFERENCES Chiarello, C. M., et al. (2005). J. Women's Health Phys. Ther. 29(1): 11-16. Mota, P., et al. (2012). J. Orthop & Sports Phys. Ther. 42(11): 940-946. Pascoal, A. G., et al. (2014). Physiotherapy 100(4): 344-348. INCREASED ACL INJURY RISK IN THE COLD – AN ASSESSMENT OF POTENTIAL RISK FACTORS

CSAPO, R., FOLIE, R., HOSP, S., HASLER, M., NACHBAUER, W.

University of Innsbruck

Introduction Epidemiological studies have provided evidence that in alpine skiing the risk for injuries of the anterior cruciate ligament (ACL) is increased when outer temperatures are particularly cold.¹ While this phenomenon may partly be related to altered surface conditions of skiing slopes, injury risk could be aggravated by temperature-associated changes in ACL stiffness or various neuromuscular parameters. The aim of this study was to test the effects of cold exposure on knee laxity as well as thigh muscle strength, explosiveness, proprioception, and electromyographic (EMG) activity. Methods Ten healthy females (age: 23.4 ± 3.2 yrs, body mass: 59.9 ± 5.5 kg, height: 167.9 ± 4.7 cm) underwent 30 minutes of exposure to a cold environment (5°C , 50% relative humidity) in a climatic chamber. Before and immediately after the intervention, knee extensor and flexor muscles were examined for EMG activity, maximum voluntary contraction strength, rate of force development and force sense. Measures of knee laxity, representative of ACL stiffness, were obtained by computerized arthrometry. Results Following cold exposure, rate of force development was reduced, with the effect being more pronounced in the knee flexor ($r = 0.945$, $p = 0.016$) than in the knee extensor muscles ($r = 0.794$, $p = 0.079$). Left-shifts of EMG power spectra indicated changes in neural drive to the medial and lateral head of the vastus muscle ($0.638 < r < 0.856$, $p < 0.05$). Antagonistic co-activation of knee flexors

during knee extension decreased non-significantly by 25-35%. No changes in maximum strength, force sense and knee laxity were found. Conclusions Cooling of the thigh and knee leads to a reduction in the capacity to generate force explosively. As indicated by left-shifts in EMG power spectra, this effect is likely mediated by changes in neural drive to muscles, and more pronounced in the knee flexor muscles. We further observed a reduction of hamstring co-activation during forceful contraction of knee extensors, although this result failed to reach significance. Since the hamstring muscles act to protect the ACL against excessive strain, these changes may contribute to the increased likeliness of ACL injuries when engaging in physical activity in the cold. Knee laxity, force sense and maximum strength, by contrast, were not significantly affected by cold exposure. OP-PM49 Exercise Testing

THE EFFECTS OF THE LOW RECUMBENT BODY POSITION IN MUSCLE DEOXYGENATION DURING RAMP INCREMENTAL EXERCISE

GILDEA, N., ROCHA, J., CORISH, O., COMERFORD, J., EGAÑA, M.

Trinity College Dublin

Exercising in the supine position whereby the active muscles are held above the level of the heart compromises performance when compared with upright cycling. The lack of gravitational assist to muscle blood flow, results in a reduction of muscle perfusion pressure and subsequently oxygen delivery (Egaña et al., 2013; DiMenna et al., 2010). In the present study we investigated the impact of the low recumbent cycling position on cycling performance, muscle fractional O₂ extraction (estimated using deoxygenated haemoglobin), and rate of increase of pulmonary oxygen uptake (VO₂) during incremental cycling exercise. Eleven young healthy male participants (mean ± SD; 22 ± 3 years; 181.5 ± 4.7 cm; 78.4 ± 10.5 kg) performed a ramp incremental cycling test to exhaustion in four cycling positions; upright, 30° recumbent (R), 15°R, and supine. Exercise was performed initially for 2-min at 10W, followed by 20 or 25 W/min increments on an electrically braked cycle ergometer, with pedal frequency held constant at an individually selected rpm. VO₂ was measured on a breath-by-breath basis using an online metabolic system, while the rate of muscle deoxygenation (deoxygenated haemoglobin/myoglobin, deoxy[Hb + Mb]) of the vastus lateralis (VL) muscle was continuously measured using near infrared spectroscopy (NIRS). Deoxy[Hb + Mb] responses displayed a sigmoidal shape across the four cycling positions. The slope of deoxy[Hb + Mb] / %workloadpeak was significantly ($P < 0.05$) lower in the upright position (0.037 ± 0.017) compared with the three other positions (30°R = 0.055 ± 0.022; 15°R = 0.054 ± 0.020; supine = 0.053 ± 0.009), but was not different among the 30°R, 15°R and supine positions. These findings suggest that the reductions in cycling performance observed between the upright and low-recumbent (30°R & 15°R), and supine postures can be partially attributed to greater oxygen extraction levels in the 30°R, 15°R and supine postures, possibly due to a gravity-induced reduction in muscle oxygen delivery. However, factors affecting the differences in cycling performance between low recumbent and supine postures are less clear. References DiMenna F, Bailey S & Jones A (2010). Influence of body position on muscle deoxy[Hb + Mb] during ramp cycle exercise. Respir Physiol Neurobiol 173, 138-145. Egaña M, Columb D & O'Donnell S (2013). EFFECTS OF VOLUNTARY INCREASES OF VENTILATION ON BREATH-BY-BREATH O₂ UPTAKES

FRANCESCATO, M.P., CETTOLO, V.

University of Udine

INTRODUCTION Breath-by-breath (BbB) oxygen uptake values are obtained in humans by automatic devices that measure O₂ and CO₂ fractions and respiratory flow at the mouth; calculations are usually based on the open-circuit algorithm, applying the Haldane transformation. This approach is prone to introduce distortions of gas exchanges, especially when changes in the pulmonary gas stores take place (Capelli et al. 2011). We compared the O₂ uptake values calculated applying the open-circuit algorithm (OC) or an algorithm based on an alternative view of the respiratory cycle (AC), which likely takes into account the variations of the pulmonary O₂ stores (Cettolo & Francescato, 2015), when ventilation was voluntarily inconsistent with the actual metabolic demand. METHODS Respiratory flow, O₂ and CO₂ fractions at the mouth were continuously recorded over 20 min (CPET Metalyzer 3B, Cortex, Germany) in 9 healthy subjects (5 M; 4 F; 33±15 years old; 78±19 kg body mass) while they sat quietly on a chair. At 5 min intervals throughout the trials volunteers were asked to abruptly increase their ventilation for about 20 s, thereafter returning to quite conditions. Heart rate was recorded throughout by means of a chest belt (Polar, Finland). Computerised procedures were developed in C language for both OC and AC, allowing us to compute ventilation and BbB oxygen uptakes from the gas and flow traces. For each subject, three averages (over 10 breaths) were calculated just before each hyperventilatory period (REST) and three averages were calculated during the increased ventilation (HYPER), yielding overall 30 values for each condition. Standard statistical tests were used. RESULTS Ventilation amounted on average to 13.8±8.9 L/min during REST and increased about ten-fold (95.2±64.1 L/min) during HYPER. Average heart rate amounted to 79.6±15.8 bpm during REST and increased significantly to 84.2±16.2 bpm (paired t-test, $p < 0.001$) during HYPER. Average oxygen uptakes during REST were not significantly different applying the two algorithms (0.288±0.063 L/min vs. 0.291±0.068 L/min for AC and OC, respectively; $p=NS$). Higher oxygen uptake were obtained during HYPER as compared to REST, the values calculated with AC being significantly lower than those calculated with OC (0.622±0.172 L/min vs. 0.714±0.273 L/min, respectively; $p < 0.001$). CONCLUSIONS In correspondence with the sudden increases in ventilation, although there was not an important increase in the metabolic requirement, the algorithms for the calculation of oxygen uptake yielded artificially high values. The new algorithm AC, however, provided lower values, suggesting that it likely was able to better compensate for the changes in the pulmonary O₂ stores. REFERENCES Capelli C, Cautera M, Pogliaghi S. THE EFFECTS OF EXERCISE MODALITY ON MAXIMAL AND SUBMAXIMAL EXERCISE PARAMETERS OBTAINED BY GRAD-ED MAXIMAL EXERCISE TESTING

CORNELIS, N., BUYS, R.

KU Leuven

Background. Cardiopulmonary exercise testing (CPET) has become part of routine medical screening and evaluation of both healthy individuals and patients with various disorders. The modalities most often used to perform these tests are the treadmill (TM) and upright bicycle (UB). Nowadays, the supine bicycle (SB) is becoming more often used, especially when combined with medical imaging. However, it is not known if the same results are achieved with this last modality in comparison with the traditional TM and UB tests. Aims. The goal of the study was to examine whether a maximal CPET on a SB leads to similar results as the TM and UB in terms of peak oxygen uptake (peak VO₂), peak heart rate and submaximal exercise measures. As a secondary goal, we preliminary explored how peak VO₂ relates to the person's preference and experience with the different exercise modalities. Methods. Twelve healthy individuals (8 male; mean age 21.6, range 21-24) participated in a randomized controlled cross-over trial performing three maximal exercise tests on a TM, UB and SB. During the tests, respiratory gas-exchange was monitored breath-by-breath and heart rate was continuously measured. Peak exercise measures were defined as the average of the last 10 s of the exercise test. Preference for a certain exercise modality was evaluated by a self-developed questionnaire. Post-exercise experience was evaluated with the Subjective Exercise Experiences Scale (SEES). Differences between the outcome measures obtained by the different CPET modalities were evaluated by means of repeated measures ANOVA. Intraclass correlation coefficients (ICC) and Bland-Altman plots were obtained for further evaluating agreement between the investigated parameters. Results. The SB exercise tests resulted in a significantly lower peak VO₂ ($p<0.001$) (2806 ± 652 ml.min⁻¹ (SB) vs 3329 ± 798 ml.min⁻¹ (UB) and 3550 ± 799 ml.min⁻¹ (TM)) and peak heart rate ($p<0.001$) (179 ± 8 beats.min⁻¹ (SB) vs 192 ± 7 beats.min⁻¹ (UB) and 193 ± 11 beats.min⁻¹ (TM)). ICC evaluation and supplementary Bland-Altman plots showed low agreement between peak VO₂ (ICC 0.545 (SB vs TM); 0.630 (SB vs UB)) and peak HR measures (ICC 0.308 (SB vs TM); 0.144 (SB vs UB)). No significant differences could be found when comparing the TM and UB post-hoc. Partial correlation, controlling for the possible influence of both preference and experience, did not change the initial differences in peak VO₂ between the exercise modalities. Conclusion. Upcoming maximal SB exercise tests, for evaluations in clinical settings, can't be considered as an evaluation of the maximal exercise capacity when compared to golden standard TM and UB.

AGREEMENT BETWEEN THE STAGES CYCLING AND POWERTAP POWERMETER

SCHNEEWEISS, P., HAERLEN, S., AHREND, M.D., NIESS, A.M., KRAUSS, I.

University Hospital of Tuebingen

Introduction Training at high intensities can only be controlled inadequately by heart rate because it is considerably affected by internal and external factors and responding delayed to exercise intensity modifications. In contrast, mobile powermeters allow the assessment and control of cyclist's training intensities more accurately. Today, several powermeters are available and are now getting affordable for amateur athletes as well. The well-established PowerTap (PT; CycleOps) quantifies cycling power output (PO) via strain gauges in the rear wheel hub and has already been validated in previous studies. The Stages Cycling Powermeter (SCP; Stages Cycling) is a cheaper device that is more flexible for usage as PO is quantified in the left crank arm via integrated strain gauges. The aim of this study was to determine the agreement between these two devices. Methods An ordinary road bike was equipped with SCP and PT and mounted on a stationary cycle trainer (Flow T2200, Tacx). 38 participants performed a sub-maximal incremental test (100-400 W; 120s per level) and a sprint test (600 W; 30s). The levels were separated by recovery periods at 70 Watt. The PO was defined according to the cycle trainer. PO and cadence of PT and SCP were recorded simultaneously once per second. Differences in PO and cadence were determined and normalized to corresponding PT values and given in percentage. Agreement between methods was quantified by use of mean differences and limits of agreement (LoA). Results Compared to the PT, SCP underestimates PO across all intensities by a mean difference of -1.88 ± 3.97 %, while LoA range from 5.9% to -9.7%. Considering cadence, SCP calculates 0.94 ± 0.16 revolutions per minute more than the PT (LoA: 0.63 to 1.25). Differences are almost consistent across all intensities. Discussion Confirming previous studies, SCP significantly underestimates PO though it is reliable. This may in part be due to differences in strain gauge configuration, the algorithms used to calculate PO and the potential influence that bilateral imbalances may have on these calculations. Although mean difference between SCP and PT is in an acceptable range, 95% of the individual PO differences account for up to 10 per cent. This means practical relevant PO differences up to 50 W between PT and SCP when cycling at higher intensities of 500 W or more. Precise training at high intensities can therefore only be warranted if precedent performance tests are carried out with the same powermeter. To determine the cadence, SCP uses an accelerometer while PT uses the repetitive PO peaks. Despite different measurement procedures, results show small differences that should be negligible for training control. Contact Patrick.Schneeweiss@med.uni-tuebingen.de

A COMPARISON BETWEEN DIFFERENT METHODS OF ESTIMATING ANAEROBIC ENERGY PRODUCTION DURING CROSS-COUNTRY ROLLER-SKIING

ANDERSSON, E., MCGAWLEY, K.

Swedish Winter Sports Research Centre

Introduction Two frequently used approaches for estimating anaerobic energy production during supramaximal exercise are the maximal accumulated oxygen (O₂) deficit (MAOD) method and the gross efficiency (GE) method (Noordhof et al., 2011). Despite clear computational differences between the two methods, only one direct comparison has been performed (Noordhof et al., 2011). In cross-country roller-skiing, both the MAOD and the GE methods have been employed (Andersson et al., 2016). Therefore, this study aimed to compare the O₂ deficits attained with these methods. Methods Eleven male and ten female cross-country skiers were tested on a treadmill employing uphill (7°) diagonal-stride roller-skiing. After collecting a 1-min baseline VO₂, participants performed a 4 × 4-min continuous submaximal protocol (~ 60-90% of VO_{2max}) followed by, a self-paced 600-m time-trial (TT). Speed and VO₂ were measured continuously during the TT. For the MAOD method, the linear relationship between treadmill velocity and VO₂ during the final 30 seconds of each 4 × 4-min submaximal stage was derived with the baseline VO₂ as a Y-intercept included (4+Y) in or excluded (4-Y) from the model. The two regression equations were then used to estimate the VO₂ demand during the TT. For the GE method, the metabolic rate during the TT was calculated by taking the average power output divided by the GE (an average of the four submaximal stages) and converted to a VO₂ demand. Results The VO₂ demand was significantly higher for the GE (68.9 ± 8.5 mL/kg/min) and 4-Y (68.4 ± 8.7 mL/kg/min) procedures compared with the 4+Y (64.3 ± 7.6 mL/kg/min) procedure ($P < 0.05$). The corresponding O₂ deficits for the GE, 4-Y and, 4+Y proce-

dures were 63.7 ± 9.7 , 62.3 ± 10.4 and, 50.2 ± 9.6 mL/kg, respectively ($P < 0.05$ for GE and 4-Y vs. 4+Y). The mean difference between the O₂ deficits estimated from the 4-Y and GE procedure -1.4 ± 3.9 mL/kg, and between the 4+Y and GE procedures was -13.5 ± 2.5 mL/kg. Corresponding typical errors for the two comparisons were 2.74% and 1.74% while the intra-class correlation coefficients together with linear equations were $r = 0.93$ ($0.99x - 0.8$) for [4-Y vs. GE] and $r = 0.97$ ($0.95x - 10.5$) for [4+Y vs. GE]. Discussion The main finding of the current study was the high agreement between the 4-Y and GE procedures which is in contrast to previous findings of Noordhof et al. (2011). Moreover, the inclusion of a Y-intercept for baseline VO₂ resulted in a 20% lower O₂ deficit compared to the 4-Y and GE procedures. References Andersson E, Björklund G, Holmberg HC, Ørtenblad N. THE EFFECT OF COMPASSIONAL HYPERALGESIA ON EXERCISE-INDUCED PAIN DURING ENDURANCE CYCLING PERFORMANCE

ASTOKORKI, A.H.Y., MAUGER, A.R.

University of Kent

THE EFFECT OF COMPASSIONAL HYPERALGESIA ON EXERCISE-INDUCED PAIN DURING ENDURANCE CYCLING PERFORMANCE Astokorki, A.H.Y., Mauger, A.R University of Kent, Chatham, UK Introduction Pain is an unpleasant, subjective experience that includes sensory and emotional components (Rainville, 2002). Several studies have shown that observing other's pain can enhance the intensity of painful stimuli – an effect termed compassionate hyperalgesia (Godinho et al., 2012). Intense exercise causes a noxious environment in the muscle that elicits 'exercise-induced pain' (EIP), and tolerance of this sensation has been associated with endurance performance. It is unknown the degree to which this sensation is effected by top-down processing, such as compassionate hyperalgesia. Methods Twenty-one participants, trained in cycling, completed 5 laboratory visits. The first visit involved an assessment of aerobic capacity (VO_{2max} test) and a familiarisation of the fixed power (FP) and time trial (TT) tests. The second visit provided a further familiarisation of the FP and TT. In the subsequent three visits, in a counter-balanced manner, participants performed a FP and TT. Immediately prior to these, participants viewed a collection of images from the International Affective Picture System database that were either pleasant, unpleasant (painful) or neutral. Participants were asked to rate each image with respect to affective valence and their level of emotion. During the TT and FP, participants were asked their EIP, RPE and had measures of HR and B[La] recorded. Results ANOVA revealed a significant difference in TT performance, PO and HR ($P < 0.05$) between conditions during the TT cycling performance, but no significant effect of condition for mean RPE or EIP ($P > 0.05$). For the FP, a significant main effect of condition for EIP, but no difference for RPE, HR or B[La]. A significant effect of condition for Depression, Tension, Anger, and Confusion following viewing the images ($P < 0.05$). No differences were found for fatigue and vigour. Discussion The results of this study demonstrate that viewing painful images prior to exercise decreased TT performance. This study demonstrates that there is an emotional element to the processing of EIP that can be influenced by compassionate hyperalgesia. It is suggested that the dorsolateral prefrontal cortex (DLPFC) plays a crucial role in physical, somatosensory pain perception, and in emotional pain (Borckardt et al., 2007). Future studies should seek to examine cortical changes in the DLPFC during exercise that elicits sensations of pain. References Rainville, P. (2002). Curr. Opin. Neurobiol., 12, 195–204. OP-PM52 Adapted Physical Activity - Temperature

VALIDATION OF AN INGESTIBLE TEMPERATURE DATA LOGGING AND TELEMETRY CAPSULE DURING EXERCISE IN THE HEAT

TRAVERS, G.J.S.1,2, NICHOLS, D.1, FAROOQ, A.1, RACINAIS, S.1, PÉRIARD, J.D.1

1:Aspetar, 2: Brunel University London

Introduction Gastrointestinal temperature measured via radio telemetry of an ingested capsule has been shown to be a valid index of core temperature (Byrne & Lim, 2007). However, the additional recording equipment that must be carried by athletes limits its use to a monitoring tool during training. Recent technological advances have led to ingestible telemetry capsules that are also capable of storing data for later analysis. The purpose of this study was to determine the validity and reliability of this new temperature logging and telemetry system. Methods A 3-point calibration in a temperature controlled water bath was initially undertaken in 24 pairs of pills for the e-Celsius (BodyCap; T-BC) and Equivital (Respironics; T-ELM) systems, along with rectal temperature probes (T-rec). Reference temperatures were determined from an uninsulated digital reference probe at 35, 38.5 and 42°C. Following calibration, 12 trained males performed 60 min of cycle exercise at ~50% peak power output in conditions of 35°C & 52% relative humidity. Gastrointestinal temperatures were compared to T-rec throughout. Results from the calibration were used to determine the mean bias and SEM. Results Calibration data indicated all measurement devices consistently underestimated water bath temperature at all three reference points ($P < 0.05$) with the exception of T-rec at 38.5 and 42°C ($P > 0.05$). Additionally, both T-ELM and T-BC consistently underestimated T-rec with a SEM of ± 0.09 and ± 0.34 at 35°C, ± 0.37 and ± 0.10 at 38.5°C and ± 0.35 and ± 0.12 at 42°C, respectively. When compared to T-ELM, T-BC was consistently lower with a mean bias of $0.16 \pm 0.48^\circ\text{C}$, $0.18 \pm 0.50^\circ\text{C}$ and $0.15 \pm 0.46^\circ\text{C}$ at 35, 38.5 and 42°C, respectively ($P < 0.05$). During the cycling trial, T-rec was significantly greater than T-BC from 15 min onward and greater than T-ELM at 50 and 55 min only ($P < 0.05$). Furthermore, T-BC was significantly lower than T-ELM at several points following 20 min of exercise ($P < 0.05$). Discussion T-BC and T-ELM consistently measured lower core temperatures compared to T-rec during exercise in the heat, contrary to previous reports (Byrne & Lim, 2006). This relationship was also consistent across a wide temperature range in controlled water bath manipulations, suggesting an inherent mean bias of the devices used in this study. However, T-BC consistently under-reported intestinal temperature by $0.15\text{--}0.18^\circ\text{C}$ compared to T-ELM. Therefore, we recommend calibrating these capsules before use in both field and laboratory settings to provide accurate and reliable measures of core temperature. References Byrne C, Lim C (2007). RECTAL TEMPERATURE, FLUID INTAKE, DEHYDRATION RATE AND BIOCHEMICAL AND HEMATOLOGICAL DATA IN THE RUNNERS PARTICIPATED IN CITIZEN'S HALF-MARATHON IN SUMMER

MATSUMOTO, T., SATO, M., MIZUNO, H., FUJIMOTO, K., YAMASHITA, N., FAN, M., HOSHI, K.

School of Health and Sport Sciences, Chukyo University

Introduction Marathon, a long distance running, is an aerobic exercise which promotes health and fitness, however it causes large heat stress and may induce heat illness, even in cool seasons, especially in the hot summer. We investigated the influence of the summer half-marathon on the runner's body in Obuse Mini-Marathon held at Obuse, Nagano, Japan, on 19th July, 2015. Methods Twenty-nine runners (24 men and 5 women) volunteered as the subjects. Body weight and tympanic temperature (Tty) were measured and venous blood samples were obtained for biochemical and hematological analysis before and after the race. Volume of fluid intake during the race was interviewed and rectal temperature (Tre) was measured after the race. WBGT was monitored along the course every 1km. Sports drink and water were supplied every 1 km. Sweat loss was calculated as weight loss plus fluid intake, and dehydration rate (%) was calculated as weight loss divided by initial weight x 100. Results & Discussion The race started at 6 AM at 22 degrees C of WBGT and closed at 11 AM at 30 degrees C of WBGT. All subjects completed the race at the time between 1h 22min and 3h 42min without any symptom of heat illness. Mean Tre immediately after the race was 38.5 C (range: 37.6-39.7 C), and 5 subjects finished with Tre above 39 C. Tty showed a correlation with Tre, but did not detect any of 5 subjects who's Tre above 39 C, suggesting that Tty is not a substitution of Tre for screening the heat illness. Mean weight loss was 1.13 kg in men and 0.45 kg in women. One man and two women finished the race with a slight increase in weight. Dehydration rate was 1.6+/-0.9% (range: 0.6% increase - 3.0% loss) and was above 2% in 10 subjects. Fluid intake was 1.2 L (0.1-2.4 L) in men and 0.8 L (0.5-1.3 L) in women. Sweat rate was 1.1 L/h (0.5-2.1 L/h) in men and 0.4 L/h (0.2-0.8 L/h) in women. The blood analysis before and after the race were as followed; Albumin: 4.6 to 5.0 g/dL, AST: 24.1 to 31.8 U/L, LDH: 213 to 275 U/L, CK: 145 to 251 U/L, BUN: 16.8 to 18.3 mg/dL, Na: 142 to 145 mEq/L, Cl: 101 to 102 mEq/L, WBC: 5514 to 9181 /micro L, RBC: 467 to 481 x 10000 /micro L, Hb: 14.2 to 14.6 g/dL, Hct: .46.3 to 47.4 %. Hemoconcentration rate was 8.0+/-0.9% calculated from the change of Albumin and 5.1+/-6.0% from the changes of Hb and Hct. Moderate increases in AST, ALT, LDH and CK greater than hemoconcentration rate indicate a minimum rhabdomyolysis. The less increase in Na and Cl compared to hemoconcentration rate, indicates insufficient intake of NaCl during the race.

EXTREME HOT CLIMATIC CONDITIONS LIMITS PHYSICAL ACTIVITY PARTICIPATION

ALMOHANNADI, A.S., FAROOQ, A., BURNETT, A., WALT, M., ALKUWARI, M.G.

ASPETAR

Introduction Even though there are several studies showing seasonal variation in physical activity participation across the globe. There are only handful of studies that have assessed physical activity behaviour when weather is relatively hot for most part of the year. Qatar experiences summer months when temperature usually ranges from (25°C–46°C). This study aimed to assess longitudinal changes in pedometer-assessed physical activity as a result of hot weather. Methods In this study we enrolled 2088 adults (66.6% men) from a community health program in Doha. Daily physical activity was recorded using pocket-sized pedometer (Omron HJ-720ITC, USA) and each participant uploaded this on the community web-platform. Data related to daily climatic conditions of Doha city was obtained from the www.wunderground.com website. Results A strong inverse relationship was found between participation of physical activity and average daily temperature. Further wind speed and visibility was associated with decrease in average physical activity participation. The negative influence of climatic conditions was similar across gender, age and nationality. Conclusions Hot weather reduces physical activity therefore interventions should be planned to promote physical activity at times of the day when temperature is warmer. Also campaigns should involve in-door activities to promote physical activity participation. References Hallal PC, Andersen LB, Bull FC, Guthold R, Haskell W, Ekelund U. THE SWEATING RESPONSE AND FLUID INTAKE OF ELITE PROFESSIONAL FOOTBALL PLAYERS DURING TRAINING AT DIFFERENT EXERCISE INTENSITIES IN HOT AND COOL ENVIRONMENTS

ROLLO, I.I., CARTER, J.M.I., RANDELL, R.K.I., JEUKENDRUP, A.E.3, LIZARRAGA, M.A.2, MEDINA, D.2

1The Gatorade Sports Science Institute, PepsiCo Global Nutrition R&D, 2FC Barcelona Medical department, FC Barcelona, Spain. 3School of Sports Exercise and Health Sciences, Loughborough University, UK

Sweat rate and sweat composition vary between individual players of a team. To date no data is available on the fluid and sodium [Na+] losses or ad-libitum carbohydrate (CHO) or fluid intake of elite professional players in response to exercise at different intensities and in diverse environmental conditions. Data were collected from 12 male professional football players on four separate training occasions under the following conditions: cool ($15 \pm 7^\circ\text{C}$, $66 \pm 6\text{ RH}$) low/moderate intensity (RPE 1-5) (CL); cool high intensity (RPE 6-10) (CH); hot ($29 \pm 1^\circ\text{C}$, $52 \pm 7\text{ RH}$) low/moderate intensity (HL); hot high intensity (HH). Training sessions were 75 ± 15 min involving intermittent running and football specific play. Before and after the first training session of the day all players were weighed in minimal clothing. During training players had free access to sport drink (Gatorade Thirst Quencher) and water. Each player was allocated their own drinks bottles which were weighed before and after training. Any urine produced was also collected and measured during the training session. Sweat samples were collected from regional absorbent patches during exercise on the thigh and back of each player. Sweat was subsequently analysed for sodium concentration [Na+] (compact Horiba B-722). Results, mean \pm SD (range). Urine specific gravity prior to exercise; CL: 1.024 ± 1.005 (1.016-1.032), CH: 1.014 ± 1.004 (1.014-1.028), HL: 1.023 ± 1.006 (1.011-1.030), HH: 1.026 ± 1.005 (1.017-1.034); F(3,33) = 2.0, P = 0.157. Sweat rate (L/h); CL: 0.66 ± 0.14 (0.40-0.87, CH: 0.88 ± 0.24 (0.70-1.50), HL: 0.99 ± 0.23 (0.60-1.37), HH: 1.56 ± 0.43 (1.08-2.70), F(3,33) = 22.7, P = 0.000. Sweat Na+ loss (mg/h); CL: 558 ± 230 (198-978), CH: 739 ± 420 (288-1846), HL: 889 ± 355 (435-1482), HH: 1493 ± 458 (979-2272), F(3,30) = 14.9, P = 0.00 (n=11). Fluid intake (ml/h); CL: 351 ± 159 (0-552), CH: 427 ± 261 (81-1058), HL: 551 ± 174 (330-791), HH: 650 ± 282 (266-1257), F(3,33) = 5.3, P = 0.04. Percentage dehydration; CL: 0.5 ± 0.3 (0.0-0.9), CH: 0.8 ± 0.4 (0.2-1.6), HL: 0.6 ± 0.4

(0.2-1.4), HH: 1.3 ± 0.3 (0.8-1.9), F(3,33) = 22.7, P = 0.00. CHO intake (g/h); CL: 10 ± 7 (0-24), CH: 12 ± 11 (0-35), HL: 17 ± 10 (4-35), HH: 14 ± 11 (0-38), F(3,33) = 1.6, P = 0.195. Elite football players' fluid loss, Na⁺ loss, ad-libitum fluid intake varies significantly in response to different exercise intensities in different environmental conditions. Ad-libitum CHO intake varies widely between players. These results may inform programs aimed to personalize player nutrition.

THE EFFECTIVENESS OF ENCOURAGING INDIVIDUALS TO STAY WELL-HYDRATED IN THE PRE-TRIAL PREPARATION PERIOD

EL-CHAB, A., DELEXTRAT, A., SIMPSON, C.

Oxford Brookes University

The effect of hypohydration on endurance performance is widely known and extensively studied. However, many researchers limit their pre-trial hydration strategies to simply encouraging participants to stay well hydrated without providing any instructions on how to do so. It is still not known whether this encouragement is successful in minimising the risk of starting an exercise test in a hypohydrated state. Therefore, the main aim of this study was to measure the incidence of participants who were hypohydrated on their arrival to the laboratory after receiving encouragement to stay well-hydrated. Forty-five normally active (non-athletes) or moderately trained (athletes) men provided a first morning urine sample at home soon after waking. Approximately one hour after, they provided a second urine sample at the laboratory. Participants were instructed to fast overnight for 10 hours from all food and drinks except from water, which they were verbally encouraged to drink to stay well hydrated. The verbal encouragement given to participants was as follows: 'keep yourself well-hydrated throughout the day, especially in the evening, before the urine collection. This can be achieved by drinking an additional amount of water to your usual intake'. Participants were not informed about the real aim of the study in order to prevent them from modifying their behaviour which could make the results invalid. The results indicated that 35% of participants were significantly hypohydrated, 30% were likely hypohydrated, and 35% euhydrated on their arrival to the laboratory. First morning urine osmolality values were (mean ± SD): 1043 ± 108 , 801 ± 44 , and 538 ± 107 mOsmol.kg⁻¹, respectively. Mean urine osmolality of the first void was not significantly different than the second void (825 ± 182 and 849 ± 235 mOsmol.kg⁻¹, respectively; p = .71). Furthermore, no significant differences were found between athletes and non-athletes (780 ± 222 and 808 ± 251 mOsmol.kg⁻¹, respectively; p = .69). These results indicate that encouraging participants to drink water in the pre-trial preparation period is not sufficient to achieve euhydration in all participants.

REHYDRATION REGIMES IN EXERCISE AND NON-INVASIVE HYDRATION METHODS; A FIRST ATTEMPT

JANTA, M., KRAUTSDORFER, S., SENNER, V.

Technical University of Munich (TUM)

Introduction Human body water and sweat play vital roles in exercise, functioning as solution for physiological processes or as medium preventing hyperthermia. Certain blood electrolyte levels reflect either hypo- or hyper hydrated states that impair performance and are meant to be related to sweat composition. Real time monitoring through wearable technologies provide valuable opportunities assessing individual states in exercise. The aim of the study was first to assess individual hydration regimes non-invasively via so called Ion Selective Electrodes and second to analyze the effect of different rehydration procedures onto physiological strain. Methods 25 healthy, male subjects (Age: 24 ± 1.8 years; Height: $183\text{cm} \pm 9$; Weight: $78\text{ kg} \pm 9.8$) were tested in a controlled environment ($t=22-25^\circ\text{C}$; relative humidity=45%; $v_a=0.1-1\text{ m/s}$; clothing: $0.1\text{ m}^2\text{K/W}$) at 60 % of their VO_{2max} on an individually adjustable ergo meter for 70 and 90 minutes. Refractometry, weighing, absorbents, ion selective electrodes, and blood samples provided information about pre-, dum, and post active hydration states and sweat rates. To control pre-test hydration, ACSM protocols were used. Three different rehydration regimes (reactive, anticipative, and ad libitum) were randomly assigned and compared with a baseline test to identify optimum ways for hydration homeostasis. Heart frequency and core temperatures were taken as parameters for physiological strain. Results None of the rehydration regimes showed significant results (p=.43) on physiological strain and sweat loss (p=.64). These results could be explained by any individual component, such as fat content or pre-test hydration state. Ad libitum rehydration was up to 50% lower than measured sweat loss. Local sweat compositions highly varied across subjects (Chest 47.6 ± 25.7 mmol/l; Lower Back 26.2 ± 19.4 mmol/l, Forearm 42.2 ± 25.8 mmol/l) and over time no changes in blood sodium concentration could be observed between three measurements ($t_1=137$ mmol/l; $t_2=138$ mmol/l; $t_3=138$ mmol/l). As result only low correlations ($R^2=.15$) were found between local sweat composition at core body parts and blood sodium levels. Discussion It's most likely, that protocol duration was key factor not observing any changes in blood volume. Due to manifold processes the body is able to counterbalance any decrease in blood sodium concentration. To current state correlations are likely to be detectable at a much later state (>2h). It seems somehow irrelevant how to rehydrate in durations around 1 hour to reduce physiological strain, although ad libitum regimes underlined people's inability to sufficiently maintain a healthy water balance. It will be important how new systems deal with or compensate individual differences and feedback effective counteractions. Interestingly, described studies showed both the complexity but necessity of new feedback systems with more research to be done.

BLOOD FLOW RESTRICTION AND RELEASE IN THE LOWER LIMBS DURING EXERCISE: EFFECTS ON TISSUE OXYGENATION AND EXERCISE PERFORMANCE

CHEROUVEIM, E.1, DIPLA, K.2, VRABAS, I.2, GELADAS, N.1

1:National and Kapodistrian University of Athens, Greece, 2:Aristotle University of Thessaloniki, Serres, Greece

Introduction Muscle ischemia is a limiting factor to performance. Ischemic precondition with application of repeated cycles of inflation and deflation of a blood pressure cuff on the limbs just before exercise has been shown to improve either maximal oxygen consumption (de Groot et al 2010) or exercise performance (Crisafulli et al 2011). However, it is not known whether the acute release of restricted muscle blood flow during exercise restores or improves exercise performance. The aim of this study was to investigate whether the acute release of muscle ischemia and the subsequent restoration of flow during incremental exercise can alter (i) cerebral and muscle oxygenation,

and (ii) exercise performance. Methods Thirteen healthy well-trained cyclists (33 ± 2 yrs), performed an incremental cycling exercise test to exhaustion on three separate conditions: a) with thigh cuffs (C) inflated to 120 mmHg on both legs throughout the exercise session, b) exercise with thigh cuff occlusion followed by deflation (CNoC) at 80% of PPO, and c) a control session, without occlusion (NC). Ventilatory and cardiovascular responses, as well as muscle and cerebral oxygenation were measured continuously throughout testing. Results Exercise performance was significantly attenuated during cuffs inflation exercise vs. control exercise, as indicated by the reduction in $\dot{V}O_{2\text{max}}$ ($18 \pm 2\%$), PPO ($27 \pm 2\%$) and time to exhaustion ($28 \pm 2\%$); whereas, the CNoC exercise rapidly restored the aforementioned variables to values observed in the control exercise bout. The reduction of exercise performance was associated with attenuated maximal cardiovascular responses, i.e. significant reductions in maximal heart rate (by $9 \pm 3\%$) and cardiac output ($14 \pm 7\%$). Muscle blood flow restriction significantly altered muscle and cerebral oxygenation at exhaustion. A blunted response in oxygenated hemoglobin ($\Delta[\text{O}_2\text{Hb}]$) was observed during cuffs inflation exercise vs. control exercise (-11.33 ± 1.35 vs. -6.29 ± 1.11 μM , respectively; $p < 0.01$), while cerebral $\Delta[\text{O}_2\text{Hb}]$ was significantly lower during cuffs inflation compared with control exercise. The acute release of external thigh pressure during exercise restored all the aforementioned parameters to level observed during control exercise bout. Discussion Exercise performance, muscle and cerebral oxygenation were attenuated by venous occlusion. These reductions were entirely restored in response to cuff deflation, following occlusion. However, the rapid deflation of the cuff during exercise did not result in enhancements of exercise performance beyond the control session. IPSILATERAL MUSCLE ADAPTATION WITH BLOOD FLOW RESTRICTION TRAINING

MAY, A.K., RUSSELL, A.P., WARMINGTON, S.A.

Deakin University

Introduction Traditional resistance training increases muscle strength in the trained limb, as well as the contralateral limb by cross-education through a mechanism that originates within the central nervous system (CNS) (Lee & Carroll., 2008). However, muscle strength adaptations do not occur ipsilaterally along the superior-inferior axis (West et al., 2007). In contrast, Madarame et al. (2008) showed muscle strength and size to increase in the limb that performed blood flow restriction (BFR) exercise, as well as the ipsilateral limb that performed light non-BFR exercise during the same training sessions. We aimed to validate this effect. Methods Untrained participants were allocated to a BFR (n=10) or control (CON; n=12) group and performed seven weeks of resistance training (3 days per week). During training, both groups performed three sets of dominant arm bicep curls (50% 1-repetition maximum (1-RM)) followed by four sets each of bilateral leg extension and knee flexion (30% 1-RM). The BFR group performed leg exercises with pressurised cuffs applied to the upper thighs, inflated to 60% of limb occlusion pressure (124 ± 11 mmHg; mean \pm SD). Maximum strength (1-RM) was measured using bilateral leg exercises and unilateral bicep curls in both the trained and untrained arms. Total muscle cross-sectional area (CSA) was measured via peripheral quantitative computed tomography in the dominant thigh and both upper arms individually. Results Bilateral leg extension 1-RM increased to a significantly greater extent following training in the BFR group (16.6 ± 1.5 kg; mean \pm SEM) when compared with CON (8.3 ± 1.6 kg) ($P < 0.05$). Knee flexion 1-RM increased similarly between groups. Bicep curl 1-RM in the trained arm showed a greater increase in the BFR group (2.3 ± 0.5 kg) compared with the contralateral untrained arm (1.0 ± 0.4 kg), and the trained arm of CON (0.6 ± 0.3 kg). Muscle CSA of the thighs and trained arms increased similarly between groups, but did not change in the untrained arms. Discussion BFR training of the lower-limbs increased muscle strength in the active upper arm greater than the non-dominant arm and the CON dominant arm. However, there was no effect on muscle size. This suggests that BFR training may induce an ipsilateral (or whole body) strength transfer to muscle that is 'sensitised' by exercise. The mechanism for this effect seems likely to originate via the CNS, similar to cross-education, or via an unknown systemic circulatory mechanism. Both of which require further exploration. EFFECTS OF POST-ACTIVATION POTENTIATION ON MUSCULAR ENDURANCE PERFORMANCE: IS IT POSSIBLE TO DO MORE REPETITIONS AFTER ECCENTRIC LOADING?

ATALAG, O., SEVILMIS, E.

Girne American University

Introduction Effects of post-activation potentiation (PAP) on jumping, sprinting, swimming and explosive type activities has been well documented. However, its effects on muscular endurance performance remains limited. Furthermore, loading protocols for PAP were comprised of muscle contractions of different varieties including isometric, dynamic and electrical stimulation but not eccentric-only. Therefore, the aim of this study is to investigate the effects of PAP on muscular endurance performance after eccentric loading. Method: 42 physically active male participants (PAP Group n=32, Control Group n= 10) who have at least 1 year of resistance training experience and who exercises 3 times/week participated in this study. On the first testing session, after the standardized warm up, 1 Repetition Maximum (RP) of participants was found. 65% of the 1 RM was calculated to find the weight that were going to be used for the muscular endurance performance. Participants completed repetitions to failure with 65% of their 1 RM. Tempo was set at 4 seconds for each repetition. On the second testing session which was done 48 hours after the first session, PAP group did eccentric Bench Press with their 120 % of 1 RM. Resting interval was decided as 8 minutes to elicit the effects of PAP. After the resting period, muscular endurance test with 65 % of 1 RM was completed. The control group did same protocol as the first day on the second test day. Results: No statistical difference was found between the repetitions that were done in the first and second test session of control group($p > 0.05$). Whereas significant increase was found for the PAP group ($p < 0.05$). No relationship between training age and the number of increased repetitions was observed ($p > 0.05$). Discussion: The results of this study showed that performance enhancing effects of PAP can be elicited by eccentric loading. Furthermore, although inter-individual variability was relatively high, it was observed that PAP can also increase muscular endurance performance. Therefore, PAP protocols in resistance training sessions might be used for athletes who want to improve their muscular endurance performance. Key Words: post activation potentiation, resistance training, bench press, muscular endurance, eccentric loading References Seitz, B. L., Haff, G. G. (2015). INSPIRATORY MUSCLE LOADING DURING REPEATED-SPURT EXERCISE

RODRIGUEZ, R.F.1, TOWNSEND, N.2, BILLAUT, F.1,3, AUGHEY, R.J.1

1: Institute of Sport, Exercise and Active Living, ISEAL, Victoria University; 2: Aspetar Orthopaedic and Sports Medicine Hospital; 3: Département de kinesiologie, Université Laval

This project examined the addition of an inspiratory load on locomotor muscle tissue reoxygenation during repeated-sprint (RS) exercise. METHODS: Ten healthy males completed three trials of ten 10 s sprints, separated by 30 s of passive rest. The first two trials were performed randomly without (CONTROL) and with inspiratory loading (INSP). The third trial (MATCH) consisted of ten 10 s intervals that were work-matched to the mean power output during the INSP trial. Breath-by-breath oxygen uptake ($\dot{V}O_2$) was monitored and expressed as percentage of $\dot{V}O_{2\text{peak}}$. A 5-breath rolling average was applied, and peaks and nadirs calculated for each 40 s sprint and recovery period. Vastus lateralis deoxy-haemoglobin (HHbVL) was monitored with near-infrared spectroscopy, and expressed as percent of limb arterial occlusion. Peaks and nadirs were calculated for HHbVL, and reoxygenation rate during the recovery periods was calculated as the time from peak to nadir. Respiratory muscle deoxy-haemoglobin (HHbRM) was expressed as a percent of baseline, and an average was calculated for each 40 s sprint/recovery period. Data was analysed using a one way ANOVA and magnitude-based inferences. RESULTS: Mechanical work completed was similar between INSP and CONT ($\Delta\text{mean } -2.7 \pm 6.4\%$; $p=0.482$; Standardised effect: -0.18 ± 0.43), despite a substantial difference in inspiratory mouth pressure, and there were trivial differences between MATCH and INSP ($\Delta\text{mean } -0.6 \pm 0.1\%$; $p<0.001$; -0.04 ± 0.01). Peak and nadir $\dot{V}O_2$ was $5.3 \pm 3.2\%$ ($p=0.011$; 0.65 ± 0.38) and $5.97 \pm 4.63\%$ ($p=0.037$; 0.73 ± 0.55) higher respectively during INSP than CONT. In contrast, $\dot{V}O_2$ was $22.9 \pm 4.8\%$ ($p<0.001$; -5.35 ± 1.27) and $21.8 \pm 3.6\%$ ($p<0.001$; -3.57 ± 0.66) lower during MATCH compared to INSP. Average HHbRM was $61.2 \pm 62.9\%$ ($p=0.054$; 0.49 ± 0.39) higher during INSP than CONT. Conversely, HHbRM was $-57.2 \pm 11.1\%$ ($p<0.001$; -1.76 ± 0.53) lower during MATCH compared to INSP. There was a trivial difference in peak HHbVL between INSP and CONT ($\Delta\text{mean } -2.5 \pm 6.7\%$; $p=0.702$; 0.15 ± 0.40), and possible small difference in nadir HHbVL ($\Delta\text{mean } -12.1 \pm 15.1\%$; $p=0.374$; -0.31 ± 0.41). Reoxygenation rate was similar between INSP and CONT ($\Delta\text{mean } 2.2 \pm 13.4\%$; $p=0.809$; 0.04 ± 0.26). CONCLUSION: A functional reserve in pulmonary O₂ uptake may exist, to be called upon to support both an elevated work of breathing and locomotor muscle tissue reoxygenation during RS exercise. The lack of difference in reoxygenation between INSP and CON implies that for 'all out' sprint exercise, local control of muscle blood flow may override neural mechanisms arising from a respiratory metaboreflex. EFFECTS OF DIETARY RESTRICTION, METHIONINE RESTRICTION AND ENDURANCE EXERCISE ON INSULIN SENSITIVITY IN RATS

WU, W.C., TSAI, C.H., TSAI, T.Y., HUANG, T.H.

National Cheng Kung University

Abstract Aim: The purpose of this study was to investigate an 8-week dietary restriction (DR), dietary methionine restriction (MR), and endurance exercise (EE), on insulin sensitivity in rats. **Methods:** Forty-eight male Sprague-Dawley (SD) rats (26-week-old) were randomly assigned into six groups, which were the control (CON, n=8) group, 40 % dietary restriction (DR40%, n=8) group, 20 % dietary restriction (DR20%, n=8) group, methionine restriction (MR, n=8) group, endurance exercise (EE, n=8) group, and a positive control group, which subjected to daily pioglitazone treatment (PIO, n=8) groups. Animals of the EE group were subjected to treadmill running at a speed of 16 m/min, 1 hour/day and five days a week. The MR rats were fed by food with 80% lower methionine content. After experimental interventions, the animals were subjected to intraperitoneal glucose tolerance test (IPGTT). Statistical methods of one-way ANOVA were used for comparing the different among groups. **Results:** In body weight, the DR40%, DR20%, and EXE groups showed significantly decreased body weight compared to the CON and the PIO groups. During IPGTT, serum insulin of the DR40%, DR20%, MR, PIO groups were significantly lower than the CON group. And, DR40% showed the most significantly change as compared with other groups. In serum glucose, the DR40%, DR20%, PIO and MR groups were significantly lower at 30 min and/or 60 min after glucose loading as compared to the CON groups. **Conclusion:** Our results indicate that DR, MR, and EE effectively reduced body weight and/or enhanced insulin sensitivity.

HEAT TREATMENT AND EXERCISE PREVENTS SKELETAL MUSCLE INSULIN RESISTANCE IN WISTAR RATS FED A HIGH-FAT DIET

ZHAO, J., XU, J., XU, M., WU, ZH., QU, CH.

China Institute of Sport Science

Background: Insulin resistance (IR) is associated with many related health complications. Previous studies demonstrated that heat and exercise could have positive function on IR separately. Earlier our study in IR rats induced by high-fat diet showed that exercise combined with high temperature had more effective on IR. **Methods:** Male Wistar rats were randomly divided into five groups: exercised (NE; n=10), heat (HC; n=10), exercised and heat (HE; n=10), sedentary (NC; n=10), and normal diet sedentary (CC; n=10). The subjects were fed a high-fat diet (60% calories from fat) for 10 weeks and treated heat and/or exercise for 8 weeks. Protein expression of soleus and extensor digitorum longus (EDL), serum, and brown fat was analyzed using Western blotting. **Results:** Our results show that heat treatment accompanying exercise shifts the metabolic characteristics of rats on a high-fat diet toward those on a standard diet. Eight weeks of heat accompanying endurance exercise increased PGC-1 α , CnA, CaMKIV and p38 MAPK protein expression in the soleus ($P < 0.01$ or $P < 0.05$), Insulin protein expression in the serum ($P < 0.05$), and UCP1 protein expression in the brown fat ($P < 0.05$) compared to the sedentary group. **Conclusions:** Exercise combined with high temperature treatment mitigates the development of IR from Irisin pathway. The study also provides potential "green" methods for therapeutic treatment of insulin resistance.

DEVELOPMENT AND COMPLETE MORPHOLOGICAL AND FUNCTIONAL REVERSIBILITY OF ATHLETE'S HEART IN A RAT MODEL

OLÁH, A., LUX, A., NÉMETH, B.T., MÁTYÁS, C., KELLERMAYER, D., RUPPERT, M., SZABO, L., TOROK, M., MERKELY, B., RADOVITS, T.

Semmelweis University

Purpose: Long-term exercise training is associated with characteristic structural and functional cardiac adaptation termed athlete's heart. However the effect of discontinuation of the training (detraining) on left ventricular (LV) function is still unclear. Our aim was to evaluate the development characteristics of athlete's heart and the reversibility of morphological and functional changes during detraining. Methods: Rats were divided into trained (n=15) and control (n=17) groups. Trained rats swam 200 min/day for 12 weeks, while control rats were taken into the water for 5 min/day. Detrained rats remained sedentary for 8 weeks after completion of the training protocol. We regularly performed echocardiographic measurements to investigate development and regression of exercise-induced cardiac changes. LV pressure-volume analysis was performed to calculate cardiac functional parameters. LV samples were harvested for histological examination. Myocardial gene expression analysis was performed using qRT-PCR. Results: Echocardiographic examinations showed rapidly developing LV hypertrophy in the trained group according to wall thickness values (LVmass index after training period: 2.45 ± 0.09 vs. 2.07 ± 0.07 g/ttkg, $p < 0.05$). This adaptation regressed after detraining (LVmass index: 1.94 ± 0.02 vs. 2.05 ± 0.05 g/ttkg, $p = 0.0634$), which was confirmed by post-mortem measured heart weight and histological morphometry. Unchanged myocardial expression of TGF- β and β -MHC and unaltered amount of LV collagen confirmed the physiologic nature of the observed cardiac hypertrophy. Hemodynamic measurements indicated decreased LV end-systolic volume (LVESV: 75 ± 5 vs. 100 ± 7 μ l, $p < 0.05$) along with unchanged end-diastolic volume (EDV), improved systolic function and contractility (slope of the dP/dtmax-EDV relationship: 35.9 ± 2.6 vs. 25.8 ± 2.8 Hgmm/s/ μ l, $p < 0.05$), ameliorated active relaxation and mechanoenergetics (mechanical efficiency: 53 ± 2 vs. $45 \pm 2\%$, $p < 0.05$) after long-term exercise training. After the detraining period regression of exercise-induced cardiac functional changes were observed: LVESV (117 ± 5 vs. 115 ± 6 μ l, $p = 0.7846$), active relaxation, LV contractility (slope of the dP/dtmax-EDV relationship: 30.5 ± 1.7 vs. 28.4 ± 4.3 Hgmm/s/ μ l, $p = 0.5871$) and mechanoenergetic (mechanical efficiency: 50 ± 2 vs. $48 \pm 5\%$, $p = 0.7760$) enhancement reverted completely to control values. Training and detraining did not affect myocardial stiffness. Conclusions: Our results confirm that the morphological and functional properties of exercise-induced physiologic LV hypertrophy completely regressed after an eight week detraining period.

OP-SH06 Psychology: Soccer & Cognitive Function

THE ORGANIZATION OF COGNITIVE REPRESENTATION OF GROUP-SPECIFIC TACTICS IN SOCCER

LEX, H.

University of Rostock

Introduction Scientific protocols describing tactical performance usually investigate indicators (e.g., running distances, maximum running speed etc.) derived from post-hoc video analyzes (Garganta, 2009). However, the results of a novel scientific approach showed that more experienced soccer players possess a functional cognitive re-presentation of team-specific tactics in soccer. More experienced soccer players end up with faster decisions, because of their functional representation structure allowing to coordinate their gaze behavior aligned to tactical needs (Lex, Essig, Knoblauch, & Schack, 2015). In soccer, performance is not only determined by team-specific tactics. Thus, the present study investigates the cognitive representation of group-specific tactics in soccer. Methods The present study investigated whether cognitive representations are established for group-specific tactics in defense (i.e. defense triangle, four-man backfield defense, golden zone defense) and offense (i.e., give and go pass, overlap, two players crossing) with regard to players expertise. Participants (N = 45) made similarity judgments of 2 x 9 match situations displayed on a tactic board (i.e., 144 decisions) in a successive splitting procedure regarding the required tactical behavior. The decisions informed about the proximity between the match situations, and formed the basis for an unweighted average cluster analysis ($p = .01$, $d_{crit} = 4.48$) complemented by an invariance measure testing structural homogeneity ($\lambda_{crit} = .68$). Results Experienced soccer players possess, in contrast to less experienced players ($\lambda = 0.0$), a structural invariant cognitive representation for offense and defense tactics identical with the representation structure of experienced coaches ($\lambda = 1.0$) and players from the Bundesliga ($\lambda = 1.0$). We found no differences between players specialized for defense and offense tactics. However, players with a coaching license showed as well a functional cognitive representation of group-specific tactics ($\lambda = 1.0$). Discussion This innovative experimental approach measuring individual cognitive representations of group-specific tactics in soccer reveals a well-integrated network of single match situations that each corresponds to functional meaningful group-specific tactics based on soccer specific playing experiences. The cognitive representations of group-specific tactics form an individual profile of each player, which allows to refer to tactical decision making on the pitch. References Garganta, J. (2009). QUESTIONNING THE ROLE OF BLUE VERSUS RED UNIFORMS IN FOOTBALL'S PENALTY KICKS

KRENN, B., HANDSTEINER, M.

University of Vienna

Introduction Past research revealed an impact of uniform colour in sports: Most notably, beneficial effects of the colour red in combat sports were reported (Hill & Barton, 2005). However, also Greenlees Eynon and Thelwell (2013) found a benefit in football's penalty kicks: Penalty takers succeeded less often when facing a goalkeeper wearing a red instead of blue or green jersey. By deepening the approach of their field study, the current experiments were aimed at particularise our understanding of the impact of goalkeepers' but also of penalty takers' uniform colour. Methods Twenty-four video clips showing a football player taking a penalty kick from the perspective of a goalkeeper (experiment 1) and 25 clips showing a goalkeeper preparing himself for saving a penalty from the perspective of the penal-

ty taker (experiment 2) were recorded. Uniform colour of the players/goalkeepers were chromatically changed to red and blue. Each clip lasted four seconds and ended when the player kicked the ball. Thus, ball's trajectory was not shown. Participants rated each clip twice: Once in a red condition, once in a blue condition. The order of the videos was randomized. Thirty-nine experienced male football players (25.64 ± 4.90 years) participated in experiment 1 and rated the level of players' resoluteness from 1 (minor) to 9 (high) and the position where the ball should hit the goal by using a 23-in. touch-screen. In experiment 2, 118 students of sport science ($63 \text{ m}/55 \text{ f}$, 22.25 ± 2.87 years) judged the videos following the same criteria as in experiment 1 but also rated the probability of success for saving the penalty kick from 1 (minor) to 9 (high). Results Paired t-tests did not reveal significant differences for penalty takers wearing red versus blue in resoluteness and anticipated lateral position of the ball. However, for ball's anticipated height a small effect was observed ($t(38) = 2.42$, $p = .02$, $d = .16$): The kicks of red-glad penalty takers were judged to be shot lower at the goal ($M = 109.52 \pm 12.75$) than those of the blue-glad players ($M = 111.69 \pm 13.52$). In experiment 2, no impact of goal keepers' uniform colour was found for resoluteness, probability of success and the anticipated position of the ball. Discussion Both experiments did not find any impact of uniform colour on ratings of resoluteness and probability of success in penalty kicks. Thus, an experimental corroboration of the results of Greenlees et al. (2013) failed. However, a rather small effect was observed for the height of the anticipated ball position. Further research is needed to clarify the origin and significance of this effect more comprehensively. References Greenlees, I.A., Eynon M., Thellwell RC. (2013). *Percept Mot Skills*, 117(1), 1-10. EFFECTS OF STRESS-LEVEL ON HAND-MOVEMENT BEHAVIOR WITH FOCUS ON SELF-TOUCH IN FEMALE PRE-AND POST-PUBERTAL SOCCER PLAYERS

DENSING, K., KONSTANTINIDIS, I., SEILER, M.

German Sport University Cologne

Introduction: Self-touch (ST) may serve for arousal regulation, both of hyper- and hypoarousal, as it may be observed in presence as well as absence of external stimulation. It remains unclear if ST with varying structural features occurs in different contexts, and if this potentially regulatory mechanism is learned or inherent. The aim of this study was to discover if the rate of ST increases with higher stress-levels, to identify structurally different forms of ST used in different contexts, and to find out if there are age differences in stress processing between pre- and post-pubertal female soccer players. Methods: We compared hand movements of 10 pre- (11.9 ± 0.72 y.) and 10 post-pubertal (21.6 ± 1.73 y.) soccer girls in non-stress (NS) and stress (S) settings. As NS setting we used an interview about a positive experience, whilst the arithmetic part of the Trier social stress test (TSST) was used as S-inducing setting. All settings lasted 5 minutes and were filmed. All hand movements as well as structural components of ST were analyzed with the NEUROGES-ELAN system by two independent raters. Results: A decrease in repetitive ST was found (right hand (rh): 1.47 ± 1.54 s/min vs. 0.11 ± 0.24 s/min, $p=0.023$; left hand (lh): 3.81 ± 3.72 s/min vs. 0.92 ± 2.53 s/min, $p=0.007$) in the post-pubertal girls in the S situation compared to the NS situation. The post-pubertal girls displayed less hand movements, including phasic (rh: 9.89 ± 6.76 s/min vs. 0.73 ± 0.97 s/min, $p=0.000$; lh: 8.7 ± 4.57 s/min vs. 1.61 ± 1.93 s/min, $p=0.000$) and repetitive (rh: 2.13 ± 2.75 s/min vs. 0.03 ± 0.09 s/min, $p=0.002$; lh: 1.35 ± 1.26 s/min vs. 0 ± 0 s/min, $p=0.000$) movements in space in the S setting. Pre-pubertal girls showed no change in hand movements in NS and S. The post-pubertal group displayed a stronger decrease in activation (rh: 1.58 ± 13.79 s/min vs. -19.29 ± 12.79 s/min, $p=0.004$; lh: -3.42 ± 8.05 s/min vs. -17.09 ± 14.31 s/min, $p=0.043$) and phasic movements (rh: -2.25 ± 1.57 s/min vs. -9.17 ± 6.88 s/min, $p=0.001$; lh: -0.93 ± 1.92 s/min vs. -7.1 ± 4.28 s/min, $p=0.000$) in the S situation compared to the pre-pubertal girls. Discussion: The puberty seems to influence regulatory mechanisms for stress-regulation and structurally different groups of ST are used in different contexts. This is unlike earlier studies which show an increase of ST movements with increasing the complexity of a test, which might be due to the cognitive complexity or the stress level of the test. Our results suggest that there are differences in stress processing between younger and older female soccer players, which should be accounted in training situations. Contact: kyra.densing@freenet.de

DIFFERENT OPPORTUNITIES TO INFLUENCE THE VISUAL "ATTENTION WINDOW"

HÜTTERMANN, S., MEMMERT, D.

German Sport University Cologne

Visual attention is essential in many areas and situations ranging from everyday life to the workplace. People have to allocate their visual attention from a focused target to a wide scope and vice versa in fractions of a second. Other events require the conscious perception of two objects or scenes at the same time. Many situations including traffic or sports suggest that the focus of attention has a limited size and can be influenced by various factors. We introduced the attention window task, a new measurement of attention breadth, in which people must observe two equally attention-demanding stimuli at the same time in order to respond correctly. Our findings indicate that differences in the spatial distribution of attention result from, for example, effects of age or experiences as well as emotional processes and those affected by current motivation. The maximum spatial extent of attention is ellipsoidal with greater breadth along the horizontal axis than the vertical one. In contrast to the visual field, the elliptical shape of the attention window does not alter by a change of the head position but constantly maintains its oval shape parallel to the ground. We discuss the application of different strategies and factors to improve and adjust performances in different everyday occurrences requiring the ability to pay attention to two peripheral objects at the same time.

THE EFFECT OF TRAIT EMOTIONAL INTELLIGENCE AND PERSONALITY ON HEART RATE VARIABILITY AND SKIN CONDUCTANCE RESPONSE IN RECOVERY PERIODS AFTER STRESS MANIPULATION

ÜNGÜR, G., BAYAZIT, O., TOK, S., BAKIR, M.

Dokuz Eylül University, School of Sport Sciences and Technology

Introduction Stress is one of main factors in regard to peak athletic performance. Physiological stress responses occur when athletes are stressed, and some individual traits may contribute to how athletes regulate these responses. Coping with stress is important in competitive sport fields, and appropriate coping strategies are found to associate with personality (Allen et al., 2011). Therefore, the aim of this study was to investigate the effect of trait emotional intelligence (EI) and personality on stress responses of elite athletes in recovery periods after stress manipulation. Methods Schutte EI Scale and Five Factors Personality Inventory were completed by 54 elite athletes. At laboratory tests; participants were exposed to social stressor (duty of speaking in front of people) and cognitive stressor (Stroop color-word test). There were five minute resting periods between and after stressors. Heart rate variability and skin conductance response (SCR) were recorded as stress responses by a portable biopotential amplifier. Results Participants, who had high score on dimensions of

optimism/mood regulation and utilizations of emotions, had lower low frequency/high frequency (LF/HF) Ratio in all resting periods, while participants with high openness trait, also had lower LF/HF ratio between stressors. Participants with high EI level had lower SCR Ratio in both resting periods, and also lower LF/HF ratio in the last resting period. In addition, participants with high conscientiousness trait, had lower SCR between stressors. Discussion The results show that EI and personality may lead to different levels of stress responses. Generally, EI and its dimensions were related to lower stress responses, in all periods. Laborde et al (2011), similarly, found that the increase of LF/HF ratio was lower for high trait EI handball athletes after stress exposure. Results may indicate that participants with high EI recovered better after stress manipulation. Also, participants with high conscientiousness trait had lower SCR between stressors. Apparently, in another study, negative significant correlation was found between conscientiousness and SCR measured before the competition (Binboga et al. 2012). Additionally, it could be said that athletes with high openness trait may be less affected by challenging conditions. References Binboga E, Guven S, Çatikkas F, Bayazit O & Tok S. (2012). ELECTROCORTICAL ACTIVITY IN A COGNITIVE INHIBITION TASK IMMEDIATELY AFTER MAXIMUM PHYSICAL EFFORT

FINKENZELLER, T.1, DOPPELMAYR, M.2, AMESBERGER, G.1

1: Paris Lodron University Salzburg (Austria), 2: Johannes Gutenberg University of Mainz (Germany)

Introduction The ability to inhibit irrelevant and to focus on relevant stimuli is essential for skilled performance in sports (Abernethy et al., 2007). Elite athletes have to perform well not only in the motor but also in the cognitive domain under maximum physical load and immediately afterwards. Up to now it is still unclear to what extent physical exertion influences basal cognitive processes and associated electrocortical (EEG) activity. The aim of the study was to analyse the time course of the impact of physical exertion on information processing speed in a cognitive inhibition task as assessed by the P300 of the event related potentials (ERP). Methods A total of 14 sport students (4 f +10 m; age = 21.14 y; max. power: 4.56 W/kg) carried out a maximal graded exercise test on a cycle ergometer using a continuous incremental exercise protocol (initial power output: 30W f and 40W m; increment 15W f and 20W m each minute). A modified version of the Eriksen flanker (EF) task (Pontifex, & Hillman, 2007) was administered preceding (t1) and two times immediately after exhaustion (t2 and t3) as well as after a break of five minutes (t4). Reaction times (RT) and EEG was recorded and latency and amplitude of the P300 component of electrode positions Fz, C3, Cz, C4 P3, Pz and P4 were analysed. Results For RT and for ERP, 2 (TASK: congruent vs. incongruent) x 4 (TIME) ANOVA-RM's were calculated. Significant main effects in RT were obtained for TIME ($F(3,39) = 5.08$, $p = .02$, $\eta^2 = .28$) and TASK ($F(1,13) = 222.17$, $p < .001$, $\eta^2 = .95$). Post hoc analyses indicated that RT were significantly lower at t3 and t4 as compared to t1. Concerning to P300 latency, statistics revealed significant TIME effects for electrode positions C3, Cz, C4, Pz and P4. In comparison to t1, post hoc results demonstrated a significant decrease in latency at C3 and Cz for t3 and t4 as well as at C4 for all three post-exercise tasks. The P300 amplitude showed no significant exercise induced alterations. Discussion Maximum physical exercise had a positive impact on information processing speed. The decrease of P300 latencies at central regions is well in line with improved information processing. It was expected that the P300 amplitude will increase after exercise in order to cope with the high physical stress while performing the EF task. However, the results do not indicate a higher allocation of attentional resources. Further studies are encouraged to research the impact of maximum physical loads on basal cognitive processes. Oral presentations**OP-PM73 Coaching: Effects of Training****EFFECTS OF STRENGTH AND CONDITIONING ON CRITICAL VELOCITY IN RUNNING AND SOCCER**

KARSTEN, B.

University of Greenwich

A regular strength training should be an integral part of the coaching process in team sports such as football. To-date no research has investigated the effects of such training on the velocity-duration relationship of Critical Velocity (CV). Objectives: To examine the effects of a moderate intensity strength training on changes in CV and sprint performances in recreationally trained football players. Methods: two football teams were divided in a football training only group (FO; n = 13 : 19 ± 1 127 yr., height 177.3 ± 5.2 cm, body mass 73.2 ± 7 kg). and a strength and football training group (ST; n=13: 18 ± 1 yr., 126 height 174.8 ± 5.4 cm, body mass 72.4 ± 6.6 kg). Both groups were tested for values of CV and 30-m sprint time prior and post training intervention. The ST group performed a concurrent 6-week upper and lower body strength and football training, whilst the FO group performed a football only training. Results: after the re-test of all variables, the ST demonstrated significant improvements for CV values by 0.32 m/s (95% C.I. = 0.16 233 to 0.48; $p=0.000$) after completing the specific training, with no significant changes in the SO group. 30-m sprint performance were slightly improved in the ST group ($p=0.078$, 0.12 m/s, 95% CI = -0.25 to 0.15) with FO players significantly worsening their performance ($p=0.000$) by about 0.98 m/s (95% CI = -1.11 to -0.84). Conclusions: combining a 6-week moderate strength training with football training significantly improves CV, whilst moderately improving 30-m sprint performances in non-previously resistance trained male football players. An integrated regular strength training can consequently be recommended to coaches to enhance critical velocity and sprint performances in football.

EFFECTS OF HIGH-INTENSITY INTERVAL TRAINING ON AEROBIC FITNESS

KARABIYIK, H.1, GURSES, V.V.2, AKGUL, M.S.1, KOZ, M.1

Ankara University

EFFECTS OF HIGH-INTENSITY INTERVAL TRAINING ON AEROBIC FITNESS Karabiyik, H.1, Gurses V.V.2, Akgul.M.S.1, Koz M.1:Ankara UniversityFaculty of Sports Sciences (Ankara, Turkey), 2:Kastamonu School of Physical Education Introduction Recently, a novel type of high-intensity interval training known as sprint interval training has demonstrated increases aerobic and anaerobic performance. However, It

has not been done a study which investigated the effects of eight-week high intensity interval training on aerobic fitness. This study aimed to establish the effects of 8-week high intensity interval training on aerobic fitness. Methods Ten adolescent boys (23.62 ± 3.02 years), completed 24 sessions of Wingate -style high intensity interval training over a 8-week period. The first session consisted of four sprints with training progressed to seven sprints in the final session. Each training session involved a 10 min warm-up followed by a HIIT program consisting of 6x30s all-out sprint a 4 min recovery. A 5 min cool down period was then performed. On the purpose of determine VO₂max (maximal oxygen uptake), VO₂peak (peak oxygen uptake) and TTE (time to exhaustion) all subject performed maximal oxygen consumption test in beginning and in the end of the study. A paired t-test was used to determine the differences in aerobic parameters between pre- and post- values. Data were expressed as mean values ± standard deviation (SD) and standard error (SE). Results Significant improvements ($p < 0.05$) were found by the end of eight week, VO₂max (%23.96), VO₂peak (%16.05), and TTE(%12.57) following the HIIT program among subjects. Discussion: Results showed that eight-week wingate style of high intensity interval training program very effective on aerobic indices. References 1.Laursen, Pb., Blanchard, Ma., Jenkins, Dg. (2002). EFFECT OF MODERATE AND HIGH INTENSITY SQUATS ON COUNTERMOVEMENT JUMP PERFORMANCE ACROSS MULTIPLE SETS OF A CONTRAST PROTOCOL

BAUER, P.1, SANSONE, P.1, MITTER, B.1, SEITZ, L.B.2, TSCHAN, H.1

1: Institute of Sport Science (Vienna, Austria); 2: Center of Resources, Expertise and Sports Performance (Toulouse, France)

Introduction Post-activation potentiation (PAP) of countermovement jump (CMJ) performance following the completion of a conditioning activity (CA) is well-documented (Suchomel et al., 2015). However, the precise effect across multiple sets of paired exercises (CAs and CMJs) remains to be elucidated. The present study was designed to evaluate the PAP effects of moderate (MI) or high intensity (HI) squat exercises on CMJ performance across multiple sets compared to a control session with CMJs only (CTRL). Methods Fifty-one resistance-trained male subjects (mean ± SD: age, 23.2 ± 3.7 y; body mass, 87.4 ± 14.2 kg; squat 1RM, 158.1 ± 30.8 kg) participated in a randomized, cross-over study. After baseline assessment they performed a contrast PAP protocol comprising three sets of either MI (6×60% of 1RM) or HI squats (4×90% of 1RM) alternated with seven CMJs that were performed at 15 seconds, 1, 3, 5, 7, 9 and 11 minutes after the squats. A CTRL session was used where the sets of squats were replaced with one minute of recovery. Jump height recorded with a force plate during MI and HI was compared to that recorded during CTRL to calculate the PAP effect. A repeated measures ANOVA was used to assess the effects of condition (CTRL, MI and HI) and time and their interaction on JH. The alpha level of .05 was adjusted using the Bonferroni method for all ANOVA pairwise comparisons. Results A significant interaction between conditions × time was found [$F(18,01, 900.61)=3.99, p<.001$]. Further analysis indicated a significant decrease in JH at 15 seconds across all three sets of MI and HI compared to CTRL. Both squat protocols produced significantly higher JH at three minutes during the first set (+3.5 ± 8.8% and +3.1% ± 8.5%), whereas performance at five minutes was only increased in MI squats. No significant improvement was found in the second and third sets at any time point ($p>.05$). Discussion Consistent with previous research, the present investigation demonstrates that CMJ performance was potentiated at three minutes during the first set of a contrast PAP protocol involving MI and HI squat exercises. Conversely, no PAP effect was observed in the second and third sets. These findings contrast with previous studies reporting an improvement in jump performance across three sets of squat contrast protocol (Baker, 2008). One possible explanation for the present findings is that fatigue may have accumulated in the second and third sets thus masking the PAP effect. Suchomel, T.J., Lamont, H.L. & Moir, G.L. (2015). A NEW METHOD FOR MEASURING THE AVAILABILITY OF THE MIDDLE ATTACKER IN VOLLEYBALL.

MERCADO PALOMINO, E., MORANTE RABAGO, J.C., PARRA ROYÓN, M., BENÍTEZ SÁNCHEZ, J.M., UREÑA ESPÁ, A.

University of Granada

Introduction In volleyball, some authors have considered the availability of the middle attacker as a measure of success (Costa et al., 2013). The use of measures that capture coordination in sports, such as geometrical centres as network analysis, have been increasing in different levels of team sports (Davids, 2013). These variables are expected to describe accurately complex systems states of coordination and temporal dynamics (Duarte et al., 2012). Notwithstanding, the spatial precision supposes a common limitation on observational studies. The present study intended (a) to develop a support tool to improve the registration of the position in the court; (b) to discover the area of action of the setter when there is availability of the middle attacker; and (c) to find a summary value that allows the comparison between teams and their relationship with other variables. Methods Volleyball Men's World Championship 2010 in Italy was analyzed, with a total of 23 games and represented by 12 national teams, using the variables Latitude and Depth of the setter, and calculating the centroid, the vector and the angle for each team. These variables were calculated by the developed support tool, which allows us to register exactly the position of the setter using an adaptable grid on the court. The data were recorded with the software of observational analysis applied to volleyball VA-Sports. Results From the positions of the setter were created specific profiles of each team where the centroid was calculated from the weighted average of the density of the frequencies. This makes possible to calculate the availability of the middle attacker through the vector, which is the distance between the centroid and the ideal zone of setting. The centroids of the teams vary between 1.049 and 1.468 meters. Discussion In conclusion, the centroid is a summary value of the area of availability of the middle-attacker, allowing us to make comparisons between teams, from the setting frequencies distribution, as well as it could be a future performance indicator. THE RELATIVE AGE EFFECT IN SCHOOL SPORTS

GIL, S.M., BIDAURRAZAGA-LETONA, I., ESAIN, I., IRAZUSTA, J.

University of the Basque Country (UPV/EHU)

Introduction An overrepresentation of participants born in the first months after the cut-off date, known as the Relative Age Effect (RAE), has been observed in some sports, such as football, hockey, rugby and basketball, particularly in elite youth competitions (1). However, less is known about this phenomenon in lower performance levels. Thus, the aim of the present study was to investigate the presence of the RAE in different sports at school level. **Methods** The date of birth of 38644 participants, aged 9-15 years old, of the school sports was analyzed (65.1% boys and 34.8% girls). These children participated in 40 different sports. Football and basketball had 3 and 2 different competition levels, respectively. The percentage of children born in each semester (1S: January-June and 2S: July-December) was compared to the distribution of the children born in the same period using a Chi square Goodness of Fit. **Results** The most popular sport in boys was football (57.4%) followed by basketball (7.3%) and in girls basketball (28%), rhythmic gymnastics (10.6%), handball (9.7%), football (9.4%) and athletics (8.7%). In boys, there was an overrepresentation of participants born in the 1S in football (52.7% vs. 47.6%; p<0.001), basketball (52.4% vs. 47.6%; p<0.05), and also in the whole group (51.7% vs. 48.3%; p<0.001). This uneven distribution was the largest in the highest competition level of the youngest football players aged 9-10 years old (68.5% vs 31.5%, p<0.001). In girls, the overrepresentation was significant in athletics (52.9% vs. 47.1%; p<0.05), basketball (54.2% vs 45.8%; p<0.001), football (54% vs 46%; p<0.05), Basque pelota (59.9% vs. 40.1%; p<0.05) and the total (52% vs. 48%; p<0.001). Within basketball there was a significantly uneven distribution in the highest competition level (61% vs. 39%; p<0.001). **Discussion** In school sports the RAE is particularly evident in the most popular sports and in the highest competition levels, even at the youngest ages, both in boys and girls. This implies that there is a selection process towards the participants born in the first months after the cut-off date, presumably due to their larger body size and a better physical performance (2). A special effort should be made to assure that all children have the same opportunities to participate in the sport, particularly from the very young ages. **Acknowledgements** We would like to thank the Provincial Council for School Sports (Bizkaiko Foru Aldundia) for the collaboration and the data provided. **References** 1-Coble S, et al. THE RELATIONSHIP BETWEEN LEADER-CREATED MOTIVATIONAL CLIMATE AND DISADVANTAGED YOUTHS' PERSONAL AND BEHAVIOURAL CHARACTERISTICS IN COMMUNITY-BASED SPORT

STEBBINGS, J., APPLETON, P.R., DUDA, J.L.

University of Birmingham

Introduction. Organised sports programs offer a unique opportunity for positive youth development (Fraser-Thomas, et al., 2005), and the sports coach plays a fundamental role in optimising participants' experiences within that setting. Considerable sport-based research has demonstrated the positive correlates of an 'Empowering' (i.e., autonomy supportive, task-involving, and socially-supportive), and negative correlates of a 'Disempowering' (i.e., controlling and ego-involving), coaching approach for young participants' motivation, engagement and psychological health (Duda, 2013). Nonetheless, research has yet to consider the correlates of these coach-created motivational climates for youths from deprived communities. In light of the current social problems associated with young people growing up in lower income areas (e.g. poor social-emotional skills, increased antisocial behaviour; Sandford, et al., 2006) the current study aimed to examine outcomes beyond the typical motivational and well-being variables studied in the mainstream sport context, with a focus on those more pertinent for the deprived youths both in and beyond the community sport setting. **Method.** In a cross-sectional design, young participants of 42 community-based sports clubs (N=503; 404 males; age range 9-28; M = 15.2) in the UK completed a multi-section questionnaire. **Results.** A series of multiple linear regressions indicated that the leaders' empowering climate was associated with lower levels of aggression from the young participants, ($\beta = -.14$, $p = .05$) and greater pro-social behaviour, both within ($\beta = .26$, $p < .001$) and outside of ($\beta = .20$, $p < .001$), the sports context. Conversely, a disempowering climate was negatively associated with emotional-control ($\beta = -.25$, $p = .001$) and self-control ($\beta = -.24$, $p = .001$), whilst being positively associated with aggression ($\beta = .27$, $p < .001$) and antisocial behaviour ($\beta = .18$, $p > .05$) within the sport context. **Discussion.** The current study offers insight into the relationships between leader-created motivational climates and the personal and behavioural characteristics of young people from disadvantaged areas. The findings point towards the need for education opportunities (e.g., the Empowering Coaching™), to ensure coaches, leaders and volunteers working in these settings are creating the most adaptive climates for their young participants. **References** Duda, JL. OP-SH18 Skills of Physical Education Teachers

CASE STUDY OF CREATIVE DANCE TEACHING METHODS IN JAPANESE TEACHER EDUCATION PROGRAMS: FOCUSING ON THE USE OF OBJECTS FOR EXPRESSION

PARK, K., MURATA, Y.

University of Tsukuba

Introduction In Japan, we hear from teachers that the free movement and improvised expression of creative dance are hardest to teach and to evaluate, but creative dance exercises that make use of objects for expression get favorable reviews from both teachers and students. Therefore, this study examined the potential of a method of teaching creative dance with the use of objects (such as newspapers and disposable chopsticks) for expression at its core, using dance classes within the Japanese teacher education programs as a case study. **Methods** Of the ten dance lessons held between April and June 2014, there were two lessons on the theme of expression using objects. These were captured on video. We also interviewed the teacher about the reason for the selection of the content. In addition, we had the students describe their impressions and thoughts about the classes in their end-of-term report, and analyzed the reports

using Tiny Text Miner. Results The expressions using newspapers were structured into 4 areas: playing with the newspaper, becoming a newspaper, handling the newspaper, and ripping the newspaper. The reasons for the use of newspapers were because its flexibility elicits diverse qualities of movement and expression, and because it requires children to stimulate their imagination and sense of theatricality in order to become a newspaper. Further, the expression with the disposable chopsticks was structured in two parts. Two students held the chopsticks between their fingers and moved, first with their eyes open and then with their eyes closed. The exercise with the chopsticks was chosen because it twisted the entire body, making it move about a point rather than a line, and also because the students were able to spontaneously improvise with the chopsticks as objets d'art. When talking about the newspaper, the words "becoming" and "getting into character" were used often. We heard that it was hard to get into the character of a newspaper, but that they were surprised at how much fun they had coming up with new movements and enjoying dancing using just a single newspaper. When talking about the expressions using chopsticks, many students said they were amazed that they could create a dance simply from expressions using an everyday item. It can be inferred that they brought this up because it had remained in their memories. Also, it is likely that this kind of exercise encourages students to try to actively engage in interactions with other people. Discussion From this case study, it can be said that expression using objects is an exercise that can be used to teach even students who have a resistance to dance. This is because this method lets students experience the enjoyment of improvisational expression and get caught up in the moment before they know it, and helps them become genuinely aware of the pleasure of movement. Furthermore, even though not even one formal piece of dance is taught, we believe that it is an exercise that can convey the essence of creative dance, which is that "expression comes from within."

PRE-SERVICE PHYSICAL EDUCATION TEACHERS' EFFECT AND CONCERN ATTITUDES TOWARD TEACHING

TASCIOLLU, R., OZBOKE, C., YILDIZER, G., YILMAZ, I.

Anadolu University

Introduction Education is process that build upon the interaction between teacher and students and guided by curriculum. From the perspectives of teachers, values, attitudes and behaviours toward education and factors that affect educational process are important to investigate. It has been previously emphasized that teachers beliefs and attitudes take shape through three consecutive process which are 1) interaction with teachers during pre-university education, 2) interaction between other students during whole educational life, 3) lastly, during their teacher education process. (Nash, 2003). Therefore it is important to hear voice of pre-service teachers in educational instructing in order to improve quality of educational process. Methods Research was conducted on 469 pre-service physical education teachers (PST) ($M_{age}=21,35$, $SD_{age}=24,49$) from 5 different universities in Turkey. "Attitude Scale For The Profession Of Physical Education Teaching" (Ünlü, 2011) was implemented. Five-point likert-type scale consisted of two factors; (1) effecton for profession (EP), (2) concern about the profession (CP). Results Research variables were university, class levels, genders, whether students participate in sports or not. Independent sample t-test results indicated that there was no significant difference between genders in both factors and total attitude points ($p>.05$). Subjects who participate in sport have significantly higher points in EP and total scale comparing to subjects who dont participate in any sport activity ($p<.05$). One-way Analysis of Variance results indicated that there is a significant difference between PST's from different universities in all factors and total attitude and class level in CP and total attitude ($p<.05$). 1st graders have significantly lower level of CP comparing to other class levels and they also have significantly higher attitude scores comparing to 3rd and 4th graders ($p<.05$). Discussion Universities location, teaching methods and materials in these universities might be the factor that affecting these differences between students of different universities. Students concern about employment may have influence on grade level differences on their attitude in relation concerns (Pehlivan, 2010). Students who participate sports could have higher affective feature and that can be reason why they had higher attitude level (Pehlivan, 2010). Both male and female PSTs going through same instructional process and they were undergo the same higher education curriculum. Thus this might be the reason of similarities between genders. THE NEEDS AND CHALLENGES OF FOUNDATION PHASE LIFE SKILLS TEACHERS IN DELIVERING PHYSICAL EDUCATION PROFICIENTLY IN SOUTH AFRICAN SCHOOLS

STROEBEL, L.C.E.I, HAY, J.2, BLOEMHOFF, H.J.3

1.University of the Free State, 2. North West University, 3. University of the Free State

Introduction Before the education transformation processes in South Africa started, the Life Skills teacher did not exist. In 1997, curriculum reform commenced in earnest by steering education in a new, outcomes-based direction. Subsequently the curriculum was simplified twice, and the most recent version, the Curriculum and Assessment Policy Statements (CAPS) for each subject transpired (DBE, 2011). Currently, in the Foundation Phase (Grade R-3), Physical Education (PE) is located in the subject Life Skills, which comprises 4 subject areas. The decline of PE and the deteriorating health of South African children (Discovery Vitality, 2014) question the effective implementation of the CAPS curriculum. The aim of the study is to determine the needs and challenges of the LS teacher with specific focus on the effective implementation and deliverance of Physical Education in the Foundation Phase (FP) in selected primary schools in the Free State province, South Africa. Methods Primary schools ($N=100$) were randomly selected from which 94 FP teachers ($N=94$) returned questionnaires. The data were analysed descriptively using absolute and relative frequencies and histograms. Comparisons to test for associations of ordinal variables between districts or school classification were done using a Chi-squared test. SAS Version 9.3 TS Level 1M2 was used for all the statistical analyses. Results The findings highlighted a number of issues and needs concerning the implementation of the CAPS. The most challenging issues were a lack of qualified PE teachers and resources, support with assessment, learners with special needs and the training of teachers. The majority of teachers indicated that an in-service training workshop would be useful. Discussion Teachers have a pronounced need for being capacitated regarding new developments within LS (programme planning, content and presentation ideas). If children are to benefit in their early childhood years when the foundation is laid for lifelong participation in physical activity and the focus is on holistic development (DBE, 2011), teachers should be supported to live up to the expectations. It is recommended that the Department of Basic Education should prioritise the training and re-skilling of LS teachers, with specific reference to PE, in pursuit of proficient delivery of quality PE. ASSESSMENT OF COMPETENCY-BASED EDUCATION BY NEWLY QUALIFIED PE TEACHERS ACCORDING TO THEIR EDUCATIONAL BACKGROUND

RAAB, A.

University of Vienna

Introduction The Austrian Ministry of Education commissioned an educational standard for PE in 2009. The document was published in 2014 as a guideline for planning, teaching and evaluating PE lessons. (Amesberger, Stadler & Grossrubatscher, 2014) The educational standard is based on an output-oriented competency model (Kurz et al., 2008, S. 211-212) and can be regarded as a paradigm shift for PE in Austria. The aim of this study, which is a part of my diploma thesis, is to analyse the assessment of competency-based education by newly qualified PE teachers according to their educational background. Methods In order to carry out this study quantitative research was conducted. Valid data sets of 72 newly qualified PE teachers were collected via an online questionnaire. The variable assessment was operationalised with perceived advantages and disadvantages of competency-based education. A factor analysis was used to identify related items. Variables of interest of the participants' educational background were their second subject (Austrian teachers are usually qualified in two subjects) – with or without educational standards – and motivation for studying PE – extrinsic or intrinsic based on pedagogical interest and experience or exercising sports (Baillod & Moor, 1997, S. 45-47). Results Three main factors of the variable assessment were determined: practical concerns, planning vs. heterogeneity of students and differentiated instruction. There is no significant difference when participants teach a second subject in which educational standards have or have not already been implemented. There are weak positive correlations between the variable differentiated instruction and motivation for studying PE based on pedagogical interest as well as on coaching experience. Discussion Assessment of competency-based education cannot be explained by the variable second subject. This is also true when the variable sex – male and female participants tended to choose different second subjects – is taken into account. It might rather be dependent on various personality traits of newly qualified PE teachers, suggesting further research. Intrinsic motivation based on pedagogical interest and experience for studying PE partly leads to a more positive assessment of competency-based education. However, additional results for extrinsic motivation and intrinsic motivation based on exercising sports were not found. References Amesberger, G., Stadler, R. & Grossrubatscher, S. (2014). IDENTIFYING PATTERNS IN EYE-TRACKING SCANPATHS TO SUPPORT TEACHERS' AND NOVICES' ABILITY TO NOTICE CLASSROOM AND MOTOR SEQUENCE LEARNING

KLEINER, K., STÖGERER, J., HÖGER, B., RAUTER, G.

University of Vienna

Introduction: Eye-tracking systems have been used in various fields (e.g. research of perception, cognition, marketing, usability), measuring people's viewing behaviour. Likewise, eye-tracking systems have been applied in various sports (e.g. cricket, table tennis, ice speed skating, basketball, handball, volleyball, shooting, Formula 1, gymnastics). One of the most important factors measured by eye-tracking systems is the scan path, indicating the order and time-frame of perceived pieces of information. Such data can be analyzed to investigate and compare the scan paths of e.g. experts and novices. **Methods:** Data collection was conducted in terms of objective data (i.e. static and dynamic measurements of scan paths) and subjective data (i.e. guided interviews). Objective quantitative data, collected by means of an eye-tracker (SMI Eye Tracking Glasses) and processed statistically, are distinguished into process metrics (e.g. efficiency) and performance metrics (e.g. number of fixations, fixation durations, scan path similarities) and serve to understand tendencies of viewing behaviour in observed situations of motor sequence learning (acquisition and correction) along the time axis. Analysis results were compared by means of string edit method. As suggested by Privitera and Stark (2000), scan path data were sorted and analyzed in a Y-matrix (parsing diagrams) which serves as a basis for the investigation of data according to various indices (e.g. repetitive, idiosyncratic, local, global) for similarities and differences. Of particular importance is the analysis result of local indices reports regarding between-subject correlations of scanning patterns (experts vs. novices) with similar stimuli (i.e. the same images). Subjective qualitative data, e.g. satisfaction, helpfulness, etc., were recorded by means of guided interviews. **Results:** The leading question aims at determining whether teachers (experts) observe differently from students (novices) (n=20 experts and novices): which aspects do experts focus on during the conduction of motoric learning sequences and situations of classroom interaction, and which cognitive patterns do they utilize to explain their behaviour? Professional vision implies the ability of selective perception (selective attention; noticing) as well as its knowledge based justification. Both are to be understood as dynamic processes which are influenced by the probands' knowledge, values and motives. The experts' vision differ from novices' vision firstly in their improved ability of pattern recognition and anticipation and secondly in their differing observation foci and theoretical perspectives. We demonstrate the usefulness of eye-tracking by exploring the ability to discern import from unimportant incidents in motoric learning sequences and complex teaching situations, as well as the ability to decide where to direct one's attention. This ability, which seems to be influenced by implicit knowledge, turns out to be a central aspect of the teachers' expertise.

"ERZIEHENDER SPORTUNTERRICHT" BETWEEN DEMANDS AND REALITY – A DIFFERENCE-ORIENTATED ANALYSIS FOCUSING ON PEDAGOGIC PERSPECTIVES

HAPKE, J., SYGUSCH, R.

Friedrich-Alexander University of Erlangen-Nürnberg

"Erziehender Sportunterricht" between demands and reality – a difference-orientated analysis focusing on pedagogic perspectives **Introduction** In Germany, the discussion about physical education has been influenced highly by the pedagogical concept named "Erziehender Sportunterricht". It means interpreting and arranging physical education under pedagogic perspectives such as "cooperation" and "accomplishment" (Kurz, 2000). The implementation of the concept primarily depends on the didactic actions and the didactic beliefs of the physical education teacher. In face of desiderata concerning this matter, the study focuses the question, how the didactic demands concerning the "Erziehende Sportunterricht" become to realization in the beliefs and actions of physical education teachers. **Methods** The study uses a difference-orientated approach including the following steps (Neumann, 2014): 1) Analysis of demands (document analysis): Publications of the science community regarding the perspectives "cooperation" and "accomplishment" (N=28) were interpreted by content analysis. 2) Analysis of reality (case studies): Didactic actions and beliefs of physical education teachers (N=9) regarding "cooper-

ation" and "accomplishment" were surveyed by video observation, problem-centered interviews and stimulated recall interviews. The data again was interpreted by content analysis along the cases and finally summarized in types. 3) Analysis of differences: Differences were discovered and interpreted by comparing demands and reality. Results In terms of the teachers' didactic actions and beliefs in reality three diverging types could be discovered: a conservative type (substantial differences), an inconsistent type (partial differences) and an intermediate type (rarely differences). All types show differences especially regarding the topics "competition" and "integration". The conservative and the inconsistent type also show differences regarding the intention to educate pupils to "maturity" and the principals "cognitive stimulating", "openness" and "individualization". Reasons can be derived from the teachers' biography or deficient structures of knowledge transfer from science to practice. Discussion The study explored how the pedagogical concept "Erziehender Sportunterricht" is realized in practice. Further research about the quantitative representation of the three types would be rewarding. Besides, the study points to possibilities for reducing differences. For example it's recommended to arrange teacher education more as knowledge exchange than as knowledge transfer. References Kurz, D. (2000). OP-SH04 Effects & Statistics

THE EFFECT OF METER STRUCTURE ON BIMANUAL RHYTHMIC TAPPING

TANOSAKI, H., SHINYA, M., OKANO, M., KUDO, K.

The University of Tokyo

Introduction The coordination of a physical action in time with a rhythmic sequence such as dancing or playing in a musical ensemble is one of the fundamental human skills. Several articles have discussed how to coordinate accurately or stably and suggested that subdivision benefit can be an effective method for reduces the variability of the asynchronies between actions and auditory cues (Repp, 2003; 2010). The aim of the present study was to examine the extent to which physical subdivision of inter-onset intervals (IOIs) in an isochronous sequence reduces the variability of the asynchronies. We compared the relative benefits of duple and triple subdivision. Methods Twenty healthy university students participated in the experiment. The participants performed bimanual finger tapping in time with an auditory metronome. Two metrical conditions were tested: in 2-beat condition, metronome sound was given every other tap; and in 3-beat condition, it was given every three taps. Six different tempi were tested: 300, 280, 260, 240, 220 and 200 ms of inter-tap-intervals (ITIs). The timing of the tapping was measured by using two load cells. Mean and standard deviation of asynchrony, defined as the time interval between metronome sound and tapping, were calculated to quantify the temporal accuracy and stability of tapping. Two-way repeated measures ANOVA was used to test the effect of metrical structure and tempo. Results Mean asynchrony data revealed no significant main effect of tapping conditions, whereas the standard deviation of asynchrony data revealed statistically significant main effects of tapping conditions(2beat : 17.7 ms, 3beat : 20.5 ms , p <.01) and of tempi (ITI = 300-200 ms : 22.3 ms, 20.2 ms, 18.4 ms, 18.2 ms 16.9 ms, 18.6 ms, p <.01). Discussion The results showed that that subdivision are more stable than triple, suggesting that metric structure affect local synchronization performance. According to the Farey sequence (Yamamoto et al., 2015), a principle of frequency locking indicate 1:2 is more temporally stable than 1:3 in coordination. Three reasons can be considered why duple subdivision is stable; one is that the auditory cues are more frequently, thus it is easy to correct the asynchronies. Another is that the same hand always taps on-beat. We considered that tapping on-beat with the left and right hands alternately induces variability. The other is that we have two hands, thus spatial condition influences temporal coordination. Future studies would be interesting to investigate these issues. References Repp, B. H. (2003). ANTICIPATION AND RECALL OF EXERCISE RELATED AFFECT

DAVIS, P.A., SLAWINSK, M., ANSLEY, L.

Northumbria University

INTRODUCTION: It is proposed that upon completion of exercise the recall of affective responses mirrors the exercise experience and remains constant over time. However, research examining memory processes indicates that the recall of an experience often differs from the actual experience and affective memory is more influential than the actual experience when predicting future behaviour. Therefore, the aim of this study was to examine individuals' recall of exercise-related affect over a period of two weeks and determine the influence of affective recall on anticipatory feelings prior to exercise. METHODS: A randomized controlled, cross-over design required 42 adults (26 females, 16 males; Mage = 30, SD = 6 years) to recall their affective responses associated with two exercise conditions of differing intensity (low to moderate vs. high). Affect was recorded using the Feeling Scale and Felt Arousal Scale immediately before the trial commenced, and 5, 10, 15, & 20 min during the trial. Recall of affect was measured with the Global Affective Evaluation scale 1, 5, & 15 min, and 4 & 8 hours post exercise, as well as 1, 2, 7 & 14 days post exercise. Within-subject changes in recalled affective experience over time were examined using one-way repeated measures ANOVAs. The predictive values of anticipatory feelings immediately prior to exercise were examined using multiple regression analyses. RESULTS: Recalled affect significantly changed following the low intensity ($p = 0.01$) and the high intensity ($p = 0.03$) exercise trials. Follow-up pairwise analyses revealed significant differences between the 8 and 24 h post exercise measurement points in the low intensity ($p < 0.01$) and high intensity ($p < 0.05$) conditions. Anticipatory feelings measured before the second trial explained 38% of variance in the measurement points obtained during the exercise ($p < 0.01$) and 77% of variance was explained by the recalled affect measurement collected after the exercise terminated ($p < 0.01$). DISCUSSION: Recalled exercise-related affect fluctuates with a worsening of the affect recalled 24 h following exercise. Anticipatory feelings prior to exercise are guided by the affective recall of previous experiences. These findings raise important applied implications for professionals aiming to optimise the maintenance of exercise and training behaviours . Contact paul.davis@northumbria.ac.uk

VALIDITY THRESHOLDS AND ERROR RATES FOR TEST MEASURES USED TO ASSESS INDIVIDUALS

HOPKINS, W.G.

Victoria University

A practical test may be used to assess individuals when a criterion or gold-standard test is expensive or inconvenient to administer. However, there has been little investigation of the effect of validity of the test (the correlation between practical-test and criterion-test measures) on accuracy of assessment. PURPOSE: To define magnitude thresholds for the validity correlation of a practical measure and to determine error rates when a cut score is used to pass or fail individuals. METHODS: Thresholds for magnitudes of the validity correlation were calculated by equating the usual standardized thresholds for a difference in means to twice the standard error of the estimate of the practical measure predicted by the criterion measure. Test-pass (false-positive) and test-fail (false-negative) error rates and their confidence limits were derived by simulation for a given validity correlation, a given threshold of the practical measure, and given uncertainty in the threshold. Error rates were also derived for a criterion with given reliability. Spreadsheets were developed for assessing specific tests. RESULTS: Thresholds for very poor, poor, good, very good and excellent validity correlations are 0.45, 0.70, 0.85, 0.95 and 0.995 respectively. For cut scores up to 1 SD from the mean, desirable test-pass and test-fail error rates (<5%) occur only for excellent validity. Thresholds and error rates with a criterion test are equivalent to those of a practical test with validity correlation equal to the square root of the test-retest reliability correlation. CONCLUSION: Validity correlations for a practical measure and reliability correlations for a criterion measure need to be much higher than generally recognized to achieve low errors of measurement and desirable error rates in diagnostic or competence testing.

18:00 - 19:30**Oral presentations****OP-PM57 Substrate Oxidation, Blood and Steroids****FAT OXIDATION DURING DIFFERENT MODES OF EXERCISE IN UNTRAINED YOUNG AND MIDDLE-AGED MEN**

FRANDSEN, J., BECK, N.T., LANGKILD, H.C., LARSEN, S., DELA, F., HELGE, W.J.

University of Copenhagen

Introduction A low fat oxidation during rest and exercise and aging per se are associated with a higher clustering of unfavourable metabolic syndrome risk factors. Interestingly, fat oxidation during exercise in middle-aged and elderly subjects has scarcely been studied, so the understanding of aging and fat oxidation is incomplete. The aim of this study was to investigate maximal fat oxidation in healthy untrained young and middle-aged subjects during cycle ergometer and treadmill exercise. We hypothesized that untrained middle-aged compared to young men would have a lower maximal fat oxidation (MFO) at a lower relative intensity (fatmax). **Method** Healthy untrained men, 8 young (46.5 ± 1 ml/min/kg, 27 ± 1 yrs) and 10 middle-aged (36.8 ± 2.3 ml/min/kg, 55 ± 1 yrs) underwent a treadmill and a cycle-ergometer incremental exercise test. Fat oxidation rate was determined by indirect calorimetry. Venous blood samples were collected at each step throughout the tests. A two-way ANOVA was applied to analyze differences in MFO and fatmax between groups and modes of exercise. A Pearson product-moment correlation analysis with MFO as the dependent variable was performed to reveal associations with VO₂max and fasting plasma glycerol concentrations. Results Lean Body mass (60.7 ± 1.8 vs. 56.3 ± 1.9 kg) and BMI (24.4 ± 0.4 vs. 23.4 ± 0.4) were not different between the young and middle-aged groups, respectively. VO₂max was lower (cycle: 36.8 ± 2.3 vs. 46.5 ± 1 ; Treadmill: 40.4 ± 1 vs. 48.6 ± 1.2 ml/min/kg) in middle-aged compared to young men, respectively. MFO was not significantly different during the graded cycle or the treadmill tests between the young and middle-aged group, respectively. Within the young group, MFO (0.462 ± 0.04 vs. 0.396 ± 0.05 g/min) and fatmax (38.1 ± 1.6 vs. $38.2 \pm 2.6\%$) were not different between cycle ergometer and treadmill exercise, respectively. Within the middle-aged group MFO (0.370 ± 0.03 vs. 0.438 ± 0.03 g/min, $P < 0.05$) and fatmax (40.3 ± 1.3 vs. $45.7 \pm 2.3\%$ $P < 0.05$) were lower during the cycle ergometer compared to the treadmill test, respectively. MFO was positively correlated to fasting plasma glycerol concentrations in the young group ($r^2 = 0.393$, $P < 0.05$) and to VO₂max in the middle-aged group ($r^2 = 0.461$, $P < 0.05$). **Conclusion** In contrast to our hypothesis, an age-related attenuation of maximal fat oxidation rate was not present during cycle ergometer exercise or treadmill exercise. In middle-aged men MFO and fatmax were higher during graded treadmill compared to cycling exercise and MFO was positively associated with VO₂max. In young men MFO was positively associated with fasting plasma glycerol concentrations. For further information, please contact Jacobf@sund.ku.dk

IMPACT OF THE "SLEEP-LOW" STRATEGY ON SUBSTRATE UTILIZATION DURING EXERCISE

MARQUET, L.A.1,2, TIOLLIER, E.2, HAWLEY, J.3, BURKE, L.4, BRISSWALTER, J.1, HAUSSWIRTH, C.2

1Laboratory of human motricity, education, sports and health, University of Nice-Sophia Antipolis, 2Research department, National institute of sport, expertise, and performance (INSEP), Paris, France

Introduction The "sleep-low" (SL) strategy consisted of the periodization of the carbohydrate (CHO) intake (1): a low-CHO recovery after a high-intensity training session (HIT) in the late afternoon followed by a low-intensity session (LIT) performed after an overnight fast. In a recent paper (2) we have observed that SL strategy improves performance during prolonged exercise associated with body composition changes. The aim of the study was to investigate the physiological mechanisms responsible for the observed improved performance. **Methods** 22 trained cyclists (age: 31.6 ± 7.2 years; maximal oxygen uptake: 64.3 ± 5.9 ml.min⁻¹.kg⁻¹) followed a standardized training program and specific nutritional guidelines during 1 week according to the group they were assigned. All participants performed the same standardized training program based on the SL strategy (6 sessions over 6 days). In the "sleep low" group (SL=12), no CHO intake was authorized for all HIT and LIT sessions. The dinner was also CHO-free and the LIT sessions were performed after an overnight fast. The CHO availability was regularly maintained in the "sleep high" group (SH=10) by consuming sports drinks during training sessions and CHO at every meals. All groups ingested the same amount of CHO per day (6 g.kg⁻¹.d⁻¹) but divided differently over the day. Performances in cycling (2h submaximal at 60% of maximal power output and 20km time-trial tests), perceived exertion, cycling efficiency and body

composition were recorded before and after the week of training. Fat metabolism was assessed from, expired gaz, serum glycerol, and free fatty acids values sampled before, and during the submaximal test. Results All the participants of the SL group increased their performance during the time trial (-1min 7sec for the SL group, $P<0.05$) after the training week. No change was observed for the CON group (-24 sec). These changes in performance were associated with a 0.48% reduction in fat mass. Analyses of substrate utilization are still running, but preliminary results indicate a possible change in substrate utilization during cycling. Conclusion SL strategy induces an improvement in performance after 1 week of training. A shift in substrates utilization could explain this result with a higher fat oxidation leading to glycogen stores sparing, and consequently leading to a higher energetic availability. References 1. INCREASED RATES OF FAT OXIDATION DURING GRADED EXERCISE AFTER A SHORT-TERM KETOGENIC DIET IN ENDURANCE-TRAINED MALES

EGAN, B.1,2, FUSCO, B.1, MCCABE, L.1, LOMBARD, A.1, CROWLEY, P.1, WALSH, J.1, HONE, M.1

UCD Institute for Sport and Health

1Institute for Sport & Health, and 2Institute of Food & Health, School of Physiotherapy, Public Health and Sports Science, University College Dublin, Ireland Introduction The ketogenic diet (KD) is a low carbohydrate, high fat diet that is used widely as a weight loss strategy and as therapy for some diseases. The relative contribution of carbohydrate (CHO) and fat utilization to energy expenditure during exercise is dependent on variables including exercise intensity, mode and dietary intake, but few studies have examined the effects of KD on exercise metabolism in athletes. The present study investigated changes in body composition and patterns of substrate utilization before and after a short-term (7 day) KD. Methods Ten young, endurance-trained males (mean \pm SD; age, 21.6 \pm 2.0 y; height, 1.83 \pm 0.10 m; body fat, 14.3 \pm 4.1%) were assessed before and after seven days of KD (CHO:protein:fat, 10:20:70%). On each assessment day, participants arrived to the lab after an overnight fast after which body composition (DXA) was assessed. Next, each performed a continuous incremental exercise test to exhaustion known as the FATmax protocol (Achten et al., 2003) on an electronically-braked cycle ergometer beginning at 95 W and increasing 35 W per stage in 3 min stages. Expired air and heart rate were monitoring continuously, and lactate and rate of perceived exertion were measured in the last 15 sec of each stage. Results Wmax (295 \pm 28 vs. 293 \pm 36 W) and VO2peak (4.18 \pm 0.35 vs. 4.13 \pm 0.41 L/min) were unchanged by KD. Body mass decreased by 2.3 \pm 1.1 kg after KD (77.8 \pm 13.2 vs. 75.5 \pm 12.5 kg; $p<0.001$). Body fat, by 0.75 \pm 0.41 kg ($p<0.001$), and fat-free mass (FFM), by 1.65 \pm 1.68 kg ($p=0.013$), were decreased by KD. Despite similar oxygen consumption, the respiratory exchange ratio was lower and rates of fat oxidation (FATox) were higher after KD across a range of exercise intensities ($p<0.05$). FATox averaged 2.4-fold higher at ~65%VO2peak after KD ($p<0.001$), with peak FATox averaging 0.83 \pm 0.23 g/min at this intensity. The crossover point for substrate utilization occurred at a higher relative exercise intensity after KD (48.8 \pm 4.0 vs. 72.1 \pm 3.6%VO2peak, $p<0.05$), which coincided with a rightward shift in the plasma lactate profile. Discussion A short-term KD results in rapid alterations in body composition comprising of loss of both body fat and FFM. Rates of fat oxidation are elevated after short-term KD concomitant with reduced reliance on CHO utilization for energy provision, even at moderate and high exercise intensities, analogous to findings from 'keto-adapted' ultra-endurance runners compared to habitual high CHO diet (Volek et al., 2016). Whether these adaptations to short-term KD or longer term keto-adaptation translate into performance benefits, particularly in high intensity sports, remains to be explored. ANDROGEN RECEPTOR GENE POLYMORPHISMS AND MAXIMAL FAT OXIDATION IN MEN. A LONGITUDINAL STUDY.

PONCE-GONZÁLEZ, J.G.1,2, GUADALUPE-GRAU, A.1, RODRÍGUEZ-GONZÁLEZ, F.G.3,4, DORADO, C.1,2, DE TORRES-PERALTA, R.S.1,2, MORALES-ALAMO, D.1,2, RODRÍGUEZ-GARCÍA, L.1, DÍAZ-CHICO, B.N.3,4, CALBET, J.A.1,2

1 Department of Physical Education, University of Las Palmas de Gran Canaria, Campus Universitario de Tafira s/n, Las Palmas de Gran Canaria, 35017, Spain 2 Research Institute of Biomedical and Health

Introduction. The aim of this longitudinal study was to evaluate if extreme CAG and GGN repeat polymorphisms of the androgen receptors (AR) influence body fat mass, its regional distribution, fat accumulation, basal metabolic rate, basal and maximal fat oxidation capacity (MFO), maximal oxygen uptake (VO2max), and serum concentration of leptin, free testosterone and osteocalcin. Methods. CAG and GGN repeats length were measured in 319 men (mean \pm SD: 28.3 \pm 7.6 years old). From these, we selected the subjects with extreme short (CAGS \leq 19) and long (CAGL \geq 24) CAG repeats, and the subjects with short (GGNS \leq 22) and long (GGNL \geq 25) GGN repeats. Results. The length of CAG repeats was not associated to fat mass. CAGS and CAGL subjects had similar basal metabolic rate and accumulated comparable amounts of fat tissue over 6.4 \pm 1.0 years of follow up. However, CAGL showed higher MFO and total lean mass than CAGS ($p<0.05$). Men with GGN \leq 22 accumulated greater amount of total fat mass than men with GGN \geq 25, particularly in the trunk region seven years later. This concurs with a trend for a greater MFO in the GGNL group ($P=0.06$), who accumulated less fat mass. Free testosterone was associated with MFO in absolute values ($r=0.45$; $p<0.05$) and MFO per kg of lower extremity lean mass per height squared ($r=0.35$; $p<0.05$). Conclusions. Longer CAG and GGN repeats polymorphism may increase fat oxidation capacity, which could reduce the accumulation of fat over the years.

THE EFFECT OF 8-WEEK WALKING EXERCISES WITH DIFFERENT INTENSITY ON SERUM HEPcidin, IL-6 LEVELS AND MARKERS OF IRON METABOLISM IN PRE-MENOPAUSAL WOMEN

BUYUKYAZI, G.1, ULMAN, C.2, CELIK, A.1, CETINKAYA, C.1, SISMAN, A.R.1, CIMRIN, D.3, DOGRU, Y.1, KAYA, D.1

1: DEU /Izmir, Turkey, 2: CBU /Manisa, Turkey, 3: EU /Izmir, Turkey

Introduction Exercise-induced iron deficiency is quite common in athletic population (Kong, et al., 2014). It has been suggested recently that hepcidin may be an important mediator in this process (Nemeth et al., 2006). Previous studies examined the effects of acute exercise on hepcidin and markers of iron metabolism (Peeling et al. 2009; Peeling et al., 2014). To our knowledge, there are no studies examining the chronic effects of walking exercises (WE) on these parameters. Therefore, the aim of this study is to examine the chronic effect of two different-intensity, eight-week WE on hepcidin, IL-6 and markers of iron metabolism in pre-menopausal women. Methods Exercise groups (EG) (moderate tempo walking group; MTWG; n=11; brisk walking group BWG; n=11) walked three days a week, starting from 30 minutes, gradually increasing up to 51 minutes. Control group (CG; n=8) did not participate in any exercise forms. BWG walked at ~70-

75% and MTWG at ~50-55 of HRRmax. Body mass index, body fat, VO₂max, serum hepcidin, IL-6 levels and some iron metabolism markers [iron, total iron binding capacity (TIBC), transferrin, transferrin saturation (STR), ferritin, hemoglobin (Hb), red blood cells (RBC), hematocrit (Hct)] were determined before and after the intervention. Results VO₂max increased in both EG significantly, favoring BWG. Hepcidin levels increased in BWG ($p < 0.01$), MTWG ($p = 0.05$), and CG ($p < 0.05$). Serum IL-6 decreased in BWG and MTWG ($p < 0.05$; $p < 0.01$, respectively). While serum iron levels did not change significantly in any groups, TIBC increased significantly only in BWG ($p < 0.01$). There was a nearly significant increase in Hb levels of BWG ($p = 0.061$) and Hct levels ($p < 0.01$); RBC increased significantly only in BWG ($p < 0.05$). We observed no statistical changes in ferritin, transferrin and transferrin STR levels of all study groups. Discussion Serum IL-6 decreased regardless of the exercise type; therefore both WE types may be useful to prevent inflammation. However, brisk walking is advisable due to the positive changes in VO₂max and some iron metabolism parameters since they may contribute to prevent iron deficiency anemia. Despite the positive effects of the exercise programs on the reduction in serum IL-6 levels, the significant increase in hepcidin levels in EG remains unclear and necessitates further studies. IMPACT OF THE UGT2B17 POLYMORPHISM ON THE STEROID PROFILE. RESULTS OF A CROSSOVER CLINICAL TRIAL IN A POPULATION OF ATHLETES SUBMITTED TO A TESTOSTERONE ADMINISTRATION STUDY.

MARTIN-ESCUDERO, P.

University Complutense of Madrid

Objective: To study the genomic influence (UGT2B17 polymorphism) on the urinary steroid profile focused on the Testosterone/Epitestosterone ratio (T/E) during testosterone administration. **Methods:** A triple-blind randomized placebo-controlled crossover trial with healthy male athletes between the ages of 18 and 55 who had practiced sport for at least 3 to 5 years and worked out regularly. Each subject was administered a single dose of either Testex Elmu Prolongatum (250mg testosterone cypionate/testosterone ciclopentilpropionate) by intramuscular injection or Baxter (Clear-Flex) saline solution (9 mg/ml) in a single uniform dose of 2 ml. For each participant, a total of 40 samples of urine were collected for steroid profile measurement. The dependent variable of the study was the T/E ratio. **Results:** A total of 12 athletes, all male, were included in the study, with a mean age of 39.9 years (SD 11.2). The polymorphism was evenly distributed (4 volunteers of each genotype). The increased levels of T/E after administration of Testex Elmu Prolongatum presented statistical significance based on the presence of the polymorphism ($p = 0.034$). Athletes in the wt-homozygous group presented mean relative increase of 30 (CI 95%: 25.2 to 36.7); the increase in the heterozygous mutant group was 19.8 (CI 95%: 15.9 to 24.7); and the increase in the homozygous mutant group was 19.7 (CI 95% 14.9 to 26.2). **Conclusions:** Increased levels of T/E in urine were observed after administration of Testex Elmu Prolongatum that was not homogeneous in terms of the presence of the polymorphism. An intraindividual evaluation approach of results is more effective than an inter individual one.

OP-PM43 Physiological Responses

DIFFERENCES IN GAS EXCHANGE KINETICS BETWEEN CYCLING AND WALKING

KOSCHATE, J., THIESCHÄFER, L., DRESCHER, U., HOFFMANN, U.

German Sport University Cologne

Introduction Oxygen uptake (V' O₂) kinetics allow an estimation of cardiovascular and respiratory regulatory processes to adequately adjust oxygen delivery to and extraction in the exercising muscles. It is well known that maximal V' O₂ differs between running and cycling. So far, V' O₂ kinetics were compared between cycle and treadmill exercise exclusively by applying square wave work rate (WR) protocols. No differences were observed for V' O₂ kinetics. Carbon dioxide (V' CO₂) and ventilation (V' E) were not investigated, yet. It was hypothesised that V' O₂, V' CO₂ and V' E kinetics would be similar for walking and cycling. **Methods** 19 active young subjects (age: 26±4 years; weight: 67.3±8.1 kg) were tested for gas exchange kinetics (V' O₂, V' CO₂, V' E) applying pseudo-random binary sequences (PRBS) on a treadmill (velocities of 3 km·h⁻¹ and 6 km·h⁻¹) and cycle (WRs of 30 W and 80 W) ergometer in randomized order. The WR protocols were matched for similar absolute V' O₂. Gas exchange kinetics were assessed applying cross-correlation functions (CCF) of WR with the mentioned parameters. Higher peaks in CCF (CCFmax) imply faster system responses (kinetics) (Hoffmann et al. 2013). Two-factorial ANOVA was applied to assess differences between kinetics responses and absolute values of V' O₂, V' E and V' CO₂. Results CCFmax(V' E) (walking vs. cycling: 0.34 ± 0.02 vs. 0.26 ± 0.02 ; $P = 0.003$) and CCFmax(V' CO₂) (0.33 ± 0.02 vs. 0.25 ± 0.01 ; $P = 0.003$) were significantly higher for walking compared with cycling. CCFmax(V' O₂) was not different (0.35 ± 0.01 vs. 0.35 ± 0.01 ; $P = 0.014$). Absolute values of V' E were significantly higher during walking (6 km·h⁻¹: 29.9 ± 4.1 vs. 80 W: 27.6 ± 3.0 ; $P = 0.001$) whereas V' CO₂ was significantly lower (6 km·h⁻¹: 0.99 ± 0.11 vs. 80 W: 1.12 ± 0.11) and V' O₂ was similar. **Discussion** The achievement of similar absolute V' O₂ values with similar kinetics responses for walking and cycling affords higher values of V' E for walking with a faster kinetics profile; but produces lower absolute values of V' CO₂ with a faster kinetics response. Therefore, the regulatory processes of V' E and V' CO₂ for the achievement of a similar V' O₂ response are different. These results should be considered comparing gas exchange kinetics between walking and cycling exercise. Since the determination of cardiorespiratory kinetics applying PRBS can be performed in a single test session this method seems promising for e.g. clinical diagnostics. EFFECT OF AEROBIC AND STRENGTH TRAINING ON GAS EXCHANGE KINETICS DURING MODERATE- AND HEAVY-INTENSITY EXERCISE IN ELDERLY

CAPELLI, C.1,2, BRUSEGHINI, P.2, CALABRIA, E.2, POGLIAGHI, S.2, TAM, E.2

1:NSSS (Oslo, Norway), 2:UNIVR (Verona, I)

Introduction Aerobic training accelerates Phase II of V'O₂ kinetics at the onset of moderate intensity exercise (M) and decreases the amplitude of the slow component (A₃) during heavy-intensity exercise (H). The physiological causes of the slow component are still matter of debate. The progressive recruitment of the less economical Type II muscle fibers during H (Jones et al., 2005) may be implied in its genesis. The increase of muscle strength caused by resistance training would decrease the number of Type II muscle fibers recruited during H at the same workload (WL), wherefrom a smaller A₃ may derive. Methods 12 active older men (69.4±4.3 yy; 78.5±10.5 kg; 171.2±5.3 cm; V'O₂peak: 29.5±4.1mL/kg/min) were exposed to 8 weeks of: i) high intensity interval training (HIT), 7 2-minute cycling repetitions @90% of V'O₂peak (V'O_{2pl}), 3 times/week and, after 4 months, ii) isoinertial resistance training (IRT), 4 × 7 maximal concentric-eccentric knee extensions, 3 times/week. Before and after trainings we measured: i) V'O_{2p} and gas exchange threshold (GET); ii) B-by-B V'O₂ at the onset of: a) moderate intensity (M, @WL equal to 80 % of GET; n = 4); and b) heavy-intensity exercise (H, @WL equal to 50% between GET and V'O_{2p} assessed before training; n = 3); iii) isokinetic concentric torque (T_c) and isometric torque (T_i) of the limb extensors. V'O₂ kinetics were modeled, after synchronization and averaging, by means of double or triple exponential functions. Results Only HIT led to a significant increase of absolute and relative V'O_{2p} ($P < 0.05$). IRT brought about a significant increase of T_c and T_i ($P > 0.05$). The time constant of Phase II of V'O₂ kinetics (t_2) during M was significantly faster only after HIT (19.5 vs. 27.3; $P < 0.05$); the amplitude (A₂) of V'O₂ response during M was significantly lower at the end of IRT (-10%, $P < 0.05$) than after HIT. After HIT, A₃ was smaller than before training. Conversely, A₃ was not affected by IRT. Discussion 8 weeks of HIT induced a significant acceleration of V'O₂ kinetics during M and decreased the amplitude of A₃ during H. On the contrary, IRT did not elicit any substantial effect on the characteristics of the slow component assessed during H. However, IRT resulted in a significant decrease of A₂ during M, indicating an amelioration of the economy of exercise. These findings are in agreement with the ones obtained in young adults (Zoladz et al., 2012) and may suggest that IRT can have beneficial effects on performance of endurance events. COMPARISON OF GPS, ACCELEROMETRY, AND HEART RATE FOR ESTIMATING METABOLIC RATE DURING LEVEL AND UPHILL OUTDOOR WALKING

LE FAUCHEUR, A.1,2, DE MÜLLENHEIM, P.Y.1, EMILY, M.3, CHAUDRU, S.2, BICKERT, S.4, PRIOUX, J.1, MAHÉ, G.2,6, NOURY-DESVAUX, B.7

1: M2S lab & ENS Rennes, FR; 2: INSERM CIC 1414, Rennes, FR; 3: Agrocampus Ouest - IRMAR, Rennes, FR; 4: CHU of Angers, FR; 6: CHU Rennes, FR; 7: INSERM 1083 - CNRS 6214 & IFEPSA UCO Angers, FR

Introduction Speed and grade are two powerful predictors of walking metabolic rate. The conventional use of accelerometry to measure such parameters in free-living environment is limited due to technical considerations. By directly measuring speed and altitude, Global Positioning System (GPS) receivers could be accurate for estimating outdoor walking metabolic rate. Moreover, no study compared GPS with other commonly used methods for estimating metabolic rate while walking. The aim of this study was to compare the accuracy of GPS, accelerometry, and heart rate (HR) monitoring, for estimating metabolic rate during level and uphill outdoor walking. Methods Thirty young adult subjects (NCT01805219) completed three 6-min outdoor walks (2.0, 3.5 & 5.0 km/h) in three randomized conditions: 1/ level walking (0.0% grade); 2/ uphill walking on a 3.4% mean grade; 3/ uphill walking on a 10.4% mean grade. Walking metabolic rate (in METs) was measured using a portable metabolic system (K4b2, Cosmed®). Subjects were equipped with i) a DG100 (GlobalSat®) GPS receiver (shoulder position, 1-Hz), ii) a wGT3X+ (ActiGraphTM) accelerometer (hip position, 90-Hz), and iii) a Polar® HR monitor (chest position, 1-Hz). GPS grade (grade=Δ altitude/distance walked) was computed from two calculation methods using i) GPS uncorrected altitude data and ii) by correcting GPS altitude data using cartography software (CartoExploreur, Bayo Ltd). METs, GPS parameters, accelerometer outputs (counts/s, for vertical axis (V) and vector magnitude (VM)), and HR, were averaged over the last 3 min of each walking period. Linear mixed models were computed for METs and the different outputs of the sensors used. Accuracy of linear mixed models was tested using the leave-one-out cross-validation method and by computing root-mean squared errors (RMSE). Results The prediction models accuracy ranked as follow: GPS speed and corrected grade (RMSE = 0.84 MET; R² = 0.86), GPS speed and uncorrected grade (RMSE = 1.03 MET; R² = 0.78), VM-accelerometer counts/s (RMSE = 1.22 MET, R² = 0.64), V-accelerometer counts/s (RMSE = 1.28 MET; R² = 0.59), HR (RMSE = 1.61 MET; R² = 0.63). Discussion GPS was accurate for predicting METs and more accurate than accelerometry and HR monitoring. Further studies are needed to assess GPS accuracy for predicting metabolic rate in environments with different obstruction levels.

PERIODIC BREATHING PREDICTS EXCESSIVELY REDUCED EXERCISE TOLERANCE IN PATIENTS WITH CHRONIC HEART FAILURE

REUVENY, R.1, SEGAL, M.2, FRIAMARK, D.3, ARAD, M.3, BEN-DOV, I.2

1. University of Haifa, 2. Sheba Medical Center

Introduction Periodic breathing (PB) is evident during exercise in some patients with chronic heart failure (CHF) and is accompanied by hyperventilation. Aim to determine whether the presence of PB predicts excessive reduced exercise capacity in patients with severe CHF relative to patient with CHF of similar severity but with no PB. Methods Sixty one CHF patients underwent cardiopulmonary exercise from 2009 to 2011 as part of their evaluation for cardiac transplantation. From this data, we selected patients in which the term 'periodic breathing' appeared in their report. Matching patients with CHF without PB were identified from the same pool. Results Fifteen CHF patients with PB and 18 patients with CHF with similar ejection fraction but without PB (control) were identified from the pool of 61 patients. The PB group had a lower peak oxygen uptake related to body weight (VO₂/kg) and anaerobic threshold (AT) than the control group, by 3011 and 394%, respectively ($p < 0.05$). The ventilatory equivalent for CO₂ production (VE/VCO₂) at the AT was higher and the end tidal pressure of CO₂ (PETCO₂) was lower in the control group as compared with PB group ($p < 0.05$). VE/VCO₂ at the AT was inversely correlated with peak VO₂/kg ($r = -0.45$, $p < 0.05$). Discussion PB in patients with severe CHF is associated with excessively reduced exercise capacity. Increased ventilatory requirement may enhance dyspnea and may add to exercise limitation in these patients. Conclusion: Periodic breathing reflects the severity of CHF and is associated with excessively reduced exercise tolerance in patients with CHF.

EFFECTS OF HYPOVENTILATION TRAINING AT SUPRAMAXIMAL INTENSITY IN SWIMMING

WOORONS, X., MUCCI, P., RICHALET, J.P., PICHON, A.

EFFECTS OF HYPOVENTILATION TRAINING AT SUPRAMAXIMAL INTENSITY IN SWIMMING Woorons, X.1, Mucci, P.1, Richalet, J.P.2, Pichon, A.3
 1: URePSSS (University of Lille, France), 2: Laboratory 'Hypoxia & Lung' (University Paris 13, France), 3: MOVE (University of Poitiers, France)
 Introduction Recently it was demonstrated that swimmers could train under hypoxic conditions at sea level through voluntary hypoventilation at low lung volume (VHL; i.e. the 'exhale-hold' technique) (Woorons et al., 2014). While intermittent hypoxic training carried out at moderate intensity does not seem to improve sea-level performance more than the same training in normoxia, it has been shown to be more effective when performed at high intensity (Faiss et al., 2013). The goal of the present study was therefore to assess the effects of VHL training at supramaximal intensity on swimming performance and to determine its physiological consequences. Methods Over a 5-week period, 16 well-trained triathletes were asked to include into their usual swimming session one set of 12 to 20 x 25 m (10-15 s recovery between reps) at supramaximal intensity, twice a week. The set was performed either with VHL (HYPO group, n = 8) or with normal breathing (NB group, n = 8). Before (Pre) and after (Post) training, all subjects performed all-out front crawl trials over 100, 200 and 400 m. Peak oxygen consumption (VO_{2peak}), ventilation (VE), tidal volume (Vt), breathing frequency (Bf), heart rate (HR), arterial oxygen saturation (SpO₂), stroke distance (SD) and stroke rate (SR) were measured throughout some of the trials and maximal blood lactate concentration ([La]max) was assessed after each trial. Results In the HYPO group, performance was improved for the 100- (- 3.7 ± 3.7 s; - 4.4 %), 200- (- 6.9 ± 5.0 s; - 3.6 %) and 400-m (- 13.6 ± 6.1 s; - 3.5 %) trials whereas there was no change in NB. [La]max was higher at Post than at Pre after all trials in the HYPO group only (+ 2.35 ± 1.3 mmol.L⁻¹ on average). There was no change in VO_{2peak}, VE, Vt, Bf, SpO₂, HR and SD in both groups at the end of the training period. On the other hand, SR was higher at Post compared to Pre in HYPO but was not different in NB. Discussion This study demonstrated that VHL training, when performed at supramaximal intensity, could improve swimming performance more than the same training carried out under normal breathing conditions for distances from 100 to 400 m. The increased [La]max in the HYPO group represents an interesting finding. In the absence of an additional aerobic, hydrodynamic or technical benefit, it suggests that performance improvement could be attributed, at least in part, to a greater activity of anaerobic glycolysis. This phenomenon was probably the consequence of the hypoxic as well as the hypercapnic effect of hypoventilation training. References Faiss R, Girard O, Millet GP. (2013). Oral presentations**OP-BN17 Kinematic Analysis of selected Movements/ Sports****EVALUATION OF INERTIAL SENSOR CALIBRATION VARIABILITY AND ITS EFFECT ON 3D KNEE JOINT ANGLES ESTIMATION**

CORDILLET, S.1, BIDEAU, N.1, BIDEAU, B.1, NICOLAS, G.1

Université Rennes 2

Introduction Recent technological advances in MEMS allow considering the biomechanical evaluation of sports practitioners outside the laboratory, with more ecological conditions. To this end, inertial motion capture is promising but still requires a calibration procedure to estimate body segment rotation, generally based on static or dynamic tasks. These tasks give the opportunity to estimate segmental rotation axis, from which body-to-sensor rotations can be obtained. Within the context of sports monitoring, accuracy and repeatability of the calibration procedure is of major importance. Firstly, the aim of this study is to determine the variability of calibration procedures. Secondly, the influence of this variability on 3D knee joint rotations is evaluated during a cycling and gait task. Methods Fourteen subjects wore inertial sensors on thigh and shank. Three reflective markers were attached on each IMU and tracked using a Vicon optoelectronic system. Each subject performed five calibration tasks (based on static and dynamic calibration) (Palermo et al. 2014, Favre et al. 2009) which were randomly repeated four times. The combination of calibration tasks enabled defining different calibration methods (static-based, dynamic-based and static/dynamic-based methods). For each method, body-to-sensor rotation matrix was calculated, leading to 3D segmental body orientations. Variability of these orientations were quantified to compare calibration methods and both inertial and optical systems. Finally, variability effects on 3D knee joint angles were studied using simulated perturbation (Brennan et al., 2011) during cycling (2° at 90 rpm, 150W) and walking (8m). Results No significant difference was found between both systems except for thigh and shank rolling standard deviation ($p<0.01$ & $p<0.05$). Dynamic-based methods are more variable for thigh rolling determination ($p<0.05$) but the largest difference was quantified for shank heading with significant lower range and standard deviation ($p<0.0001$ range of variability=2.25° and SD=1.01°). Combined static/dynamic-based method presented smallest variability. Multi-simulation showed moderate error against non-perturbated angle ($RMSE<2.3^{\circ}$). Discussion This study showed that combined static/dynamic based method engendered lower variability than the static based method. Simulation perturbation is useful to estimate confidence in knee joint angles based on inertial sensors. Future works will focus on the accuracy of the latter methods for outdoor ecological situations. References Palermo E, Rossi S, Larini F, Patanè F, Cappa P. (2014). Measurement, 52, 145-155. KINEMATIC CHARACTERISTICS OF THE BOBSLEIGH TEAM START

DABNICKI, P.

RMIT University

Victory in bobsleigh is considered highly influenced even pre-determined by engineering and technology. However, following the introduction of stringent technical rules that restricted the use of technological developments, such as structural damping and electronic control, the sport has become strongly dependent on the driver's skills and crew start time. The sport uses the so called flying start; time is taken after crossing a line that is away from the actual starting point. The start procedure is strictly regulated and is described below. The crew pushes the sled from a wooden start block that must be at least 150 cm long, 20 cm wide and 5 cm high from the surface of the ice.

The crew cannot pass the block or remove it prior to the start. Once the start is initiated the crew pushes the sled along the "push-off stretch" which is the part of the track between the start block (wooden board) and the first photoelectric cell. This stretch of the track is postulated to be 15 meters long with a gradient of 2%. As stipulated by the sport governing body FIBT (2014), after the first photoelectric cell (which represents the virtual start-line for the time-taking), the track must follow a straight path so that bobsleds starting off may reach a speed of 35 km/hr or 9.72 m/s. As a result the most important feature is to achieve maximum initial velocity of the sled rather than minimize the time from the start. This work considers the parameters that affect the start time and the initial velocity gained by the sled. The following four start phases were identified: Joint non-timed push-off, i.e. between the -15 to 0 m Driver loading Brakeman push phase Brakeman loading. To date specialists used timing gates and cameras to analyze the start. They provide valuable but insufficient information. We used accelerometers and force transducers to assess individual efforts and suggest optimal timing in the key points of the start. Based on the acceleration measurement the timing of the driver and brakeman loading (number of strides) were identified as the most important features in gaining and maintaining the maximum velocity. We have found that the necessary measurements to allow accurate a kinematic analysis are relative forces imparted by individual crew members (crucial for team selection), and sled's velocity and acceleration. It is shown that the fastest sprinters are not necessarily the best team contributors as running synergy is crucial for optimal velocity profile generation. We also illustrate that once the crew is selected just acceleration could be used to optimize the start routine. In particular we illustrate how just the change of run-up length by the driver could deliver 2.5% increase of the initial velocity which could result in more than 5% reduction in the total time. It is shown that athletes need to reach running speed of more than 10 m in order to achieve the desirable speed of 9.8 m/s. The relatively simple system is highly effective in immediate and quantifiable feedback and practical ways to improve performance are discussed.

THROWING ARM ANGLE DETERMINES PROBABILISTIC STRUCTURE OF ERRORS IN PITCH LOCATION

SHINYA, M., TSUCHIYA, S., YAMADA, Y., ODA, S., KUDO, K., NAKAZAWA, K.

University of Tokyo

Introduction Although a baseball pitcher is an athlete who achieves the highest level of accuracy, pitch errors could never be zero. According to recent motor control studies, it is important to know probabilistic structure of his/her own motor errors to choose an optimal motor plan (i.e., where you aim at) to maximize the expected gain (Ota et al. 2015). In this study, we questioned what determines the probabilistic structure of pitching errors in baseball pitchers. Methods Eighteen healthy male collegiate baseball pitchers, including over-arm, sidearm and underarm left and right pitchers, participated in the study. The participants threw a baseball aiming at a target (diameter: 7.2 cm) located 15 m apart from the participant and 90 cm above the ground. Pitch location was captured by using a 60 fps digital video camera and throwing arm angle was filmed by using a 125 fps high-speed video camera. The participants threw 100 pitches in the experiment. Probabilistic structure of the pitch errors (i.e., shape and size of the pitch distribution) was evaluated by bivariate normal distribution fitting. Results In 17 out of 18 participants, the pitch errors distributed along an eccentric ellipse. The direction of the long axis was dependent on each participant's pitching form (e.g., right overarm pitchers pitched along a right-up-left-down ellipse and left over-arm pitchers pitched along a left-up-right-down ellipse). This was confirmed by circular correlation analysis ($p = 0.98$). Discussion The ellipsoidal pitch distribution indicates that if a pitcher, at least one who as skilled as our collegiate participants, throws a ball aiming at a target, the error from the target would likely be on a certain direction, not just a random direction. We confirmed that the direction (long axis of the ellipse) was determined by throwing arm angle. These results suggest that different mechanisms, potentially errors in pitching mechanics and errors in ball release timing (Hore et al. 1995, 1996), might contribute to errors along the long axis and those along the short axis. EFFECTS OF AN ACTIVE LOWER LIMB EXOSKELETON ON KINEMATICS IN LOADED GAIT

PLEGGE, C.1, DAVID, S.2, MÜLLER, R.2, KOMNIK, I.2, DUPRE, T.2, PETERS, M.2, VIELLEHNER, J.2, POTTHAST, W.2, ALEXANDER, T.1

1: Fraunhofer FKIE (Wachtberg, Germany), 2: German Sport University Cologne (Cologne, Germany)

INTRODUCTION New types of exoskeletons (ES) are becoming available nowadays. They provide capabilities for supporting and enhancing human physical performance. In addition to applications for medical and rehabilitative purposes they are applicable for occupational purposes like enhancing load carrying capacities or physical endurance (Mertz, 2012). In contrast to medical applications in which the ES are enabling a patients' locomotion, occupational uses require a proper support of existing body movements. In our study we focused on a knee-supporting ES prototype. A biomechanical gait analysis was performed for a loaded and unloaded condition in order to find effects and differences caused by the use of an ES. METHODS Gait on level ground of 10 participants was captured under four conditions. Kinematics of the lower extremities were recorded by 16 IR cameras (VICON, Oxford, UK) at 100 Hz. Reflective markers were applied on anatomical landmarks and their positions were used to drive an anatomical model. Carrying loads of 15.8 kg or 37.1 kg were used as experimental conditions. Gait of the participants with both loads were tested with and without the ES. Walking speed was 7.5 km/h in all conditions. The kinematics of knee and ankle joint were used for the statistical analysis. All parameters were normalised to stance phase. Statistical parameter mapping (SPM) was used for analysis of the joint angle curves. RESULTS Significant differences in knee flexion were found during the second half of the stance phase. Knee extension is reduced by about 3° in both loading conditions by wearing the ES. Knee-flexion in first half of stance phase of all conditions is about 20% higher than reported in normative data. No significant changes in kinematics of the ankle joint were found. DISCUSSION The identified changes in knee extension in second half of stance phase are considered to be relatively low. Thus, an increase of overall physical endurance is questionable. An explanation of this is insufficient anatomical fitting and control algorithms of the ES. This might result in hindered knee extension. The observed greater knee flexions in first half of stance phase can be explained by the given walking speed, which was faster than in normative data (e.g. Perry, 1992), and the additional loads of 18-43% of participants' mean body weight. No changes in ankle joint kinematics were observed due to the slight changes in knee kinematics. REFERENCES Mertz L (2012). IEEE Pulse (3)4, 56-61 Perry J (1992). ATYPICAL BUT HIGHLY SUCCESSFUL MOVEMENT PATTERNS OF THE DOUBLE SIDE KICK TECHNIQUE EXECUTION OF AN ELITE POINTFIGHTING KICKBOXER. A CASE STUDY.

HÖLBLING, D., PREUSCHL, E., HASSMANN, M., BACA, A.

Institute of Sport Science University of Vienna

INTRODUCTION In Hölbling et al. (2014), technique execution of the double side kick of 44 pointfighting kickboxers, including 8 world champions, has been recorded and analysed using a Vicon 3D motion capturing system. 10 experts with long-term experience in coaching of international top athletes scored the competition techniques by assessing their chances of success (1-10) based on videos of the individual executions (ICC (3,1): 0.952). The mean scores were used to rank the participants. One "top five" participant, a multiple world champion, showed atypical movement patterns in qualitative video observation in contrast to most previous studies. The aim of this study was to determine and describe differences in technique execution of this special case participant (CP).

METHODS From the qualitative observation of CP, biomechanical parameters for quantitative description of his special technique were identified. The initial movement (IM) defined as the last bounce before the kick was first qualitatively described, categorised and nominally quantified. 4 times of measurement were defined: the highest elevation of the knee before the first and the second kick (MT1, MT2) (Hölbling et al., 2014); and the knee extension maximum (KE1, KE2) at the end of both kicking phases. For these times of measurement, flexion, abduction and external rotation of the kicking leg's hip joint were determined for CP. These parameters were then compared to all other 43 participants.

RESULTS Initial Movement (IM): CP was the only participant using a both legged bounce forward motion. Among all participants, the most used IM were rear or both foot closing bounces (25/6 participants), rear foot jump-in movements (7 participants) or just leaned back with or without bouncing movement (4/1 participants). Hip Joint Angles: Besides a high abduction, in every observed phase CP differed by a high flexion (FLX) combined with external rotation (ER) in MT1 (FLX: 82.2 / 50.9±21.0; ER: 24.4 / 11.6±16.4°), KE1 (FLX: 88.2 / 34.5±18.9; ER: 24.6 / 6.4±18.3°) and MT2 (FLX: 112 / 45.7±26.5; ER: 49.1 / 7.8±3.2°), compared to all other 43 participants.

DISCUSSION The initial movement of CP allows to reduce distance to the opponent without revealing the technique. The flexion and external rotation in hip joint enables a high first kick without further reclining of the upper body. For the second kick the external rotation in hip joint decreases, so he is able to use his hip joint to gain maximum force into the punching bag.

LOWER LIMB JOINT STIFFNESS DIFFERS BETWEEN REACTIVE AND PRE-PLANNED CHANGE OF DIRECTION TASKS

SAYERS, M.

University of the Sunshine Coast

Introduction Research has indicated that increased vertical and joint stiffness can improve sprint running and jumping performance (Butler et al., 2003), with researchers also reporting an increase in knee joint stiffness with an increase in running speed (Houghton et al., 2013; Kuitunen et al., 2002). However, despite a possible link between joint stiffness and CoD ability, analysis of the interaction between these data presented rarely in the scientific literature. The purpose of this investigation was to determine the effect of the presence of a decision making task on lower limb joint stiffness during a simple change of direction (CoD) tasks.

Methods Lower limb kinetics and kinematics were collected using a high speed (500 Hz) motion capture system linked to two force platforms (2000 Hz) from ten amateur football players (20.9 ± 4.09 years) during a series of pre-planned and reactive CoD tasks. Testing followed standard reactive agility test protocols (Veale et al., 2010) with the CoD angle set at 135°. Inverse dynamics procedures were used to calculate ankle, knee and hip joint stiffness during the CoD step, with these data compared with three-dimensional kinematics of the centre of mass, ground contact times, and ground reaction forces for six trials at each test condition. Results Ground contact times were shorter for the pre-planned CoD test than for the reactive CoD test. Knee joint stiffness was the greatest during the pre-planned CoD test and recorded a moderate correlation with linear running velocity. Conversely, hip stiffness increased significantly during the reactive CoD test and demonstrated a moderate correlation with the ability to produce lateral forces during the CoD tasks. Ankle stiffness did not vary significantly across either test condition, but was correlated moderately with the ability to produce vertical force during the CoD tasks.

Discussion This is one of the first studies to investigate the importance of joint stiffness during reactive and pre-planned CoD tasks. Results indicate that the inclusion of a decision making component had a clear impact on knee and hip joint stiffness during the CoD foot plant. In addition, increased knee joint stiffness appeared associated with superior performance during these tasks. These results highlight the importance of including decision making elements in both CoD testing and training.

OP-BN20 Motor Learning & Coordination

INTERNAL VS. EXTERNAL FOCUS OF ATTENTION INSTRUCTION FOR THE IMPROVEMENT AND RETENTION OF BALANCE FOLLOWING A 6-WEEK EXERCISE TRAINING PROGRAM.

PANTANO, K.

Cleveland State University

Introduction: It is not clear whether balance training which incorporates an external focus of attention (EFA) is superior to training using an internal focus of attention (IFA) for improving balance and following a 6-week balance exercise program. Current theory suggests EFA instruction leads to better motor skill outcomes than IFA instruction during motor learning and retention, however, most research has focused on immediate learning and not on motor skill retention. The purpose of this study was to examine if subjects receiving EFA vs. IFA instruction during a 6-week balance exercise training program would exhibit differences in outcomes at both short and long-term follow-up.

Methods: 63 healthy active college-aged subjects were randomly assigned to receive EFA or IFA instruction during a 6-week balance exercise training program consisting of 8 rotating stations of progressive balance exercises, per-

formed twice a week for six-weeks. Outcome measures included the Bess Test and Y-balance Test, whose baseline scores were compared between groups at 3-week, 6-week, 3-month and 6-month intervals. Separate ANOVA's were used for the dependent variables assessed using an alpha level of .05. Results: Sixty-three subjects, mean age 24.4 (SD 3.2, 65% female), satisfied the eligibility criteria and gave consent to participate. Thirty-three patients were included in the IFA instruction group; 30 subjects in the EFA group. At baseline, the IFA group had significantly higher scores (better balance) for both outcome measures ($P < .05$). Subjects receiving IFA instruction compared to EFA instruction had significantly greater Y-balance scores at 3-week, 6-week, and 3 month time intervals, and significantly lower scores (improved balance) for the Bess test at the 6-week and 3-month intervals, but not at long-term (6-month) follow-up. The EFA group, however, experienced the greatest rate of change (improvement in balance) at the 3-week interval (for Bess test), and 6-week, 3-month and 6-month time intervals (for Y-balance and Bess tests), when compared to baseline measures. Discussion: The results showed that, in healthy college-aged subjects, the greatest rate of change in balance following a 6-week exercise training program occurred when EFA instruction was provided and that motor skill retention of balance skills was greater in the EFA vs. IFA instruction group. Clinicians should consider using EFA vs. IFA instruction to improve motor skill learning and retention. Further study is needed to determine if similar results occur in injured or disabled populations.

CHANGES OF ATTRACTOR LAYOUT IN LEARNING A WHOLE BODY MOTOR SKILL

CHEN, H., CHI-LUN, H.

Taitung University

Introduction: Based on the dynamic theory, motor learning occurs as the interaction of intrinsic dynamic of system organization and its relevant information that attracts the movement dynamics toward the task goal (Kelso, 1995). The changing nature of attractor was approved by learning the coordination patterns of finger oscillation by Zanone and colleagues (1992). To investigate the evolution of attractor layout of learning the multi-segmental movement skills, the presented study examined the change of behavior dynamics in the process of learning a novel cycling task. Methods: Nine male college students participated as the learners to ride the bike, which with the independently crank, on a roller training plate. As they could ride successfully for at least 10 seconds, the goal relative phase (GRP) between right and left pedal of 180, 90, 270 and 0 degrees were required sequentially in practice sessions under the criterion of each GRP was successfully performed for 5 consecutive trials. There were 20 trials within each 20 seconds in one practice session and totally 8 sessions. Before and after each practice session, the probed tests of 12 trials (3 for each GRP) were implemented. Results: 1. A significant Tests \times GRPs interaction was observed. Simple main effect showed that the learners had higher error in the pre test than did in the post test for 90 degree GRP. Furthermore, the effect of GRPs was only found in the pre test in which the errors in 180 and 0 degrees RP were lower than those in 270 and 90 degrees RP respectively. 2. Three groups of learners could be classified according to their GRP's accomplishment. In all, as a new goal was accomplished, the higher r-square value of exponential function fitting could be found. Moreover, most of the learners emerged the 180 degrees RP tendency at the beginning and modified their pedaling movement smoothly as the goal information of 180 was implemented. In contrast, two of the learners revealed the tendency of 90 degrees RP at the beginning of practice and showed the conversely results. 3. Three components could explain approximately all of the variances in which the first component primarily reflected the motion of lower body in vertical direction, the second component reflected the motion in forward-backward direction. The third component revealed the minor motion for balancing. The individual difference in whole body movement coordination in learning process was found in the third component. Discussion: Individual difference in learning whole body movement coordination skill was found and could be explained by the mechanism of cooperation/competition effect (Zanone, et. al., 1992). The examination of learning curve showed that the exponential function was found and accompanied with the better performance in GRP suggesting the dynamics of system toward or around its attractor (Newell, et. al., 2001). The coordination patterns of pedaling and balance construct the motion of whole body segments. Changes of coordination were found in the coordination pattern for balancing.

STRENGTH TRAINING AFFECTS MUSCLE COORDINATION DURING BENCH PRESS – A RANDOMISED CONTROLLED STUDY

KRISTIANSEN, M., SAMANI, A., MADELEINE, P., HANSEN, E.A.

Aalborg University

INTRODUCTION Strength increase during the initial phase of a strength training program is primarily due to neural adaptations. Extraction of muscle synergies addresses aspects of muscle coordination. The aim of this randomised controlled study was to evaluate training induced adaptations in muscle synergies during bench press. METHODS Thirty untrained subjects were randomly allocated to either a training (TRA) ($N=17$, age 25.6 ± 4.9 years, body mass 77.2 ± 16.2 kg) or control group (CON) ($N=13$, age 22.9 ± 2.7 years, body mass 77.2 ± 11.1 kg). The pre- and post-test were separated by five weeks and consisted of performing 3 sets of 8 repetitions at 60% of 3 repetition maximum (3RM) in bench press. Between test sessions, TRA performed supervised upper body strength training, 3 times a week, while CON did not train. Muscle synergies were extracted from surface electromyographic data of 13 muscles using non-negative matrix factorization [1]. A muscle synergy consists of a synergy activation coefficient and muscle synergy vectors. The synergy activation coefficient represents the relative contribution of the muscle synergy to the overall muscle activity pattern, while the muscle synergy vector represents the relative weighting of each muscle within each synergy. We performed a cross-validation analysis to evaluate changes in muscle synergy vectors and synergy activation coefficients [1]. In this iterative procedure, the muscle synergy vectors extracted in the pre-test were recomputed, using the fixed synergy activation coefficients from the post-test, and vice versa. A similar procedure was performed for the muscle synergy vectors. RESULTS AND DISCUSSION As expected, TRA became significantly stronger (3RM Pre= 56.5 ± 19.6 kg, 3RM Post= 65.7 ± 19.7 kg, $p=0.001$), while no changes occurred in CON (3RM Pre= 55.2 ± 12.6 kg, 3RM Post= 55.0 ± 12.2 kg, $p=0.546$). Two muscle synergies accounted for >90% of the variance accounted for. For TRA, the similarities between pre- and post-values of muscle synergy vectors 1, 2, and synergy activation coefficient 2 were significantly lower than the similarities between the recomputed and original synergy parameters ($p=0.05$). However, this was not the case in CON. The modulation of muscle synergies during bench press by a five week strength training program can likely be explained by changes in efferent neural drive. CONCLUSIONS The present findings revealed that strength training cause changes in muscle synergies concomitantly with an increase in strength. EFFECTS OF FATIGUE ON TEMPORAL VARIABLES AND THEIR VARIABILITY DURING A REPETITIVE KARATE EXERCISE

ARAGONÉS, D., EEKHOFF, A., HORST, F., SCHÖLLHORN, W.I.

Johannes Gutenberg University Mainz

INTRODUCTION Despite the differential training approach has been successfully applied to improve skills by introducing variability, repetitive training approaches are still common in most sports (e.g., karate). Increased variability has been reported with fatigue accumulation during repetitive endurance training (Cignetti et al., 2009). Thus, skill acquisition by repeating could be attributed to fatigue-induced variability. Accordingly, our aim was to analyze temporal variables and their variability in karate during a fatiguing exercise based on repetitions. **METHODS** Sixteen healthy adults (5 women, 11 men) practicing karate with black and brown belts performed 9 sets of 60 mae-geri kicks (i.e., frontal kick) at submaximal intensity (alternating subsets of ten repetitions with right and left leg) with 90-seconds of rest period between sets. All kicks were performed at a frequency of 1 kick/2 seconds without impacting a target. Kinematic data were captured by 10 Oqus 310 infrared cameras (Qualisys AB, Sweden, 333 Hz) employing passive markers. Total kick time duration was divided into 2 phases (phase 1 from the start of the kicking foot movement until maximum knee flexion; phase 2 from this moment until full knee extension). Means and standard deviations (as a measure of variability) of the kick durations, peak angular velocities occurrence (of the hip, knee, ankle), and peak linear velocities of the kicking area of the foot (metatarsal heads) were compared within (between subsets of 10 repetitions) and between sets by means of Friedman ANOVA. **RESULTS** Kicks had a statistically significant increase with fatigue accumulation within sets in total duration and phase 1 duration (mainly between the first subset of 10 repetitions and the rest); furthermore, peak velocities occurred later (mainly of the feet). Regarding variability, significant differences were found for duration (phase 1 and 2) within the last set, and for peak velocities occurrence of the foot and joints between different sets. **DISCUSSION** With fatigue accumulation kick duration increases (phase 1 is much more affected than phase 2) and peak velocities of the feet occur later within sets. Moreover, the effects of fatigue are clearly manifested after the first subset of 10 repetitions, considering that subset 2 and 3 are not significantly different. Nevertheless, a 90-seconds rest period seems to be enough in order to produce previous values. Results demand further differentiated research related to absolute and relative variability and more variables should be considered to fully understand the effect of fatigue accumulation on variability during repetitive training. **REFERENCES** Cignetti F, Schena B, Rouard A (2009). MULTIVARIATE ANALYSES OF THROWING PERFORMANCE: THE EFFECT OF EXPERIENCE

LIU, Y.T.1, CHUANG, K.L.1, NEWELL, K.M.2

1:National Taiwan Normal University 2: University of Georgia

Introduction Movement outcomes are the consequences of the coordination among the body segments under the influence of the gravitational field. Movement experience shapes the intrinsic dynamics of the individual that influences the coordination patterns she or he produces. In this study, we show that the outcome of a simple 2-joint throwing movement that can be well described by a mechanical model and differentially links to the coordination patterns of learners with different throwing experience. **Methods** 24 college students participated in the study. Half of them were elite basketball players and the others had no sport training experiences. All the participants practiced 50 trials a day for 3 days. The task goal was to throw a ball to a target. The ball was placed in a cup attached to the dominant wrist of the participant. A high-speed camera and Kwon 2D motion analysis system were used to capture 2-d kinematics of the hip, shoulder, elbow, wrist, and the ball. Throwing outcomes, ball and throwing arms' release angles and velocities were used in modeling projectile motion, linear discriminant analyses, and canonical correlation analyses (CCA). **Results** We used the ball release angle (BA), velocity (BV), and height from the data to model the projectile motion of the ball, and the prediction of the hit rate was close to 98%. For basketball players, the "discriminant index" (DI) based on the shoulder angle (SA), shoulder velocities (SV), elbow angle (EA), and elbow velocity (EV) at ball release to differentiate "hit" or "miss" of the throws increased over 3 days from .62 to .78 ($r^2 = .94$) whereas the non-basketball players had a similar DI range between .70 and .78 without significant trend ($r^2 = .16$). The basketball players had large coefficient for all 4 variables whereas the non-basketball players tended to concentrate on the SA and EA. The canonical correlation analysis, which was used to examine the relation between the movement (SA, SV, EA, and EV) and the projectile motion (BA and BV) showed that joint angles, especially SA, and BA tended to have higher coefficients whereas the coefficients of SV, EV, and BV were relatively small. **Discussion** The throwing outcomes are determined by the ball release kinematics through the projectile motion equation. The results from CCA indicated that only BA was directly influenced by SA. The BV, on the other hand, did not show a linear relation with respect to any of the movement parameters. This indicates the nature of movement degeneracy in producing performance outcome. With an extended experience in basketball throwing, the basketball players explored all the available movement parameters over the 3 days of practice. The non-basketball players, however, mainly used the proximal SA to control the throwing movement. Movements of multi-segment coordination patterns require the multivariate analyses to fully examine the performance of different levels. Future research will continue to employ other multivariate methods in studying movement coordination issues.

THE RELATIVE IMPORTANCE OF INTER- AND INTRA-INDIVIDUAL PATTERNS DURING ANTICIPATION

NORTH, J.S., HOPE, E., WILLIAMS, A.M.

St Mary's University, Twickenham

Introduction In complex, time constrained environments anticipation is critical to successful performance. When anticipating in sport, perception of postural cues (intra-individual patterns; Diaz, Fajen, & Phillips, 2012) and relations between players (inter-individual patterns; Williams, North, & Hope, 2012) have been proposed as important perceptual-cognitive processes. Dittrich's (1999) interactive encoding hypothesis proposes that skilled performers perceive meaning by extracting relative motion between features to inform their actions. We examined the relative importance of intra- or inter-individual patterns during anticipation and how this varied as a function of task constraints. **Methods** Skilled and less-skilled soccer players completed anticipation paradigms in video-film and point-light display (PLD) format. Sequences were classified as either far or near based on how close the ball was to the participant when making the judgement. **Results** Skilled players ($M = 58.33\%$, $SD = 18.20$) were more accurate than less-skilled players ($M = 36.11\%$, $SD = 10.36$). There was a Skill x Display interaction. Skilled players had a greater advantage over less-skilled players in the video-film ($M = 69.10\%$, $SD = 13.57$ vs. $M = 38.54\%$, $SD = 9.77$) relative to the PLD condition ($M = 47.57\%$, $SD = 15.83$ vs. $M = 33.68\%$, $SD = 10.56$). Finally, there was a Display x Distance interaction. For video-film clips, there was no difference in accuracy between far and near tasks ($M = 56.60\%$, $SD = 21.28$ vs. $M = 51.04\%$, $SD = 17.26$), whereas, on the PLD clips, judgements were more accurate for the far than near task ($M = 49.31\%$, $SD = 14.31$ vs. $M = 31.95\%$, $SD = 10.03$). **Discussion** The skill advantage across conditions suggests skilled players can utilise information conveyed by inter-individual patterns during anticipation. However, intra-individual information from postural cues is important when

available to enhance anticipation. Anticipation is complex and made up of a number of different perceptual-cognitive skills. As proposed by Dittrich (1999), skilled performers extract relative motion information to perceive meaning, however whether this is processed locally (intra-individual relations between postural cues) or globally (inter-individual relations between players) is dependent on the task constraints under which anticipation occurs. OP-PM17 Running Performance

EFFECTS OF STRENGTH, EXPLOSIVE AND PLYOMETRIC TRAINING PROTOCOL ON ENERGY COST OF RUNNING IN HIGH-LEVEL ULTRA-MARATHONERS

GIOVANELLI, N., TABOGA, P., LAZZER, S.

University of Udine

Introduction Effects of strength, explosive and plyometric (SEP) training on endurance performance have been studied in different sport situations but there is a lack of information related to the effects of SEP training on ultra-marathoners. Thus, the aim of this study was to evaluate the effects of a 12-week SEP training protocol on the cost of running (Cr) in high-level ultra-marathoners and to define the causes of an eventual change in Cr . Methods Twenty-five male runners (38.2 ± 7.1 years; BMI: 23.0 ± 1.1 kg·m $^{-2}$; VO 2max : 55.4 ± 4.0 mLO $2\text{-kg}^{-1}\text{·min}^{-1}$) were divided into an exercise (EG=13) and control group (CG=12). Before and after a 12-week SEP training protocol, Cr and spring-mass model parameters at 8, 10, 12, 14 km·h $^{-1}$ were calculated. Maximal muscle power of the lower limbs (MMP), morphological properties of the gastrocnemius medialis (GM) and triceps surae tendon stiffness (ktendon) were measured. Results In EG, Cr decreased significantly ($p < 0.05$) at all tested running speeds by mean $-4.2 \pm 1.5\%$, contact time (tc) increased at 8, 10 and 12 km·h $^{-1}$ by mean $4.4 \pm 0.1\%$ and aerial time decreased by -25.6% at 8 km·h $^{-1}$ ($p < 0.05$). Further, inverse relationships between changes in Cr and MMP at 10 ($p = 0.013$; $r = -0.67$) and 12 km·h $^{-1}$ ($p < 0.001$; $r = -0.86$) were shown. Conversely, no differences were detected in the morphological properties of the GM and ktendon. In CG no differences were shown in any of the studied parameters. Discussion 12-week SEP training program lower the Cr in high-level ultra-marathoners at submaximal speeds. For these athletes the small improvement in Cr (~4%) can lead to an important step forward in the rankings. In the present study stride length and stride frequency did not change after the training protocol, but tc increased, as shown by Ferrauti et al.(2010). According to the cost of generating force hypothesis (Kram and Taylor 1990), running with longer tc should be more economical, since it requires slower and less expensive fibers and the force is applied in a longer period of time. In agreement with this hypothesis the increased tc could in part explain the lower Cr . Further, an inverse relationship between changes in MMP and changes in Cr at 10 and 12 km·h $^{-1}$ suggests that athletes who slightly improved their MMP also decreased their Cr at submaximal speeds suggesting that MMP is an important parameter in determining Cr , as previously shown (Lazzer et al. 2015). In conclusion, we suggest to add at least three sessions per week of SEP exercises in the normal endurance-training program. References Ferrauti A, Bergermann M, Fernandez-Fernandez J (2010). THE BETTER THE DISTANCE RUNNER, THE MORE SLOW-TWITCH MUSCLE TYPOLOGY?

LIEVENS, E., BEX, T., BAGUET, A., ACHTEN, E., DE CLERCQ, D., DERAVE, W.

Ghent University (Ghent, Belgium)

Introduction Classical studies on histological analyses of muscle biopsies of elite athletes have revealed that sprint-type disciplines require a predominant fast-twitch (FT) muscle fiber type composition (MFTC), whereas athletes in endurance-type disciplines thrive on largely slow-twitch (ST) muscles. However, 1) this fundamental element in exercise physiology is in present day hardly used in scientific guidance of athletes, and 2) many questions still remain unanswered regarding optimal MFTC for different sport events. Both these limitations relate to the invasive nature of the muscle biopsy, making it inapplicable in elite sports. Recently, muscle carnosine quantification by proton magnetic resonance spectroscopy (1H-MRS) was developed as a new noninvasive method to estimate MFTC (Baguet et al., 2011). By applying this technology to a large group of elite athletes, we aim to answer unresolved questions such as 'Do short-distance swimmers need a predominant fast MFTC?' and 'Do international-caliber distance runners have a slower MFTC than national-level runners?'. Methods A total of 111 elite Belgian athletes (74 runners, 7 triathletes, 11 swimmers, 14 cyclists and 5 kayakers) were recruited to measure muscle carnosine content in gastrocnemius and deltoid muscle by 1H-MRS on a 3T scanner. Carnosine is a typical FT metabolite and high concentrations of carnosine correspond to a fast MFTC. Athletes were compared to a gender- and age-matched reference population ($n=188$). Results Across the different sports disciplines, carnosine content showed the strongest significant correlation with cyclic movement frequency ($R = 0.86$, $P = 0.001$), though no significant correlation was found between the carnosine content and performance duration ($R = -0.58$, $P = 0.06$). Thus, swimmers –even those who compete in short events- have a more ST muscle typology than corresponding runners and cyclists. Interestingly, there was no difference in carnosine content between the international- and the national-level endurance runners ($P = 0.89$). The opposite was found in sprinters, as international-level athletes were characterized with higher carnosine levels than national-level athletes ($P = 0.05$). Discussion Cyclic movement frequency, rather than exercise duration came out as a factor best related to the optimal estimated MFTC in elite athletes. A more extreme MFTC seems more important to excel in sprint running than in endurance running. Our findings suggest that MR-based non-invasive estimation of MFTC can have important applications in elite sports. References Baguet A, Everaert I, Hespel P, Petrovic M, Achten E, Derave W. (2011). PACE VERSUS PREDICTION: IMPLICATIONS OF AGE, EXPERIENCE AND SEX ON MARATHON RACE PERFORMANCE

GORDON, D., BASEVITCH, I., SCRUTON, A., BIGGINS, J., BAKER, J., MERZBACH, V.

Anglia Ruskin University

PURPOSE: Pacing strategies during exercise are attributed to optimizing the balance between the artifacts of fatigue and regulation of substrate metabolism. Pace judgement is set within a continuum of information from the ability to anticipate metabolic demands and select an appropriate strategy through to the accumulation of prior experience for completion of such a task that has a known end-point. Therefore the purpose of this study was evaluate the factors which contribute to successfully regulating pace and attaining a predicted end time during a marathon. **METHOD:** Following local institutional ethical approval n= 777 runners competing in the 2015 London Marathon of which n= 393 were females and n= 384 were males participated. Using an on-line survey and opportunistic questionnaires at a pre-marathon event participants were asked to predict their race time. Athlete experience (EXP) was established based on the number of previously completed marathons using a Likert scale from 0 to greater than 10 with increments of 1 race. Age was stratified according to those adopted by the marathon organizers: 18-39yrs, 40-49yrs, 50-59yrs and >60yrs. 5Km split times were converted to speed and normalized (%) to the final split time/speed (m.s⁻¹). Prediction time (PT) was used a proxy for end-point and compared to finish time (FT). **RESULTS:** FT for whole group (WG) was 15479 ± 3311s compared to the group PT 15003 ± 2972s a significant difference of 476s (P= 0.0001). An R² of 0.863 observed for WG compared to 0.799 (0-EXP) and 0.852 (EXP-5) when comparing FT to PT. 0-EXP showed significant difference across all split times apart from 35-40 km (P=0.0001) with a decrease in normalized speed from 5km (109.0 ± 7.6) – 40km (89.9 ± 7.4%). The 5-EXP group showed significant changes in pace between 25-30 km (P= 0.001) (ES =0.35), 30-35 km (P= 0.0001) (ES= 0.44) and 35-40 km (P= 0.0001), decrease in pace from 5km (105.0 ± 5.7%) to 40km (93.7 ± 5.6%). Large effect sizes (ES) observed for 18-39yrs at 30-35km (r= 0.370), 40-49yrs at 30-35km (r= 0.337), 50-59yrs at 25-30km (r= 0.368) and 30-35km (r= 0.418) and >60yrs at 30-35km (r= 0.527). A significant difference (P= 0.0001) of 476s was observed between PT and FT for the whole group compared to differences of 531 s (p= 0.000) and 419s (P= 0.000) for the males and females respectively. **CONCLUSIONS:** These data suggest that successful marathon pacing is dependent on the experience of the athlete reflecting the development of the pacing template. Additionally experience is associated with better attainment of prediction time suggesting that less experienced runners should run with more experienced athletes with similar end-point targets.

LACTATE MINIMUM OF THE HEART RATE-BASED LACTATE MINIMUM TEST HIGHLY PREDICTS 10K AND HALF-MARATHON RUNNING PERFORMANCE IN MEN AND WOMEN

PERRET, C., HARTMANN, K.

Swiss Paraplegic Centre

Introduction Some years ago, the so-called heart rate-based lactate minimum test (LMT-HR) developed at our institute (Strupler et al., 2009) revealed a high correlation between lactate minimum (LM) and the maximal lactate steady-state (MLSS) in wheelchair racing (Perret et al., 2012), which makes this test feasible to determine individual training intensity zones. However, it remains still unclear, if this test is also suitable to estimate endurance race performance in able-bodied sports such as running. Thus, the aim of the present study was to investigate, whether 10k and half-marathon performance can be predicted based on a LMT-HR in male and female runners over a wide range of performance levels. Methods 30 participants (13 male / 17 female) performed a LMT-HR on a treadmill according to the protocol of Strupler et al. (2009). Additionally, they completed a 10k and a half-marathon race at the highest possible pace on a flat track on two separate occasions at least 5 days apart. During these races, runners were regularly informed about the distance covered, but were not aware of race pace or heart rate. For statistical analysis Spearman correlations for speed data at LM versus average speeds during the 10k and half-marathon run were calculated for male and female runners separately. Results The present study included 13 men (age: median [minimum; maximum] 38y [25;47]; height: 181cm [170;186]; body mass: 75.0kg [63.0;86.0]; VO₂peak: 54.1ml/min/kg [42.3;66.0]) and 17 women (age: 33y [24;44]; height: 167cm [161;180]; body mass: 58.0kg [50.0;70.0]; VO₂peak: 51.4ml/min/kg [41.1;61.2]). Race times for the 10k ranged between 36:02min and 56:36min and for the half-marathon between 79:36min and 128:59min, respectively. Highly significant correlations between speed at LM vs. 10k speed in men (r=0.875; p<0.001) and women (r=0.916, p<0.001) as well as between speed at LM vs. half-marathon speed (men: r=0.873, p<0.001; women: r=0.924, p<0.001) were found. Conclusions Results of the LMT-HR allow an accurate prediction of 10k and half-marathon race performance in male and female runners based on a single exercise test. Thus, in daily clinical practice the LMT-HR seems to be a very useful tool for sport scientists and coaches not only to determine individual training intensity zones but also to estimate the actual athletes' running performance potential over a wide range of fitness levels. QUALITATIVE RESPONSES TO ANAEROBIC EXERCISE BOUTS

EVERETT, K.L.A., CHAPMAN, D.W., MCKUNE, A.J., BALL, N.

University of Canberra

Introduction Qualitative measures such as Rate of Perceived Exertion (RPE) and questionnaires can be quick and inexpensive methods to monitor training load and training load responses¹. This study aimed to report the difference in RPE response to a low, moderate and high anaerobic exercise bout and to assess if responses to a modified neuromuscular fatigue questionnaire (NMFQ)² change over time dependent on different anaerobic loads. Methods Recreationally trained participants (n=6; 23.2±1.2y; 1.71±0.07m; 71.5±9.7kg) completed in a low (2sets), moderate (4sets) and high (6sets) load repeat sprinting protocol. Participants completed the load trials in randomised order with a minimum of 96h between trials. Following a standardised warm-up the repeat sprint running protocol consisted of multiple sets of 10x20m sprints on a 20s cycle, each with a 180s inter-set rest period. At the completion of each set participants provided an RPE score using the Borg CR10 rating scale. The NMFQ was completed prior to and then at 3, 6, 24 and 48h post trial. RPE and NMFQ scores were analysed using individual one-way repeated (conditions or time) measures ANOVA with LSD post hoc. A Pearson's correlation was used to examine the relationship between RPE and NMFQ. Due to the small sample size level and to avoid a type I error significance was accepted at p≤0.1. Results A significant interaction effect was observed between conditions (p=0.009) for RPE, with post hoc tests indicating a significant difference between low (p=0.003) and moderate (p=0.022) with the high condition. A significant interaction was observed for NMFQ over time in all conditions (low p=0.093; mod p=0.024; high p=0.046). Pre NMFQ scores ranged between 0-4, 1-7, and 0-5 for low, moderate and high respectively. Mean (min-max) peak NMFQ scores following low were 14 (0-14) at 48h post, while moder-

ate (13; 5-13) and high (19; 4-19) both occurred 24h following the exercise protocol. Post hoc testing revealed a significant increase in NMFQ scores from the pre time point, furthermore in high condition NMFQ scores continued to increase significantly from 3h to 24h. There was no significant relationship between RPE and NMFQ responses for low ($r=-0.5-0.1$) moderate ($r=0.3-0.6$) and high ($r=-0.2-0.4$). Discussion The results suggest that RPE measures are sensitive to changes in anaerobic loads resulting from repeat sprints. The observation that there was no correlation between RPE and the NMFQ score over time suggests a modified NMFQ has the potential to be a useful tool to monitor neuromuscular fatigue responses to training up to 48h post exercise. EFFECTS OF POST-EXERCISE COOLING ON HEART RATE RECOVERY IN NORMOTENSIVE AND HYPERTENSIVE MEN

PEÇANHA, T., LOW, D.A., BRITO, L., FECCHIO, R.Y., SOUSA, P., SILVA-JUNIOR, N., ABREU, A., SILVA, G., MION-JUNIOR, D., FORJAZ, C.L.M.

School of Physical Education and Sport and General Hospital, University of São Paulo, Brazil / Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, UK

Introduction Post-exercise heart rate recovery (HRR) is regulated by several mechanisms, including thermoregulation. The exercise-induced increase in core temperature (T_c) is partly responsible for the maintenance of elevated heart rate during recovery. Hence, strategies able to reduce T_c after exercise might be effective in accelerating HRR. This effect is particularly relevant for subjects with hypertension who have delayed HRR. Thus, this study aimed to verify the effects of post-exercise cooling on HRR after exercise in normotensive (NT) and hypertensive (HT) men. Methods 25 NT (43 ± 8 years, 28.6 ± 2.7 kg/m 2 , $114 \pm 4/77 \pm 2$ mmHg) and 23 HT (45 ± 8 yrs, 29.4 ± 3.6 kg/m 2 , $142 \pm 8/96 \pm 3$ mmHg) men randomly underwent 2 exercise sessions (30 min cycling at 70% VO $_{2\text{peak}}$) followed by 15 min of recovery. In one session, a fan was turned on in front of the subjects during the recovery period (cooling session), while in the other session, no cooling was performed (control session). ECG, photoplethysmographic blood pressure and T_c (ingestible pills) were recorded. HRR was assessed by: heart rate reduction after 60 (HRR60s) and 300s (HRR300s) of recovery, the short-term time constant of HRR (T30), and the time constant of the HRR after exponential fitting (HRRt). Heart rate variability (HRV) was assessed in the first 5 min of recovery by time-domain indices (RMS and RMSSD), at rest and 10-15 min of recovery by spectral analysis (low and high frequency components; LF and HF). Spontaneous baroreflex sensitivity (BRS, sequence technique) was also assessed at rest and during recovery. Two- (group vs. session) and three-way (group vs. session vs. time) ANOVAs were employed ($p \leq 0.05$). Results There were no differences between groups for any of the main outcomes. In both groups, post-exercise cooling reduced T_c (37.5 ± 0.3 vs. 37.6 ± 0.3 °C, $p < 0.05$). HRR300s was higher (39 ± 12 vs. 36 ± 10 bpm, $p < 0.05$) and T30 was lower (213 ± 85 vs. 284 ± 135 s, $p < 0.05$) in the cooling session. With respect to the HRV indices, RMS, RMSSD and HF were higher (2.6 ± 0.6 vs. 2.4 ± 0.6 ms, 1.8 ± 0.7 vs. 1.6 ± 0.7 ms, 16.2 ± 17.1 vs. 11.0 ± 7.5 nu, respectively, $p < 0.05$) and LF was lower (82.6 ± 14.4 vs. 86.1 ± 10.8 nu, $p < 0.05$) in the cooling session. Conclusion In NT and HT men, post-exercise cooling with a fan decreases T_c and accelerates HRR. This HRR response is accompanied by an acceleration of parasympathetic reactivation and sympathetic withdrawal during the recovery period. Funding: FAPESP 2013/04997-0, 2013/05519-4, 2015/15466-0.

QTC INTERVAL IN ADOLESCENTS AND YOUNG ATHLETES: METHODOLOGICAL CONSIDERATIONS AND INFLUENCE OF CORRECTION FORMULAS

GERVASI, S., BIANCO, M., CAMMARANO, M., PALMIERI, V.

Catholic University of Sacred Heart - Rome

BACKGROUND. A challenging problem in the pre-participation screening of young athletes is the finding of rate-corrected QT interval (QTc) at the upper limits in the electrocardiogram. Regardless factors potentially able to influence this parameter (age, sex, electrolytes, conduction abnormalities etc.), several authors underlined how often correction formulas fail to properly correct QT interval, especially for upper normal limits (440-460 msec). Furthermore, from literature review, it seems that different formulas comply differently depending on populations analyzed (pediatric, heart patients etc). Our goal was to identify the most reliable rate-correction formula and relative reference values (RV) for adolescents and young, healthy, male athletes. METHODS. Rest-ECG of 701 healthy élite male athletes (aged 9-35) were analyzed. QTc was calculated with the most utilized formulas (Bazett, Fridericia, Framingham, Hodges). Regression analysis (slope), correlation coefficients (R) of QTc/heart rate (HR) and RV for each formula were calculated and compared overall (TOT) and considering 3 different age groups (A: 9-12, B: 13-17, C: 18-35). RESULTS. R values were: Bazett 0.56(TOT), 0.52(A), 0.60(B), 0.34(C); Fridericia 0.02(TOT), 0.03(A), 0.12(B), -0.13(C); Framingham -0.78(TOT), -0.74(A), -0.74(B), -0.72(C); Hodges -0.10(TOT), 0.08(A), -0.01(B), -0.33(C). Slopes were: Bazett 1.04(TOT), 0.98(A), 1.23(B), 0.83(C); Fridericia 0.02(TOT), 0.52(A), 0.20(B), -0.31(C); Framingham -1.91(TOT), -1.63(A), -1.77(B), -2.62(C); Hodges -0.16(TOT), 0.11(A), -0.02(B), -0.87(C). RV were: Bazett 358-455 msec; Fridericia 364-439 msec; Framingham 336-455 msec; Hodges 366-442 msec. CONCLUSIONS. Fridericia's formula seems to be the most reliable and the less influenced by age ($p < 0.05$) for QT rate-correction in young male athletes (RV 360-440 msec), and should be routinely used in this population. QTc values obtained with the Bazett's formula appear considerably dependent by HR (even in the "optimal range" of 60-90 bpm), overestimated at higher HR (5% of QTc > 440 msec, of which 96% at HR > 60 bpm, 84% > 70 bpm) and underestimated at lower ones. Framingham's formula shows similar limits, but in an inverse way. Hodges' formula offers a good overall performance, but shows significant dependence from age. REFERENCES Luo S et al. ARE AEROBIC INTERVAL TRAINING AND CONTINUOUS TRAINING ISOCALORIC IN CORONARY ARTERY DISEASE PATIENTS?

PATTYN, N., CORNELISSEN, V.A., BUYS, R., VANHEES, L.

KU Leuven

BACKGROUND: Aerobic interval training (IT) seems to be superior to continuous training (CT) in improving exercise capacity (peak VO₂) in coronary artery disease (CAD) patients in some, but not in all studies. Based on theoretical calculations, these comparative studies stated that the energy expenditure (EE) of both programs is similar. To date, the caloricity of both programs has never been objectively measured. Therefore, our aim was to objectively measure the EE of the IT and CT programs described in the protocol of the SAINTEX-CAD study (based on Wisloff et al.; ITw - CTw), and the actually performed training intensities in the SAINTEX-CAD study by Conraads et al. (ITc - CTc). Wisloff et al. found a superior effect of IT, while the SAINTEX-CAD study by Conraads et al. reported that IT and CT were equally effective. **METHODS:** Eighteen male CAD patients (mean age 62.4±6.1 years) performed a two week run-in period with three IT and three CT training sessions on a cycle ergometer. The IT session included a 10 min warm-up, 4 bouts of 4 min at a higher intensity, alternated by 4 periods of 3 min at a lower intensity (total exercise time 38 min). The CT session included a 5 min warm-up, a 37 min bout at a constant intensity, and a 5 min cool-down (total exercise time 47 min). After the familiarisation period, 4 training sessions were performed in random order: an ITw (90-95% of peak heart rate (HR)), CTw (70-75% peak HR), ITc (88% of peak HR) and CTc (80% of peak HR) test. The EE was assessed by indirect calorimetry using gas exchange measures obtained with the Oxycon™ mobile. **RESULTS:** We found a higher EE for CTc compared to ITc (352 ± 90.8 kcal versus 269 ± 70.7 kcal; $p=0.026$), while CTw and ITw seemed to be isocaloric (317 ± 85.2 kcal versus 273 ± 65.3 kcal; $p=0.42$). Higher lactate levels were reached after IT sessions (ITw 5.42 ± 1.42 mmol/l, ITc 5.05 ± 1.38 mmol/l) compared to CT sessions (CTw 2.45 ± 1.04 mmol/l, CTc 3.41 ± 1.44 mmol/l) ($p<0.01$). Lactate levels during the training session increased above baseline levels (1.91 ± 0.34 mmol/l) except for the CTw session. **CONCLUSION:** CTc expended significantly more energy than ITc, showing that the programs used in the SAINTEX-CAD study were not isocaloric. In contrast, isocaloricity was met for CTw and ITw. In the SAINTEX-CAD study, both programs were equally effective in increasing peak VO₂, but it seems that a lower EE was needed with IT in order to achieve similar improvements as CT. We can thus suggest that the efficacy of IT is higher than CT.

ASSESSING FREE-LIVING WALKING IMPAIRMENT IN PERIPHERAL ARTERY DISEASE PATIENTS BY OBJECTIVELY QUANTIFYING WALKING PAIN OCCURRENCE: DEFINITION OF A METHODOLOGY USING PHYSICAL ACTIVITY MONITORS

CHAUDRU, S.1, DE MÜLLENHEIM, P.Y.2, KLEIN, H.2, JAQUINANDI, V.1, MAHÉ, G.1, LE FAUCHEUR, A.1,2

1: CIC1414 and University of Rennes 1 (Rennes, France), 2: M2S lab and ENS (Rennes, France)

Introduction A high proportion (~50 to 80%) of peripheral artery disease (PAD) patients experience ischemic pain in the lower extremities whilst walking, which forced them to stop in most cases. Although walking pain occurrence can be objectively assessed in laboratory during a treadmill test, no objective free-living assessment has been yet performed. Using physical activity (PA) monitors, our aim was to develop a method to objectively quantify in free-living conditions walking pain occurrences and stops induced by ischemic pain in PAD patients. Methods Fifteen PAD patients (defined by an ankle-brachial index ≤0.90) limited by ischemic walking pain wore a wGT3x+ accelerometer and a Micro Motion logger watch for 7 days (NCT02041169). Patients had to push a button on the watch (marker event) to report the onset of walking pain and the stop induced by the pain. In addition, patients completed a PA diary on a daily basis. We have developed an algorithm to appropriately assign to each recorded marker event the following: i) walking pain occurrence; ii) stop induced by walking pain; iii) inconsistent event (error). For this purpose, downloaded data from the wGT3x+ were analyzed using conventional handling procedure (Choi et al., 2011) and then used to discriminate walking and sedentary periods. Consistent marker events were assigned to walking pain occurrences or stops induced by walking pain using the number of counts/sec (Vector Magnitude). Diaries were scored with the Compendium of PAs and used to identify indoor/outdoor conditions. Results The algorithm developed allows quantifying walking pain occurrences and stops induced by walking pain in outdoor conditions. However it didn't allow distinguishing walking pain from walking stop in indoor conditions because of the intermittent nature of the walk with very short bouts. When applying this algorithm among the 15 PAD patients, we highlighted that, on average, patients experienced pain six times per week in outdoor conditions and this pain led the patients to stop in half of the cases. In indoor conditions, on average 6 marker events per week were recorded. Discussion The objective assessment of walking pain occurrences and walking stops induced by ischemia in free-living environment could provide interesting clinical information on patients' walking impairment. OP-PM23 Performance Testing

INTERNAL- AND EXTERNAL-TRAINING LOAD MEASURES DURING VARIOUS CRICKET TRAINING MODALITIES

VICKERY, W.1, DASCOMBE, B.2, DUFFIELD, R.3

1: Northumbria University (Newcastle Upon Tyne, UK), 2: LaTrobe University (Melbourne, Australia), 3: University of Technology Sydney (Sydney, Australia).

Introduction The use of session rating of perceived exertion (sRPE) has become common practice in recent years to monitor the training load (TL) of elite athletes and teams. However, as noted by Weaving et al. (2014) the monitoring of TL in team sports can be difficult due to the various training forms and modes undertaken. Training within cricket typically involves net-based and conditioning sessions, though more recently, game-based scenarios are increasingly prevalent. Given the lack of information regarding the monitoring of TL amongst cricket players, this study aimed to examine the relationship between measures of TL and the training mode used within a cohort of elite cricket fast bowlers. Methods Following net-based cricket ($n=51$), game-simulated centre-wicket ($n=16$) and conditioning sessions ($n=27$) in eleven elite, fast bowlers (23.3 ± 4.8 y; 1.88 ± 0.08 m; 85.6 ± 8.34 kg), TL was calculated by multiplying rating of perceived exertion (RPE: CR-10) by the session duration (in minutes). Internal-TL was further quantified using heart rate devices (HRmean, TRIMPI), whilst exter-

nal-TL was quantified via 10 Hz GPS devices, along with the number of balls bowled per session using video analysis. Pearson's product moment correlations were calculated between sRPE and measures of internal- and external-TL for each training mode. Results A small correlation ($r = -0.29$) existed between mean heart rate and sRPE during net-based sessions, however no other significant ($P > 0.05$) correlations were reported between sRPE and other internal measures of TL (HRmean, TRIMPI) across any training mode. Large to almost perfect correlations were evident between sRPE and GPS-based measure of external-TL, particularly total overall distance covered ($r = 0.87-0.91$) and distance at low-intensity ($r = 0.87-0.93$). A significant correlation ($P > 0.05$, $r = 0.68$) between the number of balls bowled and sRPE existed, but only during net-based training. Discussion The results suggest that a similar relationship between both internal- and external-TL exists across the various cricket training modes for fast bowlers. Regardless, internal measures of TL displayed a small or non-significant associations with sRPE, which may result from the activity pattern of fast bowling. Small variations in GPS-derived measures of external-TL were noted across all training modes, suggesting sRPE is a valid measure for monitoring the workload of cricket fast bowlers across a range of cricket training modes. PHYSIOLOGICAL AND PERCEPTUAL RESPONSES TO COMBINED ARM-LEG ERGOMETRY AT SELF-ED AND IMPOSED WORKLOADS

HILL, M., TALBOT, C., PUDDIFORD, M., PRICE, M.

University of Northampton

Introduction For the same relative exercise intensity, combined arm-leg ergometry appears to be more readily tolerated than arm or leg training alone, likely due to the greater active muscle mass. The addition of arm crank ergometry (ACE) to cycling (CYC) increases oxygen uptake with no greater cardiovascular or subjective strain (Gutin et al. 1988) however, specific mechanisms are as yet unknown. To clarify our understanding of the physiological and subjective responses to work of this type, we compared exercise responses during self-selected (SS) and imposed (IMP) workloads. Methods A pilot group of five males initially undertook incremental exercise tests to volitional exhaustion for ACE (133±23 W) and CYC (232±32 W) to determine peak minute power (WPEAK). Subsequent tests involved 20-min combined ACE+CYC trials at SS and IMP intensities. During IMP, intensity was set at 40% of each ergometer-specific WPEAK. Participants were asked to maintain a cadence of 70 rev·min⁻¹ for both the arms and legs as for the preliminary tests. During SS, participants were asked to self-select cadence and adjusted workload every 5 min to achieve an exercising heart rate of ~ 160 beats·min⁻¹. All participants were fully familiarised to A+L exercise. Heart rate (HR), oxygen uptake (VO₂), minute ventilation (VE) and central ratings of perceived exertion (RPE) were recorded continuously. Results Despite similar power outputs during SS (ACE; 39±8, CYC; 88±14 W) and IMP (ACE; 48±9, CYC; 94±15 W) trials, physiological responses were generally greater for IMP (HR; 172 ± 4 beats·min⁻¹, VO₂; 2.14 ± 0.41 L·min⁻¹ and VE; 71.0 ± 9.85 L·min⁻¹) compared to SS (HR; 163 ± 4 beats·min⁻¹, VO₂; 1.95 ± 0.32 L·min⁻¹ and VE; 60.9 ± 9.84 L·min⁻¹). Central RPE was similar between trials (SS; 12±2, IMP; 13±2). For the SS trial, relative VO₂ was 73±11 % and 62±7 % of the VO₂peak achieved during maximal arm and leg tests, respectively. Similarly, relative HR was 91 ± 2 % and 82 ± 2 % of HRMAX achieved during incremental arm and leg trials, respectively. For the final SS intensity, cadence was 60±5 and 64±5 rev·min⁻¹ for ACE and CYC, respectively. Load was increased by ~0.2 Kg for CYC and reduced by ~0.1 Kg for ACE. Discussion The results indicate that when participants self-select exercise intensity during combined arm-leg ergometry, they chose work rates eliciting metabolic and cardiovascular stimuli which are within the moderate range of ACSM guidelines for lower limb exercise. During SS there was a preference to reduce cadence. This study provides evidence that individuals are able to self-select a combined arm-leg training intensity that not only feels comfortable, but also falls within the training range which is expected to improve cardiovascular conditioning.

EFFECTS OF SHORT-WAVE LIGHT ON ANAEROBIC PERFORMANCE

BEAVEN, C., EKSTRÖM, J.

Malaysian National Sports Institute

Overview Short-wavelength light (450-495nm) is perceived by humans as blue and is known to stimulate biological functions. Blue light interventions enhance cognitive function and reaction times (Beaven & Ekström, 2013) and affect brain areas associated with arousal and circadian rhythmicity (Rautkylä, Puolakka, & Halonen, 2011). Exposure to short-wavelength light has been reported to elevate testosterone and increase lean muscle mass (Cao et al., 2008). Testosterone has been suggested to be acutely linked to power production (Crewther, Cook, Cardinale, Weatherby, & Lowe, 2011). Hence, we investigated whether exposure to short-wavelength light could impact performance in an anaerobic power test. Methods 21 healthy volunteers performed a 30s Wingate test on a Monark friction-braked ergometer against a resistance of 0.075kg/kgBW immediately following a 60min exposure to either a blue LED light source (470 nm) or a white light alternative. Relative peak, average, and minimum power data was collected, as well as percentage power decrease. Results There were no differences between the peak power or average power but the minimum power was clearly higher in the blue light condition (5.53 vs. 4.99W/kg; Effect Size: 0.49±0.59). As a result, the power decrease was lesser in the blue light condition (50.7 vs. 55.6%; Effect Size: 0.39±0.59). Conclusions It was apparent that the 60min exposure to blue LED lighting was capable of improving fatigue resistance exercise performance in a test of anaerobic power. While the mechanism is unclear, there is potential for short-wavelength light to manipulate athletic performance via direct visual input to the limbic and arousal system. Beaven, C. M., & Ekström, J. MATCHING OF OXYGEN DELIVERY AND UTILIZATION DURING INCREMENTAL CYCLING EXERCISE

STÖCKER, F., VON OLDERSHAUSEN, C., PATERNOSTER, F.K., SCHULZ, T., OBERHOFFER, R.

Technische Universität München

Introduction The ratio of relative changes in deoxygenated hemoglobin and oxygen uptake ($\Delta\text{HHb}/\Delta\text{VO}_2$) has recently been used as a marker for the dynamic balance of microvascular matching of oxygen delivery and utilization (DeLorey et al., 2004; Murias et al., 2010).

Low values therefore indicate a good matching of oxygen delivery and utilization. $\Delta\text{HHb}/\Delta\text{VO}_2$ showed to be primarily dependent on microvascular perfusion, which in turn is dependent on local vasodilation. The aim of this study was to examine the matching of oxygen delivery and utilization in relation to exercise intensity during incremental cycling exercise. Methods 20 men ($\text{VO}_2\text{peak } 50.3 \pm 5.7 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) participated in the study. The experimental session consisted of an incremental exercise test to exhaustion on a cycle ergometer (Lode Excalibur, Groningen, NL) starting with 60W and increasing intensity by 10 W every minute. Relative changes in HHb were measured noninvasively with a continuous wave near-infrared-spectroscopy (NIRS) device (portamon, Artinis, Zetten, NL), placed on the vastus lateralis muscle. VO_2 was measured using a metabolic cart (ZAN 6000USB; Nspire Health, Oberthulba, Germany). $\Delta\text{HHb}/\Delta\text{VO}_2$ ratio was calculated for the exercise intensities corresponding to 40%, 50%, 60%, 70%, 80% and 90% VO_2peak . A repeated-measures-design ANOVA was used to compare the effects of the various intensities on $\Delta\text{HHb}/\Delta\text{VO}_2$ ratio. Results ANOVA reported a significant main effect ($P = 0.004$). Post hoc tests showed a significantly rising $\Delta\text{HHb}/\Delta\text{VO}_2$ ratio from 40% to 60% VO_2peak ($P \leq 0.03$) while no further change could be observed above 60% VO_2peak . Discussion These results suggest that the matching of oxygen delivery and utilization gets impaired from 40% to 60% VO_2peak but remains stable thereafter. Apparently, local muscle perfusion counteracts the increased metabolic demand more effectively above 60% VO_2peak . References DeLorey DS, Kowalchuk JM, Paterson DH. HEART RATE RECOVERY AFTER A 60M SPRINT TEST IS FASTER WHEN V'VO2PEAK IS HIGH

STORNIOLI, J., MINETTI, A.E.

University of Milan

Introduction The quick recovery of many physiological parameters is an important determinant of cardiorespiratory fitness (Coote, 2009). Particularly, oxygen consumption kinetics at the start and after intense dynamic exercise have been well explored (Borresen & Lambert, 2008), often in relation with the maximum aerobic power (V'VO₂peak). Less attention has been given so far to heart rate (HR) kinetics after maximal effort. We here use a simple test, a short sprint running, suitable to check the relationship between a speed index of heart rate recovery, namely the time interval to reach 50% of the difference with the basal HR (toff-HRsprint, s) and V'VO₂peak in active and sedentary subjects. Methods Sixteen individuals subdivided in sedentary (SED, n=8; 26.3±8.0 years, 72.1±12.6 kg, 174.0±12.5 cm) and active (ACT, n=8; 25.4±3.5 years, 68.5±6.0 kg, 178.0±7.2 cm) undertook both a 60-m sprint test on firm terrain to obtain toff-HRsprint by sampling HR recovery in orthostatism and, after 10 min rest, an incremental cardiopulmonary test on a treadmill to determine the V'VO₂peak and V'VO₂ off kinetics (toff-V'VO₂, s) defined similarly as for HR. A Student's t test checked differences in SED and ACT groups among toff-HRsprint, toff-V'VO₂ and V'VO₂peak. A Pearson's product-moment test was used to assess correlation between variables. Results When compared to SED, ACT group presented significantly higher values for V'VO₂peak ($p<0.001$) and lowered for toff-HRsprint ($p=0.006$), whereas toff-V'VO₂ was similar in the two groups ($p=0.702$). When considered separately SED e ACT groups did not show significant pairwise correlations among toff-HRsprint, toff-V'VO₂ and V'VO₂peak. Differently, when pooling all subjects, toff-HRsprint and V'VO₂peak showed a significant correlation ($r=-0.64$, $p=0.008$). Discussion toff-V'VO₂ was similar between groups despite of different training levels, although toff-V'VO₂ depends on several factors, as mitochondrial density, oxidative enzyme activity and lactate removal, which are likely affected by training (Dupont et al., 2010). The toff-HRsprint and V'VO₂peak did show significant (negative) correlation only when all subjects data were pooled, indicating that HR variability needs a high sample size to reveal reliable relationships with V'VO₂peak. The present analysis of HR recovery has the potential to indirectly estimate individual V'VO₂peak. Further studies involving different sample sizes, heart rate off-kinetics at shorter maximal tests, as well as other groups of subjects, could check the stability of the obtained parameters and refine its applied physiological relevance. OP-PM44 Inflammation & Stress Response

INFLAMMATORY BALANCE OF CYTOKINES: RESPONSES TO EXERCISE IN MASTER ATHLETES

MINUZZI, L., ROSADO, F., RAMA, L., TEIXEIRA, A.

University of Coimbra

The kinetics of cytokine production may be changed by exhaustive exercise. Exercise stimulates moderate to large increases in circulating concentrations of interleukin (IL)-6, IL-8, IL-10, IL-1ra, G-CSF, and smaller increases in TNF- α , MCP-1, IL-1beta, BDNF, IL-12p35/p40 and IL-15 (Peake, 2015). Aging is often associated with low-grade systemic inflammation predisposing older individuals to an increased risk of chronic diseases. The aim of this study was to compare the cytokine production and the influence of aging in the pro and anti-inflammatory cytokine balance. Participants ($n = 38$) were divided into 3 groups: Young ($n = 8$), Old ($n = 10$) and Master athletes ($n = 20$). The young and old groups were not involved in any systematic exercise practice, while the inclusion criteria for the Master athletes was a minimum of 20 years in competitive sport. All subjects performed a maximal incremental test in a cycle ergometer. Blood samples were obtained before (PRE), 10 minutes into recovery (POST) and 1 hour after the test (1HR). VO_{2max} levels were similar for Master athletes and the Young group, both groups showing the highest values (absolute and relative) when compared to the Old group. Cytokine concentrations of IL1- α , IL-1beta and IL-8 were higher at all times for the Master group (compared to the Young and Old groups, $P < 0.05$). For the anti-inflammatory cytokine IL-10, the highest values were observed for the Young group at all times (compared to Masters and Old groups, $P < 0.05$) with the Old group showing the lowest values. The pro-inflammatory cytokines IL-1beta, IL-6 and IL-8 decreased during recovery (1HR), with reductions for all pro-inflammatory cytokines in the Masters ($P < 0.05$) and for IL-8 in the other groups ($P < 0.05$). Only the anti-inflammatory cytokines (IL-1- α and IL-10) increased following the exercise with post hoc tests showing statistically significant differences to the Old group. In the Young, IL-1beta and IL-8 increased ($P < 0.05$) immediately after exercise. In conclusion, long life training does not seem to have deleterious effects in the balance of pro- and anti-inflammatory cytokines with IL-10 levels very close to those found in the young adults.

THE EFFECTS OF HIGH INTENSITY TAEKWONDO TRAINING ON BLOOD TESTOSTERONE, CORTISOL AND LACTATE IN SOUTH AFRICAN MALE TAEKWONDO ATHLETES

DJAROVA, T.1, MATHUNJWA, M.L.2, MUGANDANI, S.2, KALINSKI, M.3

1,2: University of Zululand, 3: Murray State University (KY, USA)

Introduction Various training protocols have been used in combat sports including Taekwondo to improve the individual performance by balancing the exercise intensity and the athletes' metabolic tolerance and hormonal response (Melhim 2001, Pilz-Burstein et al 2010). Cortisol and testosterone are essential for muscle adaptation during exercise and training (Kraemer et al 2005). Post-exercise blood lactate is an indicator of the glycolysis rate induced by exercise (Obminski et al 2010). The aim of the study was to investigate the effects of high intensity intermittent Taekwondo training on blood testosterone, cortisol and lactate. Methods 14 male South African Taekwondo (TKD) athletes aged 20-26years, BMI=23.7±2.9 were subjected to 4 weeks of TKD training divided in two groups: experimental (n=7) performing high intensity intermittent (85-90% VO_{2max}) TKD training and control (n=7) performing interval TKD training of lower intensity (70-75% VO_{2max}). A structured Taekwondo tasks (sTT) test was conducted before and after the training period. Blood samples for measurements of cortisol, testosterone and lactate were taken at rest 30 min pre- and post-sTT test. Student paired t-test was used for statistical analysis. Results In the experimental group after 4 weeks of high intensity intermittent Taekwondo (HIITKD) training period, post-sTT test total testosterone was higher ($p<0.05$) by 21.7% compared to pre-sTT test values. No differences between groups were found in free testosterone, testosterone-binding globulin and cortisol. Post-sTT test cortisol/total testosterone (C/T) ratio decreased by 13.3% in the experimental group and increased by 18.5% in controls ($p<0.05$) after the training period. No differences were observed at the beginning of the training period. When comparing lactate changes in response to sTT test applied before and after the training period we observed that after 4 weeks lactate post-sTT levels were higher ($p<0.05$) by 46.2% in the experimental group and by 30.6% in the controls. **Discussion and Conclusion** Intermittent physical events may produce great strength and muscle power demands on both upper and lower body with high anaerobic energy demand (Passelergue & Lac, 2012) and simultaneously lead to changes in both anabolic and catabolic hormones (Pesce et al., 2015). The data of this study support the importance of testosterone cortisol interactions and lactate in evaluating the effectiveness of different protocols and training responses. Our findings based on higher post-sTT test total blood testosterone and decreased C/T ratio suggest that 4 weeks of HIITKD stimulated an anabolic type hormonal response in the experimental group. IMPACT OF A MOUNTAIN ULTRA-MARATHON ON CARDIAC BIOMARKERS

LE GOFF, C., GERGELÉ, L., KAUZ, J.F., CAVALIER, E., MILLET, G.Y.

University Hospital of Liège (CHU)

Objectives. While moderate exercise has beneficial effects on the cardiovascular system, consequences of a supra-physiological effort are not clear yet. In particular, the physiological consequences of ultramarathons need to be further documented. The aim of the study was to assess the changes of various cardiac biomarkers after a mountain ultra-marathon. **Material and methods.** Blood and urine samples were collected on 28 runners (17 men) participating to the Ultra-Trail du Mont Blanc (105 km, total positive elevation: 5600 m) at 3 different times: before the race (Pre), within 1 h after the finish (Post) and 7 days after the finish (D+7). Several biomarkers involved in heart disease (coronary syndrome, heart failure and fibrosis) and in inflammation were assayed on different analyzers such a COBAS® (for CKMB, TnThs, NT-proBNP, H-FABP and CRPs) and KRYPTOR® (for Copeptin). ST2 was measured manually with the Presage kit from CRITICAL DIAGNOSTIC®. **Results.** Plasma levels of cardiac markers (CKMB, TnThs, NT-proBNP, copeptin, H-FABP, ST2) and inflammation (CRPs) increased significantly at Post. Means values increased from Pre to Post as follows: 2.3 to 91.9 UI/L for CKMB ($p<0.0001$); 7.6 to 31.7 ng/L for TnThs ($p<0.0001$); 41.7 to 1190.5 ng/L for NT-proBNP, 4.2 to 22.9 pmol/L for copeptin ($p=0.001$); 3.6 to 107.8 ng/mL for H-FABP ($p<0.0001$), 29.7 to 126.2 ng/mL for ST2 ($p<0.0001$); 0.5 to 29.1 mg/L for CRPs ($p<0.0001$). With the exception of a few (H-FABP, ST2, CRPs) biomarkers in some subjects, all values were back to Pre values at D+7. **Discussion-conclusion.** Prolonged strenuous running exercise caused an elevation in cardiac biomarkers. Elevation in CK-MB levels lacks specificity for cardiac damage as runners have increased CK-MB from skeletal muscles as well. Previous studies suggested that exercise induced TnThs elevation is a benign reversible physiologic phenomenon but this parameter, as well as H-FABP, could be a sign of ischemia. Different phenomena occurred such as stretch of myocytes causing an increase in pressure or volume and neurohormonal activation which can explain the Copeptine and NT-proBNP increase, while ST2 is a biomarker of cardiac remodeling and fibrosis. CRP is an acute phase compound that tends to increase following a strenuous and prolonged bout of exercise and/or muscular injury. As the values tended to return within the normal reference range values within 7 days after the race, our study suggests that there is no permanent structural damage at the myocardium level.

HORMONAL AND ANTI-INFLAMMATORY EFFECTS OF GLUCOCORTICOID

COLLOMP, K.1,3, ZORGATI, H.1,2, COTTIN, F.1,2, DO, M.C.1,2, LABSY, Z.1,2, GAGEY, O.1,2, LASNE, F.3, PRIEUR, F.1,2, COLLOMP, R.4

Collégium Sciences et Techniques, Université Orléans

Introduction The aim of the study was to elucidate the time-course effects of short-term glucocorticoid administration on hormonal and inflammatory responses at rest and during exercise. The study focused on the sex (DHEA, DHEA-S, testosterone) and mineral (aldosterone) steroids, as well as on pro- and anti-inflammatory cytokines (IL-6, IL-10). **Methods** According to a double-blind and randomized protocol, blood samples were taken from 12 healthy recreationally-trained males after placebo or prednisone (GC, 60 mg/day/7days) ingestion, at rest and after resistance exercise. Each subject performed the trials four times on the 2nd (acute) and 7th (short-term) day of each treatment period, 3 hours after capsule ingestion. Enzyme-linked immunosorbent assays (ELISA) were used for the analyses. **Results** A significant decrease in DHEA, DHEA-S, without change in aldosterone or testosterone was demonstrated after acute GC intake. A significant increment in IL-10 and a significant decrement in IL-6 were also observed with GC both at rest and during exercise. Continued GC treatment led to another significant decrease in both DHEA and DHEA-S, whereas no change in the inflammatory markers was observed between days 2 and 7. **Discussion** Hypothalamic-pituitary axis is altered after short-term systemic GC intake through negative feedback, with marked decreases in cortisol and ACTH and works were extended to define the time required for return to the pretreatment hormone values after this therapy (Carella et al., 1993; Streck et al., 1979). However, to our knowledge, only one study examined the onset and time-course of hormonal response during short-term GC intake, and the study was limited to resting saliva cortisol and DHEA

investigation (Jollin et al., 2010). Our data demonstrate that the anti-inflammatory effects of GC were maximal and stable from the beginning of treatment, both in rest and exercise conditions. However, hormonal concentrations continued to decline during short-term intake. Further studies are needed to determine the effects of hormonal time-course alterations with longer GC treatment and the clinical consequences. INCREASING HEAT STORAGE DURING UPPER BODY EXERCISE UPREGULATES HEAT SHOCK PROTEIN 70 BUT DOES NOT MODIFY THE INFLAMMATORY RESPONSE

LEICHT, C.A., PAPANAGOPOLOUS, A., HAGHIGHAT, S., FAULKNER, S.H.

Loughborough University

Introduction: Heat shock protein (HSP) concentrations rise during heat stress (Whitham et al., 2007), and HSP can independently induce the production of cytokines (Wallin et al., 2002). Upper body exercise normally results in very modest body temperature elevations. The aim of this study was to investigate the impacts of additional clothing on the temperature, cytokine and HSP responses during this exercise modality. **Methods:** Thirteen moderately trained male individuals performed 45-min constant load arm cranking at 63% of their maximum aerobic power ($62\pm7\%$ VO_{2peak}). Exercise was performed in either a non-breathable whole body suit (intervention, INT) or shorts and T-shirt (control, CON). Core (T_c) and skin (T_s) temperatures and subjective feeling (indicated from -5, very bad, to +5, very good) were monitored during exercise, and venous blood was collected pre, post and 2h post exercise. **Results:** Exercise resulted in a significant increase of IL-6 and IL-1 α plasma concentrations ($P<0.001$), with no difference between conditions ($P>0.19$). The increase in HSP70 from pre to post was only significant for INT ($0.12\pm0.11\text{ng/mL}$, $P<0.01$; vs $0.04\pm0.18\text{ng/mL}$, $P=0.77$). Exercise significantly elevated T_c by 0.46 ± 0.29 (INT) and $0.37\pm0.23^\circ\text{C}$ (CON), respectively ($P<0.01$), with no difference between conditions ($P=0.16$). The rise in mean T_s (2.88 ± 0.50 and $0.30\pm0.89^\circ\text{C}$, respectively) and maximum heat storage (3.24 ± 1.08 and $1.20\pm1.04\text{J/g}$, respectively) were significantly higher during INT ($P<0.01$). Participants' feeling during INT was worse (-4.0 ± 1.2) when compared with CON (1.3 ± 1.9 , $P<0.01$). **Discussion:** Despite large differences in heat storage between conditions, the elevations in HSP70 during INT, even though significant, were very modest. Possibly, the T_c elevations were too low to induce a more pronounced HSP response that could ultimately affect cytokine production, as passive elevation of T_c of $\sim2^\circ\text{C}$ has the potential to increase cytokine plasma concentrations (Leicht et al., 2015). Alternative methods to elevate T_c during exercise should be explored, as further increasing heat stress using additional clothing may be perceived as too uncomfortable to be of practical value. TIME-DEPENDENT EXPRESSION OF IL-6, IRISIN AND BDNF IN RESPONSE TO EXERCISE IN RATS

YU, T.

China Institute of Sport Science

Time-dependent expression of IL-6, Irisin and BDNF in response to exercise in rats Introduction Irisin, BDNF and IL-6 are exercise-induced myokines which exert their effects in driving brown-fat-like development (Irisin) and regulating fat oxidation (BDNF and IL-6) (Bostrom et al. 2012; Pedersen et al. 2012). However, their dynamic expression in response to exercise is not fully known. Here we examined the level of Irisin, BDNF and IL-6 as well as the activation of AMPK and AKT at different time points following exercise, in order to explore the pattern of their expression and biological functions. **Methods** Sprague-dawley rats were subjected to downhill running at 17m/min for 90 minutes. Serum creatine kinase activity was tested at day 1, 3, 5, 7, and 14 following exercise to evaluate skeletal muscle injury. The serum level and skeletal expression of BDNF, IL-6 and Irisin were measured by ELISA and real-time RT-PCR, respectively. The activation of AMPK and AKT signaling pathway was confirmed by Western Blot. To compare the difference between two groups, t-test was employed using SPSS software and $p < 0.05$ was considered statistically significant. **Results** An increase of CK activity was observed at day 3 and day 5 following exercise, confirming exercise-related skeletal muscle injury. We didn't find any increase of IL-6 in the rats following exercise compared to sedentary group, although it is reported that IL-6 level is elevated dramatically during exercise. The level of Irisin and BDNF was increased both in the serum and in the skeletal muscle in day 1 and day 3 following downhill running; then, while Irisin level returned to the baseline, serum BDNF level was continuously elevated. Besides, AMPK activation was found at day 1 and day 3, but AKT was kept activated over all the time points. **Discussion** Although IL-6, Irisin and BDNF are all exercise-induced myokines, their expression is regulated differently. Irisin and BDNF are both reported to be involved in the activation of AMPK signaling pathway. However, we found that the increase of Irisin was in accordance with AMPK activation, while BDNF increase is in accordance with AKT activation. Our results suggest that BDNF may participate in skeletal muscle regeneration via AKT-mediated pathway in addition to fat oxidation. Therefore, exercise-induced myokines are regulated precisely and sequentially, which in turn exert different functions at different time following exercise. References Bostrom, P., et al. (2012). OP-PM35 Concurrent Training

QUANTIFYING ENERGY SYSTEM CAPACITY CHANGES IN CYCLING FROM 7 DAYS ISCHEMIC LEG PRECONDITIONING

PETERSEN, C.1, LINDSAY, A.1, BLACKWELL, G.1, FERGUSON, H.2

1. University of Canterbury, 2. Auckland University of Technology

Introduction A single session of ischemic preconditioning has been shown to acutely improve exercise performance in several sports including swimming (Jean-St-Michel et al., 2011), cycling (de Groot et al., 2010) and running (Bailey et al., 2012) but not repeated sprint ability (Gibson et al., 2015). Interestingly, the immediate and retained benefits of continued ischemic preconditioning as a training tool remain un-investigated. Therefore, the aim of this study was to quantify changes in capacity of both the aerobic and anaerobic energy systems from using ischemic leg preconditioning over seven consecutive days. **Methods** We conducted a randomized, controlled, single-blinded experiment with 18 recreationally active adults (23.2 ± 7.1 years; Relative VO_{2max} 38.6 ± 5.9 ml.kg⁻¹.min⁻¹). The intervention consisted of a 220 mmHg with 4 x 5-min ischemia and 4 x 5-min reperfusion per leg, conducted once a day for 7 consecutive days (days 3 – 9). The control condition used the same protocol with 20 mmHg. Cycling VO_{2max} (day 1, 11, 18) and 30-s Wingate tests (day 2 and 10) were performed pre and post intervention. Results Ischemic preconditioning had a large ($p<0.01$, $d=0.91$) effect on increasing maximal aerobic capacity by 9.5% immediately post intervention, and increased further to 12.8% seven days post (39.1 ± 5.4 to 42.8 ± 5.7 to 44.1 ± 6.2 ml.kg⁻¹.min⁻¹). There was a moderate ($p<0.01$, $d=0.46$) effect on increasing maximal aerobic power by 18.5% immediately post intervention which dropped slightly to 16.1% seven days post (268.9 ± 92.7 to 318.6 ± 121.3 to 312.2 ± 125.5 W). There was no aerobic improvement in the control group ($p>0.05$), and no improvement was evident in either group for anaerobic fitness measures ($p>0.05$). No significant differences were found at any time point in fatigue or lactate measurements between groups. **Discussion** Seven days ischemic preconditioning resulted in substantially improved aerobic but not anaerobic measures, at least with recreationally active adults. The absence of differences in lactate and fatigue measures indicates energy system differences were unlikely from increased neural drive or enhanced muscle recruitment which has previously been suggested (Bailey et al., 2012). Further mechanistic investigations are recommended as well as determining the effectiveness of the intervention for more highly trained populations. **References** Bailey T, Jones H, Gregson W, Atkinson G, Cable N, Thijssen D. RE WARM-UP PRIOR TO FOOTBALL MATCHES: IS IT BENEFICIAL FOR PHYSICAL PERFORMANCE?

ABADE, E., GONÇALVES, B., BAPTISTA, J., SAMPAIO, J., ALVES, A., VIANA, J.

University Institute of Maia

Introduction Warm-up (WU) routines are widely explored and commonly accepted for optimizing performance and preventing injury. However, official international pre-match protocols may require players to passively rest for approximately 15 minutes in the time-course between WU and the beginning of the match. Therefore, the aim of this study was to assess the contribution of different re-warm-up (re-WU) strategies on the physical performance of football players. **Methods** Twenty-two Portuguese elite under-19 football players participated in the study conducted during the competitive season. 4 protocols (WU + re-WU) were tested in 4 consecutive days. The protocols differed only in the re-WU strategy applied after the standardized WU: without re-WU (CON), eccentric re-WU (ECC), plyometric re-WU (PLY) and repeated changes of direction re-WU (RCOD). Vertical jump (counter movement, CMJ; and abalakov, AJ) and Sprint capacity (10-m and 20-m) were tested immediately after WU and 12 minutes after WU. The re-WU strategies were performed 6 minutes after WU. Magnitude-based inferences and precision of estimation were employed in data analysis. **Results** Both CMJ and AJ performances presented a likely/very likely improvement after PLY intervention (~3.8% in CMJ and ~4.8% in AJ) when compared to CON. PLY also showed a moderate very likely beneficial effect in 10-m (Cohen d, $\pm 90\%$ CL, -0.7 , ± 0.3) and a moderate most likely beneficial effect in 20-m ($ES=-0.9$, ± 0.3) performances. The RCOD presented a likely/possible beneficial effect to CMJ and AJ, and a moderate likely/most likely beneficial effect to 10-m and 20-m sprint performances. Different practical implications may be taken from the ECC since there was a $-5.1 \pm 5.6\%$ decrease in CMJ height from post-WU to re-WU which suggests a possible harmful effect when compared to CON. **Discussion** The absence of re-WU activities in the time-course between the WU and the beginning of the match may be detrimental to players' physical performance. However, the inclusion of re-WU exercises prior to match is a very delicate issue, since the manipulation of volume, intensity and recovery may positively or negatively affect the subsequent performance (Robbins, 2005). In fact, our research shows that eccentric exercise prior a football match may be harmful for physical performance. However, plyometric and repeated changes of direction exercises seem to be efficient active strategies to attenuate losses in vertical jump and sprint capacity after WU. **References** Robbins, D. W. (2005). J Strength Cond Res, 19(2), 453-458. Contact eabade@ismai.pt

EFFECTS OF COMBINED STRENGTH AND AEROBIC TRAINING ON MIDDLE AND LONG-DISTANCE PERFORMANCE: A META-ANALYSIS

BERRYMAN, N.1,2, MUJICA, I.3, BINET, C.2,4, ROUBEIX, M.2,4, BOSQUET, L.4

Bishop's University

1. Sports Studies Department, Bishop's University, Canada **2.** Institut national du sport du Québec, Canada **3.** Department of Physiology, Faculty of Medicine and Odontology, University of the Basque Country, Basque Country **4.** Faculty of sports sciences, University of Poitiers, France **INTRODUCTION:** Combined strength and aerobic training is an appropriate strategy to decrease the energy cost of locomotion (ECL), improve aerobic endurance (AE) and may enhance performance in middle and long distance events (1, 2). The aim of this study was to assess the effects of strength training on middle and long-distance performance through a meta-analysis of the available literature. **METHODS:** Articles were included in this meta-analysis if they met these criteria: 1) combined strength and aerobic training; 2) performance outcomes (official or simulated competition, maximal oxygen uptake - VO_{2max}, ECL or AE) related to middle and long-distance events in cross country skiing, running, triathlon, swimming, cycling, rowing and biathlon; 3) details about the training load; 4) sufficient

information to calculate effect size. Thirty-seven articles were included. Statistical analyses were presented in detail in a previous article from members of our laboratory (3). RESULTS: Combined strength and aerobic training provides a moderate beneficial effect on middle and long-distance performance ($SMD [95\% CI] = 0.61 [0.43 \text{ to } 0.79]$, $P < 0.01$). Combined training with a focus on maximal strength ($0.26 [0.10 \text{ to } 0.42]$, $P < 0.01$) or sub-maximal strength ($0.57 [0.10 \text{ to } 1.03]$, $P < 0.01$) had beneficial effects on $VO_{2\max}$. AE was also improved after implementation of sub-maximal strength training ($2.8 [1.85 \text{ to } 3.77]$, $P < 0.01$). Moreover, it was shown that ECL was significantly decreased ($-0.75 [0.45 \text{ to } 1.04]$, $P < 0.01$). A meta-regression analysis revealed that changes in middle and long-distance performance were associated with changes in $VO_{2\max}$ (slope: 0.52 , $P < 0.05$), AE (slope: 0.50 , $P < 0.01$) and ECL (slope: $= 0.58$, $P < 0.01$). DISCUSSION: These results provide a framework that support the implementation of strength training in addition to normal aerobic training to improve middle and long-distance performance and associated aerobic characteristics. OP-PM39 Bone Health

IMPACT BETWEEN MEDICATION USAGE, PHYSICAL ACTIVITY, NUTRITIONAL STATUS AND OSTEOMUSCULAR HEALTH IN MALE AND FEMALE ADULTS AGED 40-65 YEARS IN KOSOVA

KRASNIQI, E., KONI, M., BOSHNJAKU, A.

Medical University of Tirana

Introduction: This observational, cross-sectional study investigates the general health condition, drug consumption and the possible effects of certain medications in osteo-muscular systems amongst males and females aged 40-65, in the population of a developing, low income country such as Kosova. Many studies have been performed worldwide regarding the possible side effects of medications in our body, but very few published studies were carried out in Kosova. **Methodology:** Bone Mineral Density (BMD) and T-score at distal forearm regions (with DEXA scan), together with the isometric strength (Handgrip) were evaluated in a total of 162 subjects, out of which 53 Males (average age 55.15 ± 7.12) and 109 Females (54.27 ± 5.1). Additionally, a group of 4 questionnaires regarding general health, Brief Medication Questionnaire 1 (BMQ1), self-administered Nutritional Standard Questionnaire (NSQ) and International Physical Activity Questionnaire (IPAQ) were filled. **Results:** Significant differences were found in Body Mass Index (BMI), Physical Activity (PA), BMD and T-score between genders. When comparing the total subject's BMD and T-score based on the PA levels (1, 2, 3), significant differences were found between subject groups PA1 and PA3 as well as PA2 and PA3, but not between PA1 and PA2. This situation accounted also in both genders. Similar results were encountered when comparing the total subject's Handgrip isometric strength with significant differences between PA1 and PA3, but not between PA1 and PA2, PA2 and PA3. One difference though was encountered in females between PA2 and PA3 ($p < 0.05$) which was not the case when comparing in total subjects. When evaluating the possible effect of specific medication on BMD, T-score, and Handgrip, no differences were observed in N05B, C07A and M01A. No differences were observed in total subjects in the group A02BC as well, whereas significant differences between female consumers and non-consumers were found in all the variables. Meanwhile, significant differences were observed in H02AB and M05BA in all the variables, while in N02BE significant differences were observed in BMD and T-score, but not on handgrip. This study showed the 42% of total participants were diagnosed with Osteopenia, out of which 6.8% are on the verge of getting Osteoporosis (with T-score below -2). No one was diagnosed with Osteoporosis. **Conclusion:** This study describes the occurrence of age related conditions such as Osteoporosis and Osteopenia, prevalence of medication usage and their possible side effects in osteo-muscular system of mature adults in a developing, post conflict country such as Kosova. In addition to that, important data regarding the general health, nutritional status and physical activity levels amongst the studied population were given. To our knowledge, this is one of the few studies where the effects of the above mentioned medication groups were compared and evaluated in the bone and muscular health within a study population.

COMBINED RESISTANCE AND SPRINT TRAINING HAS A POSITIVE AFFECT ON BONE MINERAL CONTENT IN VETERAN ENDURANCE CYCLISTS

REABURN, P., MACGREGOR, C., DELVECCHIO, L., MEERKIN, J., KORHONEN, M.

Central Queensland University

Introduction The importance of regular exercise on bone health during aging is widely acknowledged (Gomez-Cabello, et al., 2012). However, these effects appear dependent on the mode, intensity and duration of exercise training (Nichols et al., 2011). Previous research has shown that high-impact and resistance training exercises increases bone mineral content (BMC) in older athletes (Nowak et al, 2010). In contrast, long duration non-weight bearing aerobic exercise such as cycling and swimming may lead to decreases in BMC in aging athletes (Velez et al, 2008). Thus, for endurance-trained cyclists, high intensity resistance exercises may be important to reduce age-related declines in BMC. The purpose of the present study was to examine the effects of 12-weeks of combined high-intensity resistance and sprint cycle training (HIRST) and high-intensity sprint cycle training (ST) on BMC in veteran endurance cyclists. **Methods** Twenty seven male veteran endurance cyclists (55.0 ± 8.3 yr) were divided into three age-matched groups - controls ($n=10$) who maintained normal endurance training (~ 8 hours per week) and two intervention groups (ST: $n=7$; HIRST: $n=10$). Sprint group. ST replaced four of their usual weekly endurance cycling training sessions with four group track sprint cycling training sessions designed in consultation with an accredited track cycling coach. Post warm-up, subjects performed 1-3 sets x 1-3 repetitions of maximal effort sprints (65-330 m). Sprint and mixed-methods resistance group. HIRST replaced four of their usual weekly endurance cycling training sessions with two group track sprint cycling training sessions similar to the ST group and two group gym-based mixed-methods resistance training sessions per week. Progressive overload was applied by completing 3 sets of every exercise but manipulating the number of repetitions (4-12) and resistance ($>70\% 1\text{ RM}$). The overall training adherence rate, with no statistical differences between groups, was $87 \pm 4\%$. Pre- and post-training, subjects undertook Hologic 'Discovery W' dual-energy X-ray absorptiometry whole body scans analyzed using APEX 4.0 software. **Results** There were no differences in baseline BMC between groups. A paired-sample t-test revealed an increase in BMC following 12-weeks of

HIRST (2850 ± 31.9 g vs 2907 ± 32.4 g) ($t(9)=-3.94$, $p=0.004$). No significant changes were observed in the control or ST groups. Discussion The results suggest that 12-weeks of HIRST can increase BMC in veteran endurance cyclists. It appears that in veteran athletes aging bone remains dynamic and that HIRST needs to be included in veteran endurance cyclist training programs to maintain BMC into older age. A COMPARISON OF BONE MINERAL DENSITY IN MALE AMATEUR BOXERS AND ACTIVE NON-BOXERS

SKINNER, T.L.1, BOLAM, K.A.1,2, SAX, A.T.1, ADLARD, K.N.1, TAAFFE, D.R.1,3,4

1: UQ (Brisbane, Australia), 2: GIH (Stockholm, Sweden), 3: School of Medicine, UOW (Wollongong, Australia), 4: ECU (Joondalup, Australia)

Introduction As a health promotion strategy, boxing training, which can be undertaken as a general fitness activity, presents itself as a potentially attractive method of upper limb impact-loading exercise. However, the influence of boxing on upper limb bone mineral density has yet to be explored. The aim of this study was to compare the forearm and arm bone mineral density of male boxers to that of active age-matched non-boxing controls. **Methods** A cross-sectional study was performed with 30 amateur male boxers (aged 18-44 years, 6 ± 4 years boxing experience, 4 ± 2 boxing sessions per week) and 32 age-matched, non-boxing, active controls. Participants had their regional and whole body bone mineral density assessed by dual-energy x-ray absorptiometry. Isometric hand grip strength, testosterone, oestradiol, sex hormone-binding globulin, vitamin D, lean and fat mass, and past and current physical activity were also assessed. **Results** Forearm and arm bone mineral density were 1.5-2.2% higher in boxers than the control group, although this was not statistically significant ($p=0.29-0.48$). There were no differences between groups for spine, hip, or whole body bone mineral density (-1.3-0.6%), or for body composition or hormone status (all $p>0.05$). Within the arms, lean mass was associated with bone mineral density in both boxers and the control group ($r=0.60-0.76$, $p<0.001$). **Discussion** There were no significant differences between amateur boxers and the control group for upper limb bone mineral density. Muscle mass appears to be particularly important to bone health of the upper limbs. Repeated impacts from boxing do not provide an osteogenic benefit to the upper extremities above and beyond general resistance training. Contact t.skinner@uq.edu.au

NO ASSOCIATION BETWEEN VITAMIN D STATUS AND MARKERS OF BONE HEALTH IN NON-WEIGHT BEARING ATHLETES

ALLISON, R., FAROOQ, A., HAMILTON, B., CLOSE, G.L., WILSON, M.G.

Aspetar-Orthopaedic & Sports Medicine Hospital

Introduction: To examine the relationship between serum 25(OH)D levels and markers of bone health, bone mineral density (BMD) & T score in a non-weight bearing, Arabic athletic population. **Methods:** One hundred and two male athletes registered with the Qatar Olympic Committee (QOC) originating from the Gulf Cooperation Council ($n=93$) and the Middle Eastern ($n=9$), presented for pre-competition medical assessment in Aspetar. All athletes participated in non-load bearing sports (archery, billiards, bowling, cycling, diving, equestrian, racing, rowing, sailing, shooting, snooker, swimming and water polo). All undertook bone densitometry, body composition analysis by Dual-energy X-ray absorptiometry (DXA) and serum 25(OH)D evaluation. **Results:** From 102 athletes, 29.4% ($n=30$) demonstrated severe deficiency, 40.2% ($n=41$) deficiency, 23.57% ($n=24$) insufficiency and 6.8% ($n=7$) sufficiency. No difference in serum 25(OH)D was observed between athletes with clinically normal T-scores ($n=76$) and those presenting with osteopenia (-1 to -2.5 SD) ($n=20$) or osteoporosis (-2.5 SD) ($n=6$) in any locations (neck, hip, spine or total). Cyclists had higher serum 25(OH)D compared to equestrian, and other indoor athletes ($P<0.006$). No significant associations were observed between anthropometric measures and serum 25(OH)D, age, BMI, body fat %, calcium, PTH and skin exposure across sporting types. Mean body mass was lower ($p<0.05$) in athletes with a T-score suggestive of osteopenia or osteoporosis. **Conclusion:** No association was observed between serum 25(OH)D levels and markers of bone health in non-weight bearing athletes. Lower body weight was associated with osteopenia or osteoporosis regardless of serum 25(OH)D level. These findings support that maintaining normocalcemia has priority over skeletal integrity.

PREVALENCE OF LOW RESTING METABOLIC RATE AND ASSOCIATED HEALTH CONSEQUENCES AMONG WELL-TRAINED MALE NORWEGIAN ENDURANCE ATHLETES

STENQVIST, T., MELIN, A., SYLTA, Ø., HJELMBREKKE, I., BORGEN, S., TORSTVEIT, M.K.

University of Agder, Kristiansand, Norway

Introduction Female athletes in leanness sports are reported to have high prevalence of reduced energy intake (EI), associated with low resting metabolic rate (RMR), reproductive dysfunction, and other severe physiological consequences such as low bone mineral density (BMD) (Nattiv et al., 2007). However, these associations are not well investigated in male athletes. Therefore, the aim of this study was to investigate the prevalence of low RMR and associated health consequences in male endurance athletes. **Methods** Forty-one well-trained cyclists ($n=21$) and long-distance runners ($n=20$) (age: 37.0 (28.5-44.5) yrs, body mass index (BMI): 23.3 (21.3-24.2) kg/m², body fat: 9.4 (6.5-11.4) %, training volume: 12.0 (8.3-18.3) h/week) presented as median and interquartile range (25-75%) were included, and divided in two subgroups according to RMR-ratio (predicted RMR/measured RMR); low (<0.85) and high (≥ 0.85). Protocols included assessment of body composition, RMR, EI and energy expenditure (4 days), hormonal- and metabolic biomarkers, and blood lipids. **Results** Nine subjects (22%) had low BMD (Z-score <-1) in either hip ($n=2$) or L1-L4 ($n=7$), seven (14%) had high levels of cortisol, nine (22%) had hypercholesterolemia, and 19 (46%) had low RMR-ratio. EI correlated well with RMR-ratio ($r=0.77$; $p<0.001$). EI as well as triiodothyronine (T3) and insulin were significantly lower ($p<0.05$), while hip BMD was significantly higher ($p<0.05$) in the low compared to the high RMR-group. **Discussion** We found a high prevalence of low BMD in this group of well-trained male endurance athletes, although not linked to low RMR-ratio or EI as earlier findings have hypothesized (Barry & Kohrt, 2008). EI correlated well with RMR-ratio, and low RMR-ratio was associated with lower levels of T3 and insulin. Furthermore, hypercholesterolemia and high levels of cortisol was common in this group of male athletes as earlier reported in female endurance athletes with energy deficiency (Melin et al., 2015) but none of these findings were linked to low RMR-ratio. OP-PM72 Coaching: Soccer

PASSING AND SHOOTING IN FOOTBALL: PLAYING WITH THE BALL... AND THE OTHERS

VICENTE, A.1,3, LOPES, H.2,3, FERNANDO, C.2,3

1.University of Beira Interior, 2.University of Madeira, 3.CIDESD

INTRODUCTION Winning in football is about scoring more goals than the opponent. To do so, players must master a set technologies that, together with other technical, tactical, psychological and physiological (among others) factors will allow them to be successful. Although it is common to believe that in football the key is to play with the ball, master the ball at high speeds and in small spaces, studies that we have been developing in recent years on isolated situations (e.g. Vicente et al. 2015) showed that there is time relations with the opponents that players must not ignore to succeed. The aim of this study was to verify whether a correlation exists between the velocity of the stimulus in passing and shooting situations in football and the attacking and defending player's responses. **METHODS** We've used a software (MeSiR2.2) designed to measure the relation between the velocity of the stimulus and the time to respond it. Four tests were used: Test 1 had a goalkeeper that moved from the center of the goal to each side (left or right) at different velocities (1 and 3 m/s) randomly; Test 2 had a striker that kicked a ball from the penalty kick spot to each side of the goal (left or right) at different ball velocities (± 40 km/h and ± 90 km/h) randomly; Test 3 consisted on a defender that moved 3 meters in a real football field to each side (left or right) at different velocities (5 and 1 m/s) randomly; Test 4 consisted on a player with a ball that kicked it to the left or right at different ball velocities (± 10 km/h and ± 50 km/h) randomly. 40 university football players and 25 semi-professional footballers had to perform each test for 20 trials and respond to each situation by moving their body towards the ball side (tests 2 and 4) or shooting a ball in the opposite direction to the movement of the player (tests 1 and 3). **RESULTS** From the 5200 trials performed from the 4 tests, results showed that players took the right decision in 83% of the situations. Data also showed that for the fastest stimulus in tests 2 and 4 the average response time was also higher (test 2=378ms / test 4=399ms) than the slowest stimulus situations (test 2=427ms / test 4=473ms). The same trend was obtained on tests 1 and 3. Participants tended to kick the ball at lower speeds in response to slower opponents movements (73% in test 1 and 68% in test 3) than in higher opponents movements. **DISCUSSION** Data showed that the stimulus velocity tend to influenced the response and the time to respond. As the stimulus was faster or slower the response was also faster or slower. The results tend to corroborate previous studies and other ecological studies we're still performing. This suggest that in passing and shooting situations in football, where players are permanently exchanging stimulus with opponents and teammates, players must be prepared to relate with the opponents and teammates being aware that they can influence their actions and response times to take advantage and increase success chances. **REFERENCES** Vicente A., Fernando C., Lopes H. (2015). 20th ECSS, Malmo.

AN ANALYSIS OF THE COMMUNICATION SKILLS OF COACHES ACCORDING TO THE PERCEPTION OF ATHLETES WHO PARTICIPATED IN INTERCOLLEGIATE FOOTBALL COMPETITION

SUNAY, H.1, CENGIZ, R.2, YASAR, O.M.1

Ankara University

Introduction Football clubs are a part of system of communication and interaction. The qualification of the athletes are parallel with the trainers qualification. According to this fact, it is very important that trainers to improve their communication skills which are basics of learning and teaching process. The purpose of the study is determined to communication skills of trainers according to athletes perspective who have participated intercollegiate football tournament. **Methods** The sampling of the study is made of 117 football players who are attended to intercollegiate football tournament during 30 April-4 May 2013. In investigation random sampling method was used. During the study basic personal information form was utilized. In addition to this Trainer communication skill survey' which was developed by Yilmaz (2008). The Levene test was used to figure out normalization of data. During the analyze of data independent T test and one way Anova test were used besides descriptive statistical techniques. SPSS 16.0 statistic program were used to analyze to data. **Results** According to study there were no significant differences between trainers communication skills and training age, position on field, educational department of football players. However, football players thoughts towards trainers communication skills are that their skills are effective but need improvement. **Discussion** In the study of Yilmaz, et.al. which was researched on 739 athletes showed that individual sport trainers have more effective communication skills than team sports trainers. But also team sports trainers have sufficient communication skills however they need to work on their communication skills. Bayrak and Nacar studied on 209 athletes and they investigated trainers communication skills and results were that trainers mostly have adequately communication skills. According to Chih-Ming Yu (2016) in the organizations which have positive organizational climate, effects the communication skills of trainers. In contrary trainers should spend more time to develop on their communications skills. SOCcer PLAYERS AND COACHES' PERSPECTIVES TOWARDS ERGOGENIC AIDS AND SUPPLEMENT USE IN THE ETHEKWINI REGION

KISTEN, T., NAIDOO, R.

University of Kwa-Zulu Natal

Introduction: Doping is regarded as a form of cheating where athletes use substances that are on the prohibited list, predominantly for gaining an edge over their competitors. Where sports participation was previously seen as recreational activity, it is now an intense environment for the adolescent athlete, placing high demands for performance in order to get drafted into professional sports. There is increased pressure on athletes to perform. This leads to increase use of performance enhancing substances and supplements to achieve increased performance levels and cope with the heavy demands that are placed on the player. **Aim:** The aim of this study was to determine the perspectives of U-19 soccer players and their coaches towards the use of ergogenic aids and supplements in the

eThekini region, KwaZulu-Natal. Methodology: The study was a mixed-methods design. Both quantitative and qualitative designs were employed. The sample comprised of participants playing first team U-19 soccer from clubs in the eThekini region and their respective coaches. A questionnaire was administered to players to assess the knowledge, attitudes and practices towards doping in sport, to determine their source of information and to determine which supplement was most frequently used. An interview was conducted with the coaches to assess his/her knowledge, attitude and beliefs about supplementation, and where do they get their information from about supplements. Both descriptive and inferential statistics were employed to analyse and report the data. Results: The U-19 soccer players and coaches believed that consuming prohibited substances in sport is unethical. Majority of the U-19 soccer players (73.9% either agreed or strongly agree) and coaches believed that doping in soccer is on the increase. Almost a quarter (24.7%) of the U-19 soccer players consumed performance enhancing substances (PES), cannabis, alcohol and/or smoke. Coaches believed that there players do not consume PES or substances. Majority (84.4%) of the U-19 soccer players and majority of coaches stated that educational programmes are needed. Conclusion: The U-19 soccer players and coaches believe that doping is prevalent in soccer. Players and coaches believe that sport organisations need to implement more educational programmes about doping and on how to consume PES.

HIGH POTENTIAL IN BALL SPORTS FROM THE PERSPECTIVE OF ELITE PLAYERS AND THEIR YOUTH TRAINERS: A QUALITATIVE STUDY

FABER, I.R.1, BUSTIN, P.M.J.1, HEUVEL, VAN DEN S.C.G.H.1, OOSTERVELD, F.G.J.1, ELFINK-GEMSER, M.T.2, NIJHUIS-VAN DER SANDEN, M.W.G.3

1: Saxion, The Netherlands; 2: University Medical Centre Groningen, The Netherlands; 3: Radboud University Medical Centre, The Netherlands

Introduction Many sports associations use talent development programs for identifying young high potential players and to support children aiming to become elite players. Selection criteria to participate in such programs are often based on performance results, coach's judgments, physical appearance, perceptuo-motor tests for speed, agility and coordination, motivation, self-efficacy and parental support. However, identifying young children with the potential to become a world class player is a challenge, since the key factors for future success remain ambiguous. This qualitative study attempts to get a grip on what is meant by 'high potential' in elite ball sports from the perspectives of world-class players and the trainers of their formative years. **Methods** Semi-structured interviews were conducted in elite players (n=14; football, basketball, beach-volleyball, tennis, table tennis, squash, waterpolo, field-hockey) and their trainers (n=14) to unravel the multi-dimensional concept of 'high potential'. After transcribing the interviews, open and axial coding was carried out by three independent coders using an inductive approach. Consecutively, all authors were involved in the peer debriefing process. Datasaturation was established. **Results** The coded fragments of all interviews were reduced to seven interrelated themes describing the perspectives of the elite players and trainers with regard to high potential: 'early exposure', 'deliberate play', 'fit to the sport', 'learn fast', 'taking the next step', 'constant competition' and 'reaching the top of the world'. Each theme shows that high potential of a player can only be described in terms of the triptych: the player, the task (sport) and the environment. **Discussion** The results of this study are consistent with the ecological-dynamic approach (Newell , 1986). Based on the results is 'change over time' was added as an extra dimension to the model (Elferink-Gemser & Visscher, 2012). In addition, the results give direction to future studies that focus on the measurement of potential in young players within the framework of talent identification and development.

OP-SH14 Physical Education, Health & Students Perspectives

TEACHING HEALTH FOR UNDERSTANDING: A CASE STUDY OF STUDENTS' REASONING ABOUT AEROBIC FITNESS AND HEALTH

LUNDVALL, S.

GIH, Swedish School of Sport and Health Sc.

Introduction The interfaces between health, physical education and schooling have a long history. At present, critical questions are being raised about the enforcement of a particular health in school physical education, in Sweden called physical education and health (PEH). The starting point of this article is a case study from a practice based research project. The case study aimed to explore within the context of a period of lab work how upper secondary school students reason about aerobic fitness and how this influences their health. The pedagogical model was based on health literacy as a framework for learning outcomes. **Method and Results** A phenomenographic approach has been used when analyzing the student reports in order to identify and distinguish students' ways of reasoning about and understanding the learning object in focus. Three categories of reasoning emerged: (i) students only repeating basic facts, (ii) students integrating knowledge with a simple way of reasoning about/assessing their own outcomes, and (iii) students reasoning about aerobic fitness and health relating to changing conditions and context. When distinguishing pupils' ways of reasoning, the focus of almost all reports was on measurable results and expectations of improved fitness results. Only a few reports revealed an ability to transform understanding and experiences of what influences health into a process of coherence and relationships. **Discussion** The performance expectations created tensions, and even conflicts, between what the student assignments aimed to achieve and physical education traditions. The existing different ontological paradigms in physical education were difficult for the students to use. The findings also indicate the absence of other dimensions of health related to a moving body. From this follows that steering documents and physical education teachers have to consider what different perspectives on health that PEH should, could or ought to provide. Future studies are needed to increase knowledge of how to move away from 'teaching to be healthy' in PEH towards different ways of how students 'do health and make sense of themselves as healthy'. This may offer new educational perspectives on (physical) health.

ADOLESCENTS PARTICIPATING IN PHYSICAL EDUCATION FOCUSING ON PLAY AND HEALTH, OR SPORTS; WHO IS MOST ACTIVE?

BERNTSEN, S., STEA, T.H., ROHDE, G., OMFJORD, C.S., ABILDSNES, E.

University of Agder

Introduction Physical education (PE) in schools can play an important role in both improvement of movements' skills and health promotion. However, content and design of PE programs may influence adherence to PE class and learning outcomes. The aim of the present study was to compare objectively recorded light-, moderate-to-vigorous intensity physical activity (MVPA), walking steps and sedentary time in adolescents participating in either PE focusing on play, health and facilitating positive experience (Play and Health), or sports skills, technique and improvement of physical performance (Sports). Methods A total of 181 first year students (141 girls) attending to vocational studies of Restaurant and Food Processing ($n = 58$), Design, Arts and Crafts ($n = 60$) or Healthcare, Childhood and Youth Development ($n = 102$) from two high schools in Kristiansand, Norway, participated in a new PE program. 101 (24 boys) students (17 yrs old (standard deviation 2.4)) wearing an activity monitor (SenseWear™ Armband Mini, BodyMedia Inc., Pittsburgh, Pennsylvania, USA and analysed with SenseWear™ Professional Research Software Version 8.1, BodyMedia Inc) were included in the analysis. Cut-point defining MVPA was Metabolic Equivalents above 3. Differences in MVPA and steps between students in the two PE groups were assessed by analysis of covariance adjusting for days of activity recordings, age, sex and parental education. Results Students participating in PE focusing on Sports were walking significantly ($p < 0.001$) more steps/day compared to the group focusing on Play and Health (mean \pm 95% confidence intervals; 9167 (7945, 10390) vs. 6661 (5514, 7808) steps/day). There was a tendency ($p = 0.145$) that students choosing PE focusing on Sports participated in more MVPA (48 (31, 65) vs. 34 (18, 50) min/day). Neither light PA, sedentary time nor sleep hours were significantly different between the two groups of students. Discussion The results of the present study indicate adolescents choosing PE focusing on Sports tend to be more physically active than students choosing PE focusing on Play and Health. When designing PE programs students' preferences and physical activity experiences has to be kept in mind since these factors may influence adherence to PE class and learning outcomes. SPORT-RELATED HEALTH COMPETENCE: A COMPETENCE MODEL AND TEST INSTRUMENT FOR PHYSICAL EDUCATION

TÖPFER, C., SYGUSCH, R.

Friedrich-Alexander-University Erlangen-Nuremberg

Introduction In the context of an increasing focus on learning outcomes in the German educational system, sport pedagogy has been challenged in terms of measuring pupils' competence in physical education at school (Gogoll, 2014). Focussing on competence-related aspects of health promotion in physical education, first of all, a theoretical model of sport-related health competence was derived (Gogoll, 2014; Sørensen et al., 2012; Töpfer & Sygusch, 2014). On this basis the following study aims on the development of a test instrument measuring sport-related health competence. Methods A paper and pencil test was designed to assess sport-related health competence, targeting pupils in classes 7 to 10 in German schools. A combination of quantitative and qualitative methods were used to develop the test. Items were developed and selected on the basis of three pretests with pupils ($N = 312$), and three expert ratings involving sports scientists, students and teachers ($N = 38$). Final testing of the instrument included a sample of 670 pupils aged 12 to 17 (mean = 14.4). The test consisted of 33 items representing the three dimensions of the competence model. Item selection and test scaling utilised statistical methods based on both classical test theory and item response theory. Results Selected results based in particular on item response theory are summarised as follows. The mean value for item difficulty overall (item parameter α_i) is intermediate (mean = 0.09; SD = 1.36; Min = -2.36; Max = 3.49). The applicability of the Rasch model (Partial Credit Model) was successfully proved for a subset of 25 items (LR-test: $\chi^2 = 50.81$; df = 40; p = 0.118). The test exhibits an acceptable level of reliability (EAP/PV = 0.79). All items show good values for item fit based on weighted mean square (WMNSQ) within the range 0.8-1.2. Discussion The study was successful in developing a comprehensive test measuring sport-related health competence. As some items were found unsuitable during the process of item development, it would be valuable to expand the pool of test items in order to cover the broad range of health-related topics in physical education. In addition, the scope of the test should be extended so it can be used with younger and older pupils to assess progress in sport-related health competence at school. References Gogoll, A. (2014). WHAT CHILDREN DO AND DON'T LIKE ABOUT TAKING PART IN SPORT: USING FOCUS GROUPS TO INVESTIGATE EXPERIENCES OF CHILDREN WITH HEARING LOSS

SOMERSET, S., HOARE, D.J., LEIGHTON, P.

University of Nottingham

Introduction Limited participation in physical activity and sport has been linked to poorer mental and physical health in children (Bailey 2006). For children in particular, participation in sport can help to develop social skills, communication and improved self-confidence resulting in an improved quality of life (Janssen & LeBlanc 2010). Children with hearing loss should have the same opportunities to participate in sport and receive the benefits as their hearing peers. Anecdotal evidence suggests this isn't always the case. This is concerning given there are 45,000 children in the UK with permanent hearing loss. The aim of this study was to understand what encourages or discourages children with hearing loss to take part in sports. Methods Ethical approval for the study was obtained from the University of Nottingham School of Medicine ethics committee. We conducted eight focus groups with children with hearing loss aged 10 to 15 years. A total of 45 children (19 male, 26 female) recruited from local schools and sports clubs took part. Information was gathered on the children's thoughts and feelings about participation in sport. The focus groups included an activity to facilitate discussion about sports. This included whether they played sports and who with, whether they did or did not like sport, and why they got involved in sport. Focus groups were audio recorded and transcribed. Transcripts were analysed using thematic analysis. Results Several key themes were identified as being associated with levels of sports participation. These included friendships, family and communication. Children with hearing loss with active siblings had participated in more sports. Communication was a common theme throughout regardless of the type of hearing-assistive technology a child used. Children found communication easier during sport if they were allowed to use their

technology and had particular difficulty during sports such as swimming. Children expressed a desire not to have to identify themselves at a club as having a hearing loss. This affected their confidence when participating in sport. Discussion Not surprisingly, children with hearing loss are more likely to participate in sport if they have a good support network of parents, coaches and friends. Key barriers to participation for these children are communication, lack of visual information, lack of opportunity and a lack of awareness. By addressing these issues more children with hearing loss will take part in sport and will continue their participation. References Bailey R. (2006). 3Faculty of Physical Education and Sports, Comenius University; 4

Introduction: Mild cognitive impairment (MCI) is accelerated cognitive decline associated with an increased risk of Alzheimer's disease. Prevalence of MCI increases in elderly (>65yrs of age). Regular physical exercise is physiological and effective means of preserving or improving cognitive functions, especially at early stages of cognitive decline. Methods: Cognitive healthy seniors (n=6/6, M/F, 65.2±2.2yrs) and seniors with amnestic MCI (aMCI, n=3/11, M/F; 72.7±1.8yrs) were recruited. Phenotyping before/after 3-month intervention included cognitive tests (Addenbrooke's Cognitive Examination, ACE-R; Mini Mental State, MMSE; computerized test MemTrax), assessment of resting metabolic rate (RMR, indirect calorimetry), body composition (quadrupedal bioimpedance), glucose metabolism (oral glucose tolerance test, oGTT) and physical activity (questionnaires & accelerometers). Individual cognitive domains of ACE-R were evaluated. Physical fitness (Rockport Walking Test), muscle strength (dynamometry) and motor functions (10-Meter Walk Test, 10-MWT; Chair Stand Test, CST) were assessed. Exercise intervention consisted of supervised progressive aerobic-strength training: 1h 3x/w, 60-70% VO₂max or 60-70% 1RM, resp. Results: Three-month training improved cognitive functions in MCI individuals (ACE-R: p=0.009), modulating specifically short-term memory (p<0.001). Body composition, BMI, glucose metabolism and RMR did not change with training (p>0.05). However, 2h insulinemia (oGTT) was negatively associated with verbal fluency (r=-0.32, p=0.03) and attention/orientation (r=-0.32, p=0.02). MemTrax score did not change with training (p>0.05), however, reaction time improved in both control (by 41%) and MCI (by 50%) groups (p<0.0001). Short term memory performance (ACE-R) correlated negatively with serum lactate in baseline fasting state (r=-0.40, p=0.05), immediately after 45min bicycling (r=-0.49, p=0.01) and after 1h recovery (r=-0.69, p=0.001). MMSE score was associated with maximal force of knee extension, walking speed and CST (p<0.05 for all). Discussion: Three-months supervised aerobic-strength training improved cognitive and muscle functions in seniors with MCI. Our results indicate the importance of metabolic health and physical fitness for cognitive performance. Grant support: SAS-NSC Joint Research Cooperation grant, VEGA 2/0191/15

EFFECT OF "EXERCISE PROGRAM" APPLIED TO ALZHEIMER'S PATIENTS ON COGNITIVE FUNCTIONS AND QUALITY OF LIFE

LOK, S., LOK, N.

Selcuk University Faculty of Sport Science

Introduction: Alzheimer's disease is a progressive neurodegenerative disorder that causes various neuropsychiatric behavioral disorders and dysfunctions in activities of daily living together with intellectual retardation (Arent and Lutz 2015). Exercises done by Alzheimer's patients are very important in improving the quality of life of older people and increasing cognitive function or preserving the existing wellbeing. Objective: The aim of this study was to investigate the effect of an 'Exercise Program' applied to patients with moderate Alzheimer's disease on their cognitive functions and quality of life. Methods: The study was experimental with a pretest-posttest control group. The experimental group included 60 Alzheimer's patients (30 in the experimental group, 30 in the control group) who were determined by physicians, who were diagnosed with Alzheimer's, who were in the moderate stage of the disease (SMMSE score: 13-22), and who were allowed to do physical activity practice. The elderly people in the experimental group were administered an exercise program during a total of six weeks as determined by experts. The exercise program consisted of 30-minute walks and 30-minute regular rhythmic exercises three days per week. The control group were not administered any exercise. Before starting and at the end of the exercise program, the patients were administered the Standardized Mini Mental State Examination (SMMSE) and the Quality of Life Scale in Alzheimer's patients. Data were analyzed using Mann-Whitney and the Wilcoxon test. Results: The mean age of the experimental group was 76.62±4.74 and that of the control group was 77.26±6.84. The pre-exercise SMMSE mean score of the patients in the experimental group (16.34±4.57) increased significantly (19.26.3±5.74) after the application (z=3.164; p=0.00). However, there was no significant difference between the pre-test and post-test mean scores in the control group (p>0.05). Similarly, the quality of life mean score of the patients in the experimental group increased from 20.06±3.24 before the exercise program to 26.75±4.72 following the program (z=0.623; p=0.00). A comparison of the post-test mean scores received by the experimental and control groups on the SMMSE and the Quality of Life Scale in Alzheimer's patients showed that the experimental group received significantly higher scores than the control group (p<0.05). Discussion: The exercise program, which was administered three days per week throughout six weeks, improved the cognitive functions and quality of life of the Alzheimer's patients in this study (Arent and Lutz 2015; Scarmeas et al., 2009). INDEPENDENT AND COMBINED INFLUENCE OF SALIVARY TESTOSTERONE AND DHEA IN THE COGNITIVE ABILITY TESTS OF INSTITUTIONALIZED ELDERLY WOMEN WITH LOW LEVELS OF PHYSICAL ACTIVITY

TEIXEIRA, A.M.1, FURTADO, G.1,2, UBA-CHUPEL, M.1,2, RAMA, L.1, PEDROSA, A.F.1, BANDELOW, S.3, FERREIRA, J.P.1, HOGERVORST, E.3

1 Faculty of Sport Science and Physical Education, University of Coimbra, Portugal; 2 CAPES Foundation, Ministry of Education, Brazil; 3 School of Sport and Exercise Sciences, Loughborough University,

Introduction: Aging has been associated with cognitive decline in longitudinal studies of elderly individuals (Williams et al , 2010) with strong evidence linking this cognitive decline with low levels of physical activity (LPA) (Robitaille et al., 2014). Some studies explored the hypothesis that these associations may be mediated by hormonal biomarkers and cognitive abilities (Hogervorst et al, 2012). The aim of this study was to investigate the independent and combined influence of salivary Cortisol (SCOR), Testosterone (sTES) and DHEA levels in the cognitive abilities of elderly woman with low LPA. **Methods:** A cross-sectional with 102 women (age = 82±7.30 years) recruited from four social and health care elderly centres was done using Mini-mental State Exam (MMSE), Symbol Modalities Test (SMT), Hopkins Verbal Learning Test (HVLT), Verbal Fluency Test (VFT) and Digital Spans Test (DST) to characterize their cognitive abilities. Salivary levels of COR, TES and DHEA were measured by ELISA. The International Physical Activity Questionnaire was used to stratify the participants by LPA. Descriptive statistic, Pearson's correlation coefficient and multiple linear regression were used to verify the association between variables. **Results:** There was a significant inverse correlation between cognitive HVLT and SMT tasks with sTES and DHEA levels ($p<0.05$). Correlations between PAL and MMSE, HVLT and VFT were also found. A linear regression showed that in subjects with mild/moderate cognitive impairment, sTES significantly influenced the cognitive profile in MMSE and SMT. **Discussion:** Our results show that salivary hormone levels of testosterone and DHEA were associated with cognitive performance and the later associated with physical activity levels. RELIABILITY OF A COMPUTERIZED BASKETBALL-SPECIFIC COGNITIVE ASSESSMENT

BARNES, K., ANDERSON, M., BAKER, L.

PepsiCo

For many athletes, especially team sport athletes, optimal performance involves more than just physical skill; it also requires high-functioning cognition. A reliable measurement of cognitive performance is needed for talent identification/development and to determine the efficacy of nutritional interventions. However, the ability to reliably measure cognitive performance depends strongly on the type of assessment being used. It is generally agreed that the best measure of cognition in team sport athletes involves an assessment that simulates the specific sport directly. Yet, very little information is available on cognitive performance tests specific to basketball athletes, particularly where reliability has been assessed. **Purpose:** To determine the reliability of a basketball-specific cognitive assessment protocol during a simulated basketball game with youth athletes. **Methods:** Seventeen competitive, male basketball players (17 ± 1 y, 72.6 ± 11.9 kg, 184.0 ± 8.8 cm) completed a familiarization visit followed by two identical experimental trials. Prior to each trial, subjects ate a consistent 24 h diet and were asked to only consume a 500 ml bolus of water and a provided granola bar in the 3 h period prior to the trial start time. The basketball protocol consisted of four ~20-min quarters (including rest breaks), in which subjects performed basketball drills on a court (involving sprinting, jumping, shooting, dribbling, and passing). Heart rate (HR; Polar Electro, Kempele, Finland) was measured continuously throughout the trial. At the beginning of each trial, subjects were given a brief mock scouting report consisting of a video (~7 min) with a voice-over informing the subjects of the fictitious team they will be playing. The scouting report included key skills and weaknesses of the opponents as well as the coach's key offensive and defensive strategies. At the end of each quarter the subjects were asked to answer four questions based on the scouting report. Paired samples t-tests, coefficient of variation (CV), and intraclass correlation (ICC) were used to assess the reliability of the athlete's cognitive performance between the two experimental trials. **Results:** Mean HR was not different between trials (160 ± 11 bpm vs. 161 ± 10 bpm, $p=0.77$). There was no difference between trials in the mean number of questions answered correctly per quarter (3.2 ± 0.4 vs. 3.3 ± 0.5 correct answers, $p=0.21$). The CV and ICC for the mean number of correct answers per quarter was 8.8% and 0.759 ($p=0.003$), respectively. **Conclusion:** This novel basketball-specific, cognitive assessment is reliable in 14-19 y old basketball players, and may be a useful tool to assess cognition for talent identification or development purposes, as well as to determine the efficacy of nutritional interventions.

DOES MENTAL IMAGERY HAVE A POSITIVE EFFECT ON CLOSED MOTOR SKILLS IN TENNIS, FIELD HOCKEY AND SOCCER?

HEGAZY, K.1,2, JEKAUC, D.3,4, WOLL, A.1

1: KIT /Karlsruhe, Germany, 2: UA /Alexandria, Egypt, 3: HU /Berlin, Germany, 4: UK /Konstanz, Germany/

Introduction Research has shown that preparatory imagery, or using imagery immediately before a performance, can improve performance in strength tasks and muscular endurance tasks (Vealey & Greenleaf, 2006). In addition, combining imagery with relaxation is more effective. Few studies have addressed the efficacy of mental imagery to improve precision on closed motor skills (Coelho et al., 2007; Hegazy, 2012). Therefore, the aim of this study was to analyze the effects of mental training on precision in tennis serve, field hockey hit and soccer penalty kick. **Methods** The intervention used an experimental design with a pre- and posttest. The experimental groups received both technical practice and mental training units including imagery and relaxation exercises on the court for a total of four weeks. The control groups received only technical practice for the same time period. A total of 156 subjects from Germany and Switzerland, aged between 14 and 35, were divided into 60 in tennis (35 male, 25 female), 54 soccer male and 42 field hockey male and one female all amateur athletes with a high skill level. The dependent variable was measured by a hit ratio of a precision test for tennis serve, field hockey hit and soccer penalty kick. In this test, each player played 20 attempt aimed at a target area. **Results** The results of ANOVA with repeated measurements showed a highly significant interaction effect between time and group in tennis ($F_1, 55 = 22.6$; $\text{ETA}^2 = .29$) and field hockey ($F_1, 41 = 19.9$; $\text{ETA}^2 = .33$). However, in soccer the interaction effect was not significant ($F_1, 52 = 3.71$; $\text{ETA}^2 = .67$). **Discussion** This improvement of precision, in the intervention group in comparison to the control group, demonstrates the effectiveness of posi-

tive imagery on closed motor skills in tennis and field hockey. The effect of the intervention can be seen as large (Cohen's $d > 1.00$) in both games. For tennis, the intervention group improved their performance in the precision task by 4.1 hits in 20 trials, whereas, the control group improved only by 1.0 hits. For field hockey, the intervention group improved their performance in the precision task by 2.7 hits in 20 trials, whereas the control group decreased their performance by 0.4 hits in 20 trials. However, in soccer, the difference between the intervention and the control group was not significant. References Coelho RW et al. (2007). Perceptual and motor skills, 105(2): 458-468. OP-SH16 Physical Activity in Children

INTERVENTIONS IN OUTDOOR PLAY AREAS OF KINDERGARTEN AND EFFECTS ON USAGE PATTERNS AND PA OF GIRLS AND BOYS

DIKETMÜLLER, R.

University of Vienna

Introduction Results in the HAPPY-study indicate that preschool children spend 85% of waking time being sedentary (Hinkley et al., 2012), and less than 50% of the children meets physical activity (PA) guidelines and recommendations (Tucker, 2008; Nicaise et al., 2011). The findings of the baseline study (E1) in the "KinderGarten"-project (8 kindergartens, n=333 children; Diketmueller et al., 2014) showed significant differences in PA-levels between girls and boys, esp. of boys with migrant background (highest proportions of time in MVPA). Whereas the offer of specific physical activity programs was associated with higher PA levels of both sexes, large-sized outdoor areas did not automatically lead to higher levels of PA. So the intervention focused on spatial changes, regulations of using the spaces as well as pedagogical concepts. Methods In the evaluation study (E2) of the project physical activity behavior of children in 4 kindergartens (2,5-6yrs) was collected on three time-points during outdoor play time through direct observation, where types of activity of girls and boys were identified and integrated into maps of activities. In addition, PA was measured by accelerometer (n=140). The results (maps of activity) and the accelerometer data were compared with the findings of the baseline study. Results Based on a methodological triangulation, the comparison of the findings of the baseline and evaluation study (E1, E2) illustrates changes in PA behavior due to spatial, organizational and pedagogical changes: markings led to less conflicts between children, to larger -scaled activities in the outdoor area and to a significant increase of steps of girls. Changes in regulations, like the allowance of using secluded or "hidden" spaces (e.g. behind trees, bushes, ...) empowered the children to explore new spaces, enlarged the number of activity patterns and significantly the amount of PA of girls and boys. Discussion The discussion of the results with kindergarten teachers show who important the discussion and visualization of results in activity maps of each kindergarten and the accelerometer-derived physical activity data were to ensure awareness of kindergarten teachers. EVALUATION OF BASIC MOTOR COMPETENCIES IN PRIMARY SCHOOL CHILDREN – VALIDITY OF THE MOBAK-1 TEST INSTRUMENT

HEIM, C.1, SEELIG, H.2, HERRMANN, C.2

1: Goethe-University (Frankfurt, Germany), 2: DSBG (Basel, Switzerland)

Introduction A central aim of physical education (PE) is the promotion of basic motor competencies (in German: Motorische Basiskompetenzen; MOBAK) which are prerequisites for children's active participation in sports culture. While instruments for measuring motor abilities in schoolchildren have been developed, less is known about the measurement of MOBAK. We introduce a newly developed measure of MOBAK for children aged six to eight years (first and second grade) made up of eight dichotomous items (e.g., throwing, catching, rolling, jumping; see Herrmann, Gerlach & Seelig, 2015). Methods N=1099 primary school children (493 girls, M=6.9 years, SD=0.52) took part in a study focused primarily on construct validity of the test instrument. In addition, we investigated the relationship between MOBAK and motor abilities such as strength and demographic and individual differences variables BMI, sex and age. Confirmatory factor analyses (CFA) and structural equation models (SEM) were performed using MPlus. Results We found two factors consisting of four items each, confirming results of previous studies (Herrmann et al. 2015). The first factor "Locomotion" included the items throwing, catching, bouncing and dribbling, the second factor "Object-Control" included the items balancing, rolling, jumping, and moving variably. CFA revealed good model fit indices ($\text{CFI}=.95$; $\text{RMSEA}=.044$). Adding the motor ability tests long-jumping and sprinting into the model with the eight MOBAK-items did not result in a change of the MOBAK factor structure. Instead, motor abilities formed a separate factor "strength", which had a significant influence ($\text{CFI}=.97$; $\text{RMSEA}=.030$) on the factors "Locomotion" ($\beta = .60$) and "Object-control" ($\beta = .50$). An additional model including the variables BMI, sex and age as covariates of "Locomotion" and "Object-Control" indicates a satisfactory model fit ($\text{CFI}=.90$; $\text{RMSEA}=.036$). As expected older pupils achieve better results than younger pupils in both "Locomotion" ($\beta = .09$) and "Object-Control" ($\beta = .24$), whereas we found mixed results for BMI (pupils with high BMI achieved lesser results only for "Locomotion" ($\beta = -.35$) but not for "Object-Control") and sex (boys being better in "Object-Control" ($\beta = -.46$) whereas girls achieved higher results in "Locomotion" ($\beta = .07$)). Discussion The developed MOBAK test instrument meets psychometric validity demands, i.e. factorial, prognostic and discriminant validity. The eight-item test instrument is suitable for the evaluation of effects of PE. References Herrmann C, Gerlach E, Seelig H. (2015b). INCREASING PHYSICAL ACTIVITY LEVELS IN PRIMARY SCHOOL PHYSICAL EDUCATION: THE SHARP PRINCIPLES MODEL

POWELL, E., WOODFIELD, L.A., NEVILL, A.M., POWELL, A.J.

Newman University

INTRODUCTION There is limited evidence of effective physical education (PE) interventions in England to increase children's moderate to vigorous physical activity (MVPA) (Lonsdale et al., 2013). Thus the main aim was to implement and evaluate the effectiveness of a one-year intervention, to increase children's MVPA levels during primary school PE. **METHODS** A quasi-experimental non-equivalent groups design was employed, involving four classes (children aged 7 to 9 years: baseline, n=111; post intervention, n=95) from two primary schools in the West Midlands, England. In March 2014 schools were purposefully selected according to size and demographics. The intervention was grounded in the Self Determination Theory (SDT) (Ryan and Deci, 2000), the Social Ecological Model (SEM) (Mc Leroy, 1988) and three 'active ingredients' from the Behaviour Change Taxonomy (BCT) (Michie et al., 2011). The intervention included: the development of a new PE school policy; the creation of a new curriculum map; providing on going support; and developing teachers' awareness of children's PA in PE. Children's MVPA in PE was assessed at baseline and post intervention, using the System for Observing Fitness and Instruction Time (SOFIT); a total of 28 PE lessons were observed. Four teacher interviews were conducted with the intervention school, to explore teachers' perceptions of the intervention. **RESULTS** A two-way ANOVA indicated large interaction effect sizes for time spent in MVPA ($F(1, 27) = 11.07$, $p=0.003$, $\eta^2=.316$) and VPA ($F(1, 27) = 8.557$, $p=.007$, $\eta^2=.263$). MVPA in the intervention school increased significantly (42-72%) whereas in the control school MVPA remained constant (42-45%). The qualitative findings revealed two main emergent themes: a paradigm shift and teachers' advanced pedagogical understanding. **DISCUSSION** As the intervention was successful in increasing MVPA in PE, a 'SHARP Principles Model' was created with the following pedagogical principles at its core: Stretching whilst moving; High repetition of motor skills; Accessibility through differentiation; Reducing sitting and standing; and Promoting in class PA. The application of the SHARP principles could be seen as the first step towards improving pedagogical practice in PE when used with a curriculum focused school programme, having the potential to improve the quality of PE in primary schools in England. **REFERENCES** Lonsdale C, Rosenkranz RR, Peralta LR, Bennie A, Fahey P, Lubans DR (2013). EFFECTS OF A 5-DAY OUTDOOR SPORTS INTERVENTION ON ENVIRONMENTAL ATTITUDES IN CHILDREN

LIMMER, M., ROTH, R.D.

German Sport University Cologne

Introduction: The ability of environmental education programs is shown to influence environmental attitudes positively (Kruse and Card, 2004; Johnson and Manoli, 2011). But there is not much about the effect of outdoor sport programs on environmental attitudes. The present study examines the impact of 5-day extra-curricular outdoor sport interventions on environmental attitudes in 11-14 years old children. **Methods:** 288 students completed the intervention (male: n=157, 12.1 ± 1.2 years; female: n=131, 11.9 ± 1.1 years). To measure students' environmental attitudes, we administered the "Two-Major-Environmental-Values-Scale" (2-MEV) developed by Bogner and Wiseman (2006). The 2-MEV consists of two higher order factors: utilization and preservation of nature. A pre-, post- and retention-test design was used. For further analyses students were assigned to the type of their secondary school (secondary general school (GEN; n=41), intermediate secondary school (INT; n=20), comprehensive school (COM; n=31), grammar school (GRAM; n=196)) and the population of the town where the school is situated (POP+: >100.000 (n=107), POP-: <100.000 (n=181)). **Results:** Wilcoxon signed-rank tests revealed a positive short-term effect for the overall group for the factor utilization (pre: 2.26 ± 0.73 , post: 2.13 ± 0.75 ; $p=0.000$). Further comparisons showed a positive effect on utilization (pre: 2.42 ± 0.82 , post: 2.22 ± 0.84 ; $p=0.000$) and preservation (pre: 3.11 ± 0.79 , post: 3.23 ± 0.77 ; $p=0.018$) scores for POP+, but only on utilization for POP-(pre: 2.16 ± 0.65 , post: 2.08 ± 0.68 ; $p=0.003$). Additionally there was a positive increase also for the factor preservation in GEN students (pre: 2.86 ± 0.89 , post: 3.10 ± 0.89 ; $p=0.010$), whereas there were no program-induced changes for INT or COM. No persistence of changes in environmental attitudes could be found. **Discussion:** The 5-day extra-curricular outdoor sports programs affected students' environmental attitudes positively. The outdoor sports interventions showed similar effects compared to environmental education interventions (Sellmann and Bogner, 2013). Interventions seem to be most effective for children from urban areas and for secondary general school students representing a lower level of education. However, the improvement did not persist after the program. Consequently, a program design focusing even more on a combination of outdoor sports and education for sustainable development may support a long-term outcome. **References:** Bogner FX, Wiseman M (2006). SO SIMILAR AND SO DIFFERENT TO OTHER KIDS! PHYSICAL ACTIVITY AND SPORTS AMONG CHILDREN WITH DOWN'S SYNDROME

SOLLERHED, A., HEDOV, G.

Kristianstad University

Introduction About 100 children with Down's Syndrome (DS) are born in Sweden every year. According to the Swedish National Sports Confederation, these children have the right to play sports and to be physically active like other children. Sports for children should be based on children's own needs and circumstances and take into account of the variations in development. The question is whether this also is applied to children with DS? Children with DS have been shown to have low fitness, poor motor skills, high prevalence of overweight and very low participation in sports activities (Whitt-Glover et al, 2006). **Methods** Information was obtained by a questionnaire performed among families with children with DS. Information was given by the parents. The questionnaire was partly inspired by the questionnaire CAPE (Children's Assessment of Participation and Enjoyment) (King et al, 2004). Furthermore, new additional questions focusing on physical activity and sports participation, attitudes and living habits among both children and adults were included. The sample consisted of 60 children with DS aged 8-18 years and their families in Southern Sweden. The statistics were carried out by using PASW. **Results and discussion** The activity patterns among children with DS seemed to be quite similar with patterns among other children. A polarized picture emerged in which some are very active and some are completely inactive. Relationships between parents' own level of physical activity and children's activity could be shown, as well as associations between parental involvement in the activities and children's activity levels. However, the parents expressed the difficulties children with DS have to participate in sports together with other

children. The difficulties were mainly lack of motor skills, perceptual difficulties, poor movement planning and difficulties in changing directions that were seen as the main obstacles for the children with DS. Some parents also indicated a lack of endurance capacity and rapid mood swings as additional factors that contributed to the difficulties. The parents didn't experience any negative reactions from other children or parents when children with DS participated in the same sports activities as other children. However, the parents had a feeling that the children with DS pull down the activity tempo of the whole group, but they have not been exposed to direct comments from other parents about this. OP-PM34 Pacing Strategies

OPTIMAL PACING STRATEGIES AND ASSOCIATED METABOLIC RESPONSES DURING 4-MIN SELF-PACED RUNNING TIME-TRIALS

MCGAWLEY, K., WATKINS, J., PLATT, S., ANDERSSON, E.

Mid Sweden University

Introduction A fast start followed by a progressive slowing (i.e., a positive pacing profile) has been identified during competitive sporting events lasting 1.5 – 5 min (Ansley et al., 2004; Tucker et al., 2006). An increase in power output towards the end of such events may also occur, which can result in a negative (i.e., faster second half) pacing strategy (Foster et al., 2004). The aim of the current study was to investigate individual pacing strategies and the distribution of physiological resources during 4-min self-paced running time-trials (TTs). Methods Five male and five female recreational runners (age 32 ± 7 y) with best 5- and 10-km run times of 19.5 ± 1.8 min and 40.1 ± 3.3 min completed a sub-maximal ramp test and five, 4-min self-paced running TTs on a motor-driven treadmill on separate days. The treadmill was fitted with lasers allowing participants to automatically modify speed during the TTs. The accumulated oxygen deficit (AOD) was calculated by estimating the VO₂ demand throughout each TT from the submaximal linear relationship for speed and VO₂, then subtracting actual VO₂. Results Distance covered, accumulated VO₂ and AOD for best and worst performances were 1137 ± 94 and 1094 ± 94 m ($P < 0.001$), 203 ± 19 and 199 ± 22 mL/kg ($P = 0.02$) and 34.1 ± 7.4 and 31.1 ± 7.2 mL/kg ($P = 0.08$), respectively. Peak lactate was significantly higher after best (11.1 ± 2.2 mmol/L) vs worst (9.7 ± 1.5 mmol/L) performance ($P = 0.03$), while relative aerobic contribution (approx. 86%, $P = 0.20$) and peak heart rate (approx. 96% of maximal heart rate, $P = 0.41$) were not different. Significantly more distance was covered during the first 2 min of the best vs worst performance (565 ± 53 vs 528 ± 41 m, $P < 0.001$). This was associated with a significantly higher accumulated VO₂ ($P = 0.01$) and AOD ($P < 0.001$) during the first 2 min for the best vs worst performance. By contrast, there was no difference between the best vs worst performance for distance covered (572 ± 47 and 567 ± 57 m), accumulated VO₂ or AOD during the final 2 min. Discussion Findings from the current study show that negative pacing strategies were adopted during both the best and worst performances. Best performance was associated with a greater mean speed, accumulated VO₂ and AOD during the first half of the TT compared with worst performance. A fast start appears effective in minimizing the performance deficit in the first half of a 4-min running TT and maximizing aerobic and anaerobic energy production. THE PSYCHOPHYSIOLOGICAL DETERMINANTS OF PACING DURING PROLONGED ENDURANCE EXERCISE: PERFORMANCE LEVEL COMPARISON

VENHORST, A., MICKLEWHITE, D., NOAKES, T.D.

University of Cape Town

Introduction: The Central Governor Model (CGM) revolutionized our current understanding of fatigue and ignited a paradigm shift in the exercise sciences from catastrophic failure towards central regulation. However, the CGM and alternative psychobiological models rely heavily on the Gestalt measurement of perceived exertion to explain behavioral change. This is an oversimplification of the underlying psychophysiological construct. Drawing from Gate Control Theory of pain, a modified three-dimensional model of effort was applied to explore the distinct inputs that shape the perceptual milieu and underpin the goal directed behavior of pacing. Methods: Delineated contributions of the sensory-discriminatory, affective-motivational, and cognitive-evaluative dimensions were approximated by means of scales: physical-rating of perceived exertion (p-RPE) and mental sense of effort (TEA), affective valence (FS) and felt arousal (FAS), and perceived action crisis (ACRISS), respectively. Cyclists of different performance levels (PL3, n=12 and PL4, n=11) performed a 70 km individual time trial over a virtual profiled course. The interrelationships between pacing strategy, performance, hematological, and perceptive variables were explored. Results: PL4 performed at greater workloads ($p = 0.015$) and higher relative intensities ($p = 0.042$) compared to PL3, and had greater blood norepinephrine ($p = 0.045$) and lactate levels ($p = 0.039$). Despite greater physiologic strain, PL4 felt more pleasure ($p = 0.045$) and better maintained hedonic tone and arousal levels ($p = 0.022$), which deteriorated in PL3 over the last third of the course. FAS correlated with all markers of cardiovascular fitness and performance ($p < 0.05$). Split times were faster in PL4 except during the downhills ($p = 0.001$), which coincided with lower p-RPE ($p = 0.018$) compared to PL3. p-RPE correlated with dynamic change in cortisol ($p < 0.01$). Discussion: The current data revealed differences in pacing strategies between performance levels and indicate that perceptions of peripheral strain (approximated by p-RPE) were closer related to dynamic changes in pace than perceptions of mental strain (approximated by TEA). Data also showed a performance level dependent relationship between core affect and performance providing evidence for the important role of affective states in the regulation of exercise behavior. Well-trained cyclists paced themselves in a way that prevented the development of an action crisis, suggestive of performance level dependent differences in the integration and interpretation of perceptual sensory and affective cues. The proposed model provides additional and differential information on the complex processes underpinning exercise behavior. Contact andreas.venhorst@gmail.com

MODERATING EFFECT OF TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION ON PACED EXERCISE

HIBBERT, A.W.1, VARLEY, M.C.1,2, BILLAUT, F.1,3, PETERSEN, A.1, POLMAN, R.C.J.1,4

INTRODUCTION Afferent information from exercising muscle contributes to the sensation of exercise-induced muscle pain (O'Connor et al, 1999). Muscle pain enables conscious awareness of muscle stress and provides information in order to make appropriate pacing decisions (Mauger et al, 2010). Transcutaneous electrical nerve stimulation (TENS), is a process in which low-voltage electrical currents are delivered in order to inhibit ascending afferent information. The use of TENS in reducing exercise-induced pain has not yet been fully explored. This study aimed to investigate the effect of TENS on exercise-induced muscle pain, pacing strategy and performance during a 5-km cycling time trial (TT).

METHODS On 3 separate occasions, 10 recreationally active participants underwent a 30-min TENS protocol (High intensity (TENS), low intensity (PLACEBO) or no TENS (CONTROL)) applied to the quadriceps, prior to performing a 5-km TT. Quadriceps fatigue was assessed by maximal voluntary contractions (MVC) and evoked responses to magnetic stimulation. Subjective scores of exertion, affect and pain were taken every 1-km.

RESULTS Application of TENS was associated with greater mean power ($p=0.08$), and resulted in reduced TT duration compared to PLACEBO ($p=0.09$). Increased performance after TENS was achieved with greater power output at the start of the TT (250-m (Increased by 21%; $p=0.02$) compared to CONTROL, and 750-m (Increased by 19%; $p=0.05$) compared to PLACEBO). TENS application did not produce any differences in MVC or evoked responses. Sensations of pain ($p=0.31$), perceptual scores of exertion ($p=0.70$) and affect ($p=0.20$) did not exhibit any significant difference between conditions.

DISCUSSION Pacing and performance during the 5-km TT was influenced by the application of TENS. Stimulating afferent fibres did not influence sensations of pain and exertion but allowed for an increased power production. This data supports evidence that self-paced exercise is modified so that exercise-induced pain is regulated to an individual's sensation threshold (Mauger et al, 2010). Analgesic effects to pressure pain have been reported 30-mins after TENS application has ceased (Moran et al, 2011). However, residual analgesia for exercise-induced pain may be limited, thus explaining how the TENS session followed a similar pacing strategy to CONTROL and PLACEBO conditions, after the initial greater power output.

PREVIOUS ACTIVE COGNITIVE TASK DOES NOT AFFECT SUBSEQUENT SELF-PACED EXERCISE IN THE HEAT

ROUSSEY, G., GRUET, M., VERCUYSEN, F., BERNARD, T.

University of Nice Sophia Antipolis / University of Toulon Var

INTRODUCTION Prolonged periods of strenuous cognitive activity has recently been demonstrated to negatively influence the self-regulated physical tasks and is likely to compromise endurance performance (Brownsberger et al., 2013). In this framework, no studies have yet investigated whether or not hot ambient conditions modified the previously observed production of less power during hard effort bout. The aim of this study was to compare impact of two different (active vs passive) cognitive tasks preceding a hard self-paced exercise in temperate and hot ambient conditions on power output, thermal state and thermal comfort perceived.

METHODS In a randomized cross-over design, ten well-trained male cyclists completed four 30-min cycling trials at self-selected intensity representative of hard effort (RPE15-Hard), either in temperate (TMP, 20°C) or in hot conditions (HOT, 35°C). Before exercise, participants completed during 60 min either a Stroop-incongruent activity task or a time-matched passive task (control). Physiological, psychological indices were assessed throughout the four trials.

RESULTS Pre-exercise tasks induced similar subjective feelings of fatigue in spite of higher mental workload induced by cognitive activity task ($p<0.05$). No effect on power and any other assessed variable during the cycling trial has been observed in both ambient conditions. Mean power was significantly lower in HOT than in TMP (64.8 ± 4.0 vs 70.7 ± 5.0 %PMA respectively, $p<0.001$) but pacing design were not be affected. Average values of skin temperature ($p<0.001$) and thermal sensation ($p<0.001$) were significantly higher in HOT whereas heart rate and central temperature were similar.

DISCUSSION The present study, using an original model of self-paced exercise (Tucker et al. 2006), shows strong links between mean power, higher skin temperature and thermal sensation in the heat. These findings support that perceived exertion plays a key role in self-selected work rate during exercise in the heat through behavior thermal feelings (Schlader et al. 2011). Similar levels of mental fatigue reached the previous two cognitive tasks could explain the lack of difference in perception of effort.

OP-PM45 Extracellular Biomarkers

INCREASES IN CIRCULATING CELL-FREE DNA DEPEND ON INTENSITY DURING REPEATED SPRINT EXERCISE

HALLER, N., TÄNNY, P., PETRY, J., SIMON, P.

Johannes-Gutenberg-University Mainz

Introduction: Circulating cell-free DNA (cfDNA) is becoming increasingly important in molecular diagnostics. Diseases and disease states like cancer, sepsis or trauma associated with inflammation lead to elevated cfDNA levels.² Additionally, acute and chronic increases in cfDNA concentrations have been demonstrated to occur in a variety of exhausting exercise settings.¹ Here we assessed for the first time the effects of two repeated sprint exercises differing in pause time on cfDNA levels in human blood plasma. **Methods:** 9 subjects (mean age: 23.6 years \pm 1.7 years; mean height: 179.6 cm \pm 7.9 cm; mean weight: 80.9 kg \pm 9.9 kg) were randomly assigned in two groups (A and B). After a 15 minute warm-up all subjects performed 5 sprints of 40m each. The pause between the sprints was 5 minutes for group A and only 1 minute for group B. After a pause of 75 minutes, the participants repeated the sprint exercise but switched in terms of pause time (cross-over design). Capillary cfDNA from the finger tip and lactate from the ear lobe was measured before, after the warm-up, after every sprint and after the whole series. Venous plasma was drawn before, after the first and after the second sequence of sprints. **Results:** Venous cfDNA increased on average 2.4-fold after the short pause sprints and significantly lower 1.9-fold after the 5 minute pause sprints ($p < 0.05$). Respective lactate increases were 3.4 fold after long pause exercise and 4.9-fold after 1 minute pauses (n.s.; $p \geq 0.258$). Capillary samples did not increase constantly. Venous cfDNA correlated significantly with lactate ($r = 0.69$; $p < 0.05$). **Discussion:** We show for the first time, that repeated sprints lead to a significant increase in venous cfDNA. Shorter pause time and thus a higher intensity of the exercise lead to significantly higher increases of venous cfDNA. Lactate in contrast showed significant increases after 5 sprints but there was no significant difference between short and long pause sprints. Capillary cfDNA blood sampling seems not to be applicable for such short term exercise. Future studies will have to clarify whether cfDNA could be a more appropriate marker for intensity than established parameters. Additionally, controlled longitudinal studies have to clarify intra-individual differences in cfDNA concentrations and reveal the potential of cfDNA as a marker in exercise settings. **References:** Breitbach, S., Tug, S., & Simon, P. (2012). Circulating Cell-Free DNA. Sports Medicine, 42(7), 565-586. Van Der Vaart, M., & Pretorius, P. J. (2008). Circulating DNA. Annals of the New York Academy of Sciences, 1137(1), 18-26.

EFFECTS OF VO₂-UPTAKE ADJUSTED DOWNHILL AND UPHILL RUNNING ON CFDNA AND CONVENTIONAL EXERCISE MARKERS

OCHMANN, D., HELMIG, S., SIMON, P.

Johannes Gutenberg-University Mainz

Effects of VO₂-uptake adjusted downhill and uphill running on cfDNA and conventional exercise markers **Introduction** We observed in previous studies that running leads to significantly higher increases of cell-free DNA (cfDNA) in capillary blood than a comparable cycling protocol. Following the idea that this effect might be based on the more eccentric nature of running compared to cycling, we examined here whether uphill or downhill running adjusted to VO₂-uptake leads to a differential effect on physiological markers and cfDNA increases. **Methods** Following VO_{2max}-testing ten male triathletes took part in four different endurance runs (group). A 5 min warm-up, was followed by 3x10 min at either 60 % or 80 % of VO_{2max} at -3.5 % or +6.5 % incline on a treadmill. The tests included continuous recording of spiroergometric data, and assessment of heart rate, lactate and cfDNA at rest, following warm-up, after every 10min interval, and 3, 15, and 30min after the runs. The normalized and homoscedastic Data fulfilling sphericity conditions were analyzed by multi-factorial analysis of variance with up/down, 60%/80% and point in time (Rest, 10', 20', 30') as in-fluential factors. **Results** Compared with lactate, heart rate, and RER, cfDNA showed the most robust and significant step-wise increases during the run with an 8.0-fold (95% CI: 6.4-9.9; $p < 0.0001$) increase from rest to 30 min, adjusted for intensity and up/down. Except for heart rate none of the other factors was able to differentiate between uphill and downhill running at 60% of VO_{2max}. However at 80% VO_{2max} heart rate was not able to differentiate between uphill/downhill, while cfDNA values were on average 2.0-fold (95% CI: 1.6-2.5; $p < 0.0001$) higher during downhill running at a significance level equal to the RER ($p < 0.0001$) and much higher than lactate ($p = 0.03$), both showing slightly higher values downhill. **Discussion** Compared to other physiological markers cfDNA reacts more sensitive to different intensities over a course of an endurance run. Compared to lactate, it showed a stronger association with eccentric load and duration of exposure. This suggests that the cfDNA could be a more sensitive marker especially in intermittent sports with varying intensity and duration and in particular varying eccentric load proportions than conventional exercise markers.

„CELL FREE CIRCULATING DNA IN SALIVA DURING INCREMENTAL EXERCISE“

SCHMIDT, S., HELMIG, S., STERZING, B., SIMON, P.

University Mainz

Introducion: Cell free circulating DNA (cfDNA) is an upcoming biomarker in sports physiology. Significant increases of cfDNA have been described in various exercise settings as well as under pathological conditions (Ziegler et al.). Increases of cfDNA can be up to 100-fold above normal resting levels, depending on intensity, severity or duration of the event or stimulus. So far it is unknown whether alterations in blood cfDNA are accompanied by respective changes in saliva. The aim of this study was to correlate measurements of cfDNA in saliva

with those in blood during incremental exercise test. Methods: 10 subjects participated in a standardized step-wise incremental exercise test on a treadmill with 3min intervals and increases of 2 km/h with every step starting at 6 km/h until exhaustion. Capillary blood and saliva samples using the SARSTEDT salivette were taken before and after every step. Quantification of cfDNA in saliva and blood was done by a direct quantitative polymerase chain reaction (qPCR) that does not require DNA purification (Breitbach et al.). Results: Resting levels of cfDNA in saliva were on average about 2-fold higher than values in capillary plasma. While increases of cfDNA from rest to exhaustion in capillary plasma were 4.6-fold ($p=0.0001$) the concentrations in saliva did not change significantly (1.6-fold, $p=0.651$). No significant correlations of cfDNA values from saliva with markers for physical load like blood cfDNA, lactate, heart rate or Borg-values were found. This situation did not improve by correcting the cfDNA values with the respective changes in osmolality of the saliva. In contrast a medium up to high correlation was found between capillary blood cfDNA concentrations and Borg-values ($r=0.63$) or lactate ($r=0.79$). Discussion: CfDNA values in saliva were principally measureable but in contrast to values from capillary blood failed to show an immediate response upon physical stress. At rest cfDNA values in saliva were higher than in blood. This could be due to either a physiological mechanism of cfDNA release, additional cfDNA sources other than blood or by technical bias involving sample preparation. To enable non-invasive measurement of cfDNA from saliva that reflects physiological alterations these factors need to be studied in more detail. References: • Ziegler, A., U. CIRCULATING MICROVESICLES DYNAMICS WITH EXERCISE AND THEIR IMPACT ON HUMAN VASCULAR CELL FUNCTION

WILHELM, E.N.1, GONZÁLEZ-ALONSO, J.1, RAKOBOWCHUK, M.2

(1) Brunel University London, Uxbridge, UK; (2) Thompson Rivers University, Kamloops, Canada

Introduction: Microvesicle formation and release into the bloodstream may be a mediated response that ultimately controls vascular cell phenotype and function, but the effect of a typical endurance exercise session on circulating microvesicle concentrations, and their impact upon surrounding endothelial cells remains unknown. Here, we tested the hypothesis that exercise intensity modulates the time-course of platelet-derived (PMV) and endothelial-derived (EMV) microvesicle appearance in the circulation through changes in vascular shear stress and biochemical agonists; and that microvesicles obtained during exercise would enhance angiogenic and reparative potential of endothelial cells. Materials and methods: Nine young healthy men (25 ± 4 years, 1.79 ± 0.09 m, 80.5 ± 12.0 kg) had venous blood samples taken to measure plasma microvesicle, interleukin-6 (IL-6) and noradrenaline (NA) concentrations prior, during, and throughout the recovery period after 1 h of moderate (MI) ($36\pm5\%$ of VO_{2max}) or heavy (HI) ($62\pm4\%$ VO_{2max}) intensity semi-recumbent cycling and during a time matched control trial. Local haemodynamics were determined by ultrasonography. In vitro experiments were performed by incubating human umbilical vein endothelial cells with resting and exercise-derived microvesicles to examine their effects on cell morphogenesis, proliferation and migratory capacity. Results: Circulating PMVs only increased from baseline with HI exercise (from 21.2 ± 3.4 to 55.8 ± 24.8 and $48.0\pm16.6 \times 1000$ PMV/ μ l at 30 and 60 min, respectively; $P<0.05$), returning to baseline early in post-exercise recovery ($P\geq0.05$), whereas EMVs were unchanged ($P\geq0.05$). Brachial artery vascular shear rate (non-exercising limb) increased more during HI (3.1 ± 1.5 fold) compared to MI (1.9 ± 0.4 fold) exercise ($P<0.05$), and changes in PMVs were related to limb shear rate ($r=0.43$), and NA ($r=0.21$) ($P<0.05$), but not to IL-6 ($P\geq0.05$). Incubation of microvesicles obtained during exercise with endothelial cells enhanced their proliferation, migration, healing of scratch wound (all $P<0.05$), and angiogenesis compared to resting microvesicles and microvesicle free plasma control. Discussion: These results demonstrate substantial increases in circulating PMVs with heavy exercise and that shear stress is a potential mechanism triggering this response. The increased microvesicle pool also enhanced functional capacity of human endothelial cells by stimulating angiogenesis and repair. This involvement of microvesicles may be considered a novel mechanism through which exercise mediates vascular healing and adaptation.

METABOLOMIC INVESTIGATION OF THE EFFECTS OF DIFFERENT EXERCISE TYPES IN INDIVIDUALS WITH METABOLIC SYNDROME

SIOPI, A., DEDA, O., MANOU, V., KELLIS, S., THEODORIDIS, G., CHRISTOULAS, K., MOUGIOS, V.

Aristotle University of Thessaloniki

Introduction Metabolic syndrome (MetS), a condition that involves known cardiometabolic risk factors, such as hyperglycemia, hypertension and increased blood pressure, shows alarmingly increasing rates. Exercise holds a primary role in the treatment and prevention of MetS. A metabolomics study was performed to investigate whether the response of the human urinary metabolic fingerprint to exercise depends on the presence of MetS or the type of exercise performed. Methods Twenty-three sedentary men were divided into two groups: healthy ($n = 9$) and MetS ($n = 14$). All participants completed four trials randomly: rest, high-intensity interval exercise (HIE), continuous moderate-intensity exercise (CMIE) and resistance exercise (RE). Urine samples were collected pre-exercise and 1, 3 and 24 h post-exercise for targeted metabolomic analysis by liquid chromatography-mass spectrometry (HILIC-UPLC-MS/MS), followed by repeated-measures ANOVA on the 63 identified metabolites. Results Overall, 6 metabolites presented significant differences between groups, 30 metabolites presented significant differences between trials and 46 metabolites exhibited significant fluctuations over time. Alanine was the only metabolite to present a significant 3-way interaction. Nine metabolites shared the pattern of being higher in the MetS group at all trials except CMIE, where the order was reversed. Fifteen other metabolites presented differences between groups at different trials. Alanine, asparagine, glutamate, glycine, guanine, 4-hydroxyphenyllactate, serine, threonine, tryptophan and xylose were higher in MetS in RE. For glycine, tryptophan and tyrosine, that was also the case in REST and HIE. Eight metabolites showed significant interactions between time and group; of those, hypoxanthine, kynurene and proline were higher in MetS 1 h after exercise. Independent of group, alanine, hypotaurine, methionine, serine, tryptamine and trimethylamine increased 1 h after RE only. Guanine, homocysteine, hypoxanthine, kynurene, lactate, monoisoamylamine and pyruvate increased 1 h after HIE and RE, while hypoxanthine remained elevated 3 h post-exercise. Twelve more metabolites showed differences between trials and time points. Discussion We have found a multitude of diverse responses of the urinary metabolic fingerprint to different types of exercise in men with and without MetS. Our findings suggest the differential stimulation or inhibition of several metabolic pathways of potential physiological relevance and support the value of urinary metabolic fingerprinting in the study of exercise metabolism. SIRTUIN PATHWAYS AND REDOX HOMEOSTASIS: STUDY ON YOUNG AND OLD TWIN COUPLE

GRAZIOLI, E., DIMAURO, D., FANTINI, C., DURANTI, G., BIANCHINI, S., SGRÒ, P., SBRICCOLI, P., SABATINI, S., PARISI, P., DI LUIGI, L., CAPOROSSI, D.

University of Rome

Sirtuins are NAD⁺ dependent deacetylase that play a key role in the regulation of many processes related to homeostasis, such as the regulation of metabolism, apoptosis, DNA repair and inflammatory response. Studies on humans reported a relation between the alteration of their expression and the incidence of various diseases such as metabolic, cardiovascular, cancer and neurodegenerative diseases. Accordingly to literature, the maintenance of their optimal level of activity is considered important to ensure a low risk of pathologies related with the aging process. Indeed, SIRT1 has been correlated with the redox homeostasis maintenance and with the levels of oxidative damage. The aim of this study is to verify the correlation between sirtuins' expression, histone deacetylation, redox status in young and old monozygotic/dizygotic twins couple and the possible relation with a physically active status. For this study we took advantage from blood samples of young (20-40 years old) and old (70-80 years old) monozygotic and dizygotic twin couples, where we analyzed the different expression of SIRT1 and SIRT2, lysine acetylation proteins, Histone H4 acetylation and the protein carbonilation in PBMCs and the plasma level of oxidized and reduced glutathione and malondialdehyde. We also evaluated the intra-pair correlation of all the markers reported above. The twin couples performed functional tests (i.e. Vo2max, 1RM strength test, balance test) and the Baecke questionnaire Physical Activity (General physical activity, Sport and Leisure level) in order to understand if there is a relation between the fitness level, the sirtuins activity and the redox homeostasis balance. Our analysis reported a decreased SIRT1 levels in the Old group that should lead to a reduced response to redox and inflammatory homeostasis and to the stress hormonal response. Interestingly we experienced that the genetic component seems to be influenced by aging in lymphocytes, especially regarding the oxidative system. Life span and other senescent processes are very sensitive to genetic background; this is the reason because the twin model can help to better understand the interaction between genetic and further epigenetic effects in the age.

NOVEL ROLE OF SIRTUIN RELATED MECHANISMS IN OVERLOAD-INDUCE HYPERSTROPHY OF SKELETAL MUSCLE IN RAT

KOLTAI, E., BORI, Z., CHABER, C., DUBOUCHAUD, H., FUNAKOSHI, T., MACHIDA, S., RADAK, Z.

University of Physical Education

Introduction Skeletal muscle is a dynamic organ, which can change its metabolic rate by many fold during intensive contractions. The multi-nucleated myocytes as a result of resistance training can readily increase their size, indeed, the role of satellite cells in this process is still contradictory. The major member of sirtuin protein family, SIRT1 has been implicated as one of the key regulator in cell metabolism, but its involvement in muscle hypertrophy have not been investigated. SIRT1 has been shown to deacetylate eNOS, FOXO1 and activate Akt (Lee and Goldberg, 2013). Therefore, we suggested that SIRT1 can be a potential regulator of prosynthetic and catabolic processes during compensatory hypertrophy of skeletal muscle. Methods Middle aged (15 months) male Wistar rats were used in the study and assigned to control and hypertrophy (N=7) groups. Overload of the plantaris muscle was performed bilaterally via removal of their major synergistic muscles, the gastrocnemius and soleus, as described previously. The surgical procedure was performed under deep anesthesia. The overload period lasted for 2 weeks. Plantaris muscle samples frozen in liquid nitrogen were analyzed by immunohistochemistry, ELISA, western blot and fluorescence technic, and the differences between groups were calculated by t-test ($p<0.05$). Results Fourteen days of overloading resulted more than 30% increase in the mass of plantaris muscle ($p<0.01$) compared to control group. Histochemical evaluation of satellite cell marker, Pax7 proteins showed significantly elevated Pax7 levels in hypertrophy group. The markers of muscle differentiation, MyoD and PCNA levels were significantly higher in hypertrophy group compared to control. The level of NAD dependent SIRT1 increased by hypertrophy and the NAMPT levels showed similar changing pattern. p53 is deacetylated by SIRT1 and the level of acp53 decreased in hypertrophy group. Contrary, the eNOS and Akt levels elevated significantly by muscle hypertrophy, while the FOXO1 protein concentration decreased by this treatment. The changes in the levels of ubiquitin ligase and protein ubiquitination suggest, that during hypertrophy ubiquitin mediated signaling pathway also activated. Discussion Our data suggest that novel regulatory role of SIRT1 in overload-induce hypertrophy of skeletal muscle. The rate of NAD⁺ biosynthesis and the SIRT1 activity - judged by acp53 level - further support the activation of SIRT1-related pathways during hypertrophy. SIRT1 modulates prosynthetic pathways through eNOS, Akt activation and down-regulation of catabolic processes by inhibiting FOXO1 and proteasome's protein degradation. References Lee, D., Goldberg, A.L., 2013. SIRT1 protein, by blocking the activities of transcription factors FoxO1 and FoxO3, inhibits muscle atrophy and promotes muscle growth. EARLY INSULIN RESISTANCE INDUCED BY PHYSICAL INACTIVITY IS ASSOCIATED WITH A REDUCTION IN MUSCLE GLUT4 CONTENT, AND NOT TO DEFECTS IN SKELETAL MUSCLE INSULIN SIGNALING

PIERRE, N., APPRIOU, Z., NAY, K., LEFEUVRE-ORFILA, L., SALIGAUT, D., MARTIN, B., DERBRÉ, F.

Laboratory "Movement, Sport and health Sciences" (M2S), University Rennes 2-ENS Rennes

Introduction Physical inactivity is a major consequence of technological developments and contributes to increase the risk of development of type 2 diabetes, cardiovascular diseases, colon and breast cancer, depression and dementia. Insulin resistance, the hallmark of type 2 diabetes, is becoming a leading cause of death and morbidity in the world. Dramatic reduction of physical activity rapidly induces insulin resistance. Herein, we aim to determine the early molecular events by which physical inactivity affects skeletal muscle insulin sensitivity. Methods To this purpose, young mice were placed in cages with free access to running wheels for seven weeks. Then, wheels were blocked for 10 days to study the effect of physical inactivity. At the end of the protocol, blood was removed to determine glucose and insulin concentrations in fasting state. Due to their role in insulin signaling defects, muscle triglycerides and ceramides levels were determined by UHPLC-ESI-MS/MS. Skeletal muscle insulin sensitivity was assessed by an ex-vivo experiment in which the tibial anterior was stimulated with insulin. In this approach, the phosphorylation states of the insulin receptor substrate 1 (IRS-1) at Ser302 and Akt at Ser473 were assessed by Western blot and used as markers of the insulin pathway. Muscle glucose transporter 4 (GLUT4) mRNA and protein

levels were measured by, respectively, Q-PCR and Western blot. Results and discussion HOMA2-IR index and serum insulin level were higher in inactive than active mice, demonstrating thereby that 10 days of physical inactivity induces insulin resistance. Glucose tolerance (OGTT test) was not different between inactive and active mice. In the ex-vivo experiment, the phosphorylation states of the insulin signaling markers, IRS-1 at Ser302 and Akt at Ser473, were not modified by physical inactivity. Despite an intramuscular triglyceride accumulation in inactive mice, both saturated and unsaturated ceramide levels remained unchanged compared to active mice. Altogether, these results indicate that a short period of physical inactivity does not affect the insulin pathway. GLUT4 mRNA level did not differ between both groups, but GLUT4 protein content was significantly lower in inactive compared to active mice. Consequently, physical inactivity-induced early insulin resistance seems related to a reduction in muscle GLUT4 protein content rather than defects in insulin signaling. DNA METHYLATION AGE IS ASSOCIATED WITH MUSCLE STRENGTH

SILLANPÄÄ, E., ISMAIL, K., OLLIKAINEN, M., KAPRIO, J., LAAKKONEN, E.K., RANTANEN, T., KOVANEN, V., SIPILÄ, S.

University of Jyväskylä

Novel biomarkers of biological aging – telomere length and DNA methylation age – correlate strongly with chronological age across the life course (Chen et al. 2011, Horvath 2013). It is, however, unclear how these measures of cellular wear and tear are associated with muscle strength and functional capacity, which are known to decline with older age and are associated with mortality. We investigated, if leukocyte telomere length (LTL) and DNA methylation age (DNAm age) are associated with physical performance and body composition. 48 monozygotic twin sisters were examined. Relative LTL was measured by qPCR (Ahola et al. 2013). Methylation age (DNAm Age, predicted years) was calculated from the DNA methylation data using the online DNAm age calculator tool (Horvath 2013). Body mass index was calculated from measured weight and height (BMI, kg/m²). Percentage of body fat and total body lean mass was estimated by bioimpedance. Physical performance was measured by grip strength, knee extension strength and 10 m walking test. Data was analysed by regression models using all individuals and within-pair dependency of twin individuals was taken into account using the cluster option (Stata 14). Mean LTL was 0.91 ± 0.15 and mean DNAm age was 58.4 ± 6.6 years, which is slightly lower than chronological age 61.3 ± 5.9 years. Pairwise correlations between twin sisters were high in LTL ($r=0.71$, $p<0.001$, $n=22$ twin pairs) and in DNAm age ($r=0.89$, $p=<0.001$, $n=24$ twin pairs). LTL was not associated with physical performance measures or body composition. Higher DNAm age was associated with higher BMI ($r^2=0.079$, $p=0.045$) and lower grip ($r^2=0.17$, $p=0.001$) and knee extension strength ($r^2=0.23$, $p=0.003$). After adjusting these models for chronological age DNAm age was independently associated with grip strength ($p=0.001$). Intrapair correlations showed that there is a strong genetic impact both in LTL and DNAm age. Present findings suggest that LTL has at most weak associations with body composition and physical performance. A novel estimate of the individual biological aging process, DNAm age, seems to be associated with BMI and muscle strength. Higher DNAm age was associated with lower grip strength independently of chronological age. Whether DNA methylation explains decline in muscle strength with aging needs further studies. OP-BN12 Running Biomechanics 1

CHANGES IN RUNNING KINEMATICS AND KINETICS AFTER A 12-WEEK RUNNING PROGRAM FOR BEGINNERS

MAAS, E., VANWANSEELE, B.

KU Leuven

Introduction Running is a popular and feasible way of becoming physically active. With reported incidences of overuse injuries up to 70 percent¹, the injury risk amongst recreational runners is substantial. In a recently published systematic review by Videbaek et al.², it was reported that novice runners have a higher injury risk compared to more experienced recreational runners. This difference in injury risk may result from differences in loading patterns during running between trained and untrained runners. In our previous study (unpublished results), we found a difference in running style between highly trained and untrained runners. We hypothesize that running kinematics and kinetics change with training. Therefore, the aim of this study is to determine the changes in running kinematics and kinetics following a 12-week running program for beginners. Methods 17 novice runners (11 females, 6 males) underwent a 3-dimensional running analysis before and after following a running program. This program consisted of 12 weeks of three running sessions per week, in which the training distance was increased weekly. Overground running kinematics and kinetics were measured using a 10-camera Vicon system (Vicon, Oxford, UK) with a full-body marker model, and a force platform (AMTI, Watertown, US). Joint angles and moments of the hip, knee and ankle of one leg per subject were calculated in Vicon Bodybuilder and averaged over three stance phases. Peak joint angles, moments and ground reaction forces (GRF) were analyzed using a paired-samples t-test. Results After the running program, runners ran with less hip adduction during stance phase (mean difference 1.3 degrees, SD = 2.5, p = 0.049). There was no difference in other joint angles and joint moments between the pre- and posttest. Peak vertical GRF was decreased (mean difference 0.09 bodyweight, SD = 0.1, p = 0.025). Discussion/conclusion This study showed that with training, novice runners decreased their hip adduction and peak vertical GRF. Although the absolute differences are small, both variables are associated with injury risk^{3,4}. These findings support the hypothesis that runners change their running kinematics and kinetics with training in a way that reduces injury risk. References 1 Ferber R et al. THE EFFECT OF SEX, PERFORMANCE STANDARD, AND SPEED ON RUNNING ECONOMY

BLACK, M.I., HANDSAKER, J.C., ALLEN, S.J., FORRESTER, S.E., FOLLAND, J.P.

Loughborough University

Introduction The efficiency with which metabolic energy turnover can be converted into forward locomotion i.e. running economy is an important determinant of endurance running performance. Traditionally, running economy has been defined as the oxygen required to maintain a given speed or to cover a given distance. However, it is now known that the oxygen cost is not reflective of the underlying energetic demands and, thus, is an invalid measure of running economy (Fletcher et al. 2009). Due to the methodological inaccuracies of previous investigations, the influence of sex, performance standard, and speed on running economy is unclear and warrants further investigation. **Methods** Following ethical approval, 24 elite (males, n=14; females, n=10) and 73 recreational (males, n=35; females, n=38) runners completed a discontinuous incremental treadmill test for the determination of the caloric unit cost of submaximal running (Erun, kcal.kg⁻¹.km⁻¹), speed at lactate turnpoint (sLTP) and VO_{2max}. Fingertip capillary blood samples were obtained at the completion of each 4 min stage, and breath-by-breath pulmonary gas exchange data were measured continuously throughout. **Results** For the whole cohort, males and females had similar Erun when measured over the same range of running speeds (8-11 km.h⁻¹, P=0.345), or when subsamples of runners were analysed between 8-17 km.h⁻¹ (all P>0.05). The elite group had a lower Erun at each absolute (-10%) and at each relative (-19% to -7%) running speed compared to the recreational group (all P<0.001). Erun of the elite group was significantly influenced by speed whether expressed in absolute or relative terms (both P<0.001). For example, post hoc tests revealed a 'u-shaped' relationship in which Erun was greater for low (8-10 km.h⁻¹) and high (17 km.h⁻¹) speeds compared to moderate speeds (11-16 km.h⁻¹). A similar profile of response was observed when speed was expressed relative to the sLTP. **Discussion** The results demonstrate that when running economy is expressed as the caloric unit cost of running that: 1) there is no sex-specific difference; 2) elite endurance runner's exhibit better running economy than recreational endurance runners, and; 3) there is an optimal speed for economical running. ARE TWO-DIMENSIONAL MEASURED PEAK FRONTAL PLANE JOINT EXCURSIONS RELATED TO THREE-DIMENSIONAL MEASURED KINEMATIC PROFILES DURING RUNNING?

DINGENEN, B., STAES, F.F., SANTERMANS, L., STEURS, L., GEENTJENS, J., EERDEKENS, M., PEERS, K.H.E., THYSEN, M., DESCHAMPS, K.

KU Leuven

Introduction: The ability to accurately assess kinematics during running in clinical settings is an essential component in the process of preventing running (re-)injuries. The primary purpose of the present study was to investigate the temporal relationship between two-dimensional (2D) measured peak frontal plane joint excursions and three-dimensional (3D) measured kinematic profiles during the stance phase of running in elite athletes. The second purpose was to assess the intra- and intertester reliability of the 2D measured joint angles. **Methods:** Fifteen elite injury-free athletes (6 males, 9 females; age: 18.79±1.67 years) participated in the study. All participants completed 4 overground running trials with a self-selected speed. Maximal contralateral pelvic drop, hip adduction and knee valgus angles were measured through 2D video analysis during midstance. Simultaneously with the 2D video analysis, 3D motion analysis was performed to measure kinematic profiles of the contralateral pelvic drop, hip adduction and knee valgus angles throughout the whole stance phase of running. Both legs were tested. The mean of 4 trials was calculated for both 2D and 3D outcomes. One-dimensional statistical parametric mapping linear regression was used to investigate the temporal relationship between peak 2D angles and 3D kinematic profiles. The 2D videos of the right legs of all athletes were analyzed twice by two independent testers. Intra-class correlation coefficients were calculated to assess the intra- and intertester reliability of the 2D measured angles. **Results:** The 2D measured contralateral pelvic drop and hip adduction angles were significantly related to the corresponding 3D measured kinematic profile during respectively 0 to 82% (P<0.0001) and 22 to 76% (P=0.0095) of the stance phase. No significant relationships were found for 2D and 3D measured knee valgus. The intraclass correlations coefficients showed excellent intra- and intertester reliability for the 2D measured angles (0.90-0.99). **Discussion:** Two-dimensional measured contralateral pelvic drop and hip adduction angles were significantly related to their corresponding 3D measured kinematic profiles during the majority of the stance phase. Furthermore, these 2D angles can be measured with excellent intra- and intertester reliability using 2D video analysis. These findings support the use of clinical-friendly frontal plane 2D video analysis to measure contralateral pelvic drop and hip adduction angles during running as an alternative methodology for 3D motion analysis. THE EFFECT OF AN INNOVATIVE NON-MOTORIZED TREADMILL ON WALKING AND RUNNING BIOMECHANICS

PETRONE, N.1, MARCOLIN, G.1, NARDON, M.1, PAVAN, P.1, BENVENUTI, P.2, ZANUSO, S.3

1: UNIPD (Padova, Italy), 2: University of Verona (Italy), 3: University of Greenwich (UK)

Introduction Walking and running on a treadmill is a diffused sporting activity for wellbeing and sports specific training. Developers of fitness equipment put their efforts in enhancing the flexibility of machines that multiplies the exercises, providing different combination of effort and ambient biofidelity. Traditional motorized treadmills can be compared with non-motorized ones (Sinclair et al., 2013), flat surfaces with curved surfaces (Smoliga et al., 2015). Aim of the study was to study the effect on walking and running biomechanics at different speeds performed by a group of subjects in three different treadmills: a conventional motorized flat treadmill (Technogym Artis TRD), a passive curved treadmill (WOODWAY Curve) and an innovative tunable non-motorized curved treadmill named SkillMill™ (SKM). **Methods** Surface EMG of 12 muscles on right hand side of each subject were investigated applying 2 pre-gelled bipolar electrodes on each muscle: Tib.Ant.(TA), Gastr. Med. (GAM), Vastus med.(VAM), Biceps fem. (BFCL), Rectus fem. (RF), Gluteus max. (GLMA), Rectus abd. (RA), Adductor (ADCL), Erector spinae (ERS), Pect. major (PECM), Lat. dorsi (LD), Triceps brach. (TBCL). Kinematics data were collected by means of an optoelectronic system (BTS), using 12 reflective markers placed in specific bony landmarks. Eight healthy male subjects with similar level of fitness were involved. Each one was asked to walk at 6 km/h, run at 12 and 18 km/h. Walking against an additional resistance on the SKM treadmill (PWLK) was also included in the tests. EMG signals were rectified, integrated with a moving window of 200 ms, filtered at 6 Hz and normalized to the gait cycle. Signals were averaged over 5 consecutive cycles, defined between two consecutive right heel strikes. **Results** Walking on non-motorized curved treadmills resulted in an increased ROM at the ankle (+10%) and the trunk (+50%); on the contrary, when running on the curved treadmills trunk ROM decreased significantly. The trunk mean forward leaning angle increased on curved treadmill, in particular with high resistance on SKM (PWLK). Peak Muscle activation resulted consistently higher in GASM, VAM, BFCL, GLMA, during PWLK than other conditions. When running on SKM at moderate and high speed, GASM and GLMA showed higher

average activations than on TRD. Discussion Results highlight the ability of an adjustable non-motorized treadmill in enhancing the muscle activation on antigravitational muscles; the combination with a curved surface widens the range of motion at the ankle but reduces the trunk ROM when running. This can be correlated with lower impact loads at the feet, as reported by the subjects, due to the curved treadmill surface. References Fellin, R.E., Manal, K., Davis, I.S. RELIABILITY OF BIOMECHANICAL INJURY INDICATORS THAT UNDERPIN RUNNING GAIT

DISS, C., MAY-HEGGIE, A.

University of Roehampton

Introduction The aim of the study was to evaluate the reliability of discrete biomechanical running gait measures associated with injury. In addition, waveform analysis was conducted to examine the similarity between data sets from different data collection sessions. Methods Ten participants performed 10 running trials ($3.60 \pm 0.18\text{m/s}$). Lower limb marker coordinate and ground reaction force data were collected using a 12 camera infra-red system (100Hz) synchronised with a force plate (1000Hz). The data collection protocol was repeated 1 week later. ANOVA was used to determine differences between the group means from each data collection session for discrete vertical force (VGRF) measures, lower body joint angles and moments. For both data collection sessions the reliability (R) of each measure was determined when the group mean was calculated from 10 trials/participant and 1 trial/participant. The Spearman-Brown prophecy formula established the number of trials required to achieve $R>0.90$ for each measure. Statistical parametric mapping (SPM) was used to analyse waveform similarities throughout the stance phase of running gait. Results No significant differences were found between each data collection session for all discrete measures examined. An $R>0.95$ was achieved for all discrete measures when the group means were determined from 10 trials/participant. Reducing the trials to 1/participant caused a decrease in R for all measures particularly the peak hip flexion moment and hip, knee, ankle sagittal plane ranges of motion. To achieve $R>0.90$ across all measures a minimum of 5 trials/participant were required however for the rate of vertical force to first peak, knee flexion and adductor moments only 1 trial/participant was required. The SPM analysis showed significant differences in the VGRF during the first 20% of the stance phase. Discussion Excellent reliability ($R>0.95$) of biomechanical indicators of injury can be achieved when the mean of ten trials/participant are used which can then be accurately used to enhance the understanding of running related injuries. In situations where fewer trials are available we recommend a minimum of five to achieve $R>0.90$. Waveform analysis provided further insight on the continuous biomechanical changes throughout the stance phase of running. The VGRF differences in the first 20% of the stance phase between the two data collection sessions further supports that the impact phase during running is 'an independent phenomenon' (Bobbert et al., 1991) and that the attenuation of the continuous forces remain inconclusive. Runners demonstrate high variability and seem to develop extensive adaptive capability where impact is concerned. References Hamill J, Haddad J, McDermott W. (2000). J App Biomec, 16, 407-418. OP-BN09 Postural Control

THE INFLUENCE OF POSTURAL THREAT AND TASK DIFFICULTY ON CORTICOSPINAL EXCITABILITY AND SHORT-INTRACORTICAL INHIBITION

KELLER, M.1, TOKUNO, C.2, CARPENTER, M.G.3, TAUBE, W.1

1: SMS (Fribourg, Switzerland), 2: DOK (Brock, Canada), 3: SOK (Vancouver, Canada)

Introduction When individuals experience a potential threat to their balance, they respond by standing with less sway variability but at a higher sway frequency (Adkin et al., 2000). While this "stiffening" strategy is believed to arise through spinally-mediated mechanisms (Sibley et al., 2007), no studies have attempted to examine whether processes at the cortical level also adapt in situations of postural threat. Therefore, our participants completed three balance tasks of varying difficulty at ground level (low threat) or 3 m above ground level (high threat). This combination of balance tasks and surface heights enabled the determination of whether cortical excitability was altered through changes in postural task difficulty, postural threat or both. **Methods** We examined the interaction between postural threat (low threat vs. high threat) and balance task (supported standing vs. normal standing vs. unstable standing) on corticospinal excitability (MEP) and short-interval intracortical inhibition (SICI) in the soleus (SOL) and tibialis anterior (TA) muscles. **Results** MEP amplitudes of SOL were influenced by task ($p<0.001$) and height ($p=0.03$) main effects. Not only were SOL MEPs larger during the low compared to the high height condition, post-hoc tests revealed that MEPs were different between all three standing tasks. The largest test MEPs occurring during the unstable, followed by the free standing and supported standing condition. MEP amplitudes in TA were solely affected by a task main effect ($p<0.001$). MEPs obtained during the unstable condition were larger than those from the free and supported conditions. The amount of SICI was influenced by a task main effect both in SOL ($p=0.01$) and TA ($p<0.001$) but not by height. In SOL, there was a decrease in SICI during the unstable compared to the free standing condition ($p=0.019$) as well as a trend towards a decrease during the free compared to the supported standing condition ($p=0.077$). Post-hoc analyses in TA indicated reduction of SICI during the unstable compared to both the free ($p=0.005$) and supported ($p=0.003$) standing conditions. **Discussion** Our data suggest that the presence of postural threat does alter corticospinal excitability, indicated by modulation of the MEP. However, based on the SICI data, it is unlikely that intracortical inhibitory processes are responsible for this modulation. Intracortical inhibition seems rather to be limited to situations when the physical constraints, i.e. the task difficulty, of a postural task are modified. POSTURAL CONTROL IN THE CONTEXT OF GOAL-DIRECTED ACTION

LIPPENS, V., NAGEL, V.

University of Hamburg

Introduction In opposite to the classical "quite stance"-paradigm of research on postural control, Stoffregen and his colleagues (e.g., Stoffregen et al., 2007) supposed from an ecological point of view that postural control is functionally integrated into a context of action, which is specified by a superordinate task or goal ("suprapostural tasks"). Results of a meta-analysis (Bund & Lippens, 2009) clearly support the ecological approach to human postural control. Postural control is not an end in itself! Methods In general, our experimental settings in investigating balance performance are similar to those of Stoffregen et al. (2000), except that we prefer the more challenging postural control conditions on an unstable platform (@ MFT S3 check system; e.g., Raschner et al., 2008). The participants (N= 24; age=~ 24 y) underwent randomized repeated trials (without and with suprapostural task: searching for letters in a text) of monopodal standing on the balance-measurement platform. Results An ANOVA of the balance data (index of sensomotoric) revealed a main effect for the factor task ($F(1, 22) = 13.1$, $p = .00$, $\eta^2_{\text{part.}} = .37$). No effect for the sequencing of the trials was found. No differences in performance of the suprapostural task were obtained. Discussion According to other recent studies (e.g., Lippens et al., 2007) these results show a considerable effect of suprapostural tasks on balance performance. Movement patterns emerge according to personal, environmental and task constraints (Newell, 1986). The modulation of task and environmental constraints is an underestimated method to investigate appropriate movement task solutions for postural control. The reduction of body sway, during the performance of a visual suprapostural task, is consistent with the concept of functional integration. The postural performance is "nested" within other task goals" (van Emmerik 2007, p. 34; cf. Riccio 1993).

INDIVIDUAL POSITION VARIABILITY UNDER DIFFERENT CONDITIONS TO ASSESSMENT POSTURAL ANALYSIS WITH THE AID OF RASTER STEREOGRAPHY

BOHLMANN, M.1, MAIER, M.2, SEIBERL, W.1, SCHWIRTZ, A.1

1Department of Biomechanics in Sports Technical University of Munich, Germany, 2Faculty of Medicine Ludwig-Maximilians-Universität Munich, Germany

Introduction Raster stereography is a common method to measure 3d-surfaces to assess human posture. Currently, there is no standard for positioning of subjects in front of the device. In addition, the position variability of subjects in front of a measurement device has not been investigated and no norm data is documented. The visual system as well as the positioning of the feet play an important role for postural control processes. Research is needed to determine any intervention effects on posture beyond natural variability. The aim of the study was to define natural positioning variability of subjects. In addition, potential influences of the visual system and the feet positioning on positioning variability were of interest. Methods In this study 3d back shape analysis (MiniRot-Kombi, abw GmbH) of 15 subjects (9 ♀, 6 ♂; 40.3 ± 11 yrs; 172.7 ± 10.8 cm) were assessed in 4 different randomly arranged conditions: eyes open and closed and standardized foot position or not. Based on 6 predefined anatomical landmarks, 6 postural parameters were determined: deviation of the spine in the frontal plane, deviation of the spine in the sagittal plane, difference of the angulus inferior left and right in y-axis and in z-axis, differences of the SIPS left and right in y-axis and in z-axis. The position variability was defined by means of mean standard deviation (SD) for one parameter over 10 repeated measures per condition. A potential influence of the condition on the variability of the six parameters of the back surface was tested using linear mixed model statistics ($\alpha \leq 0.05$). Results The mean position variability is ranging for the deviation of the spine in the frontal plane from $2.4 \text{ mm} \pm 0.71$ to $3.06 \text{ mm} \pm 2.4$, for the deviation of the spine in the sagittal plane from $4.96 \text{ mm} \pm 1.88$ to $5.91 \text{ mm} \pm 2.29$, for the difference of the angulus left and right in y-axis from $1.69 \text{ mm} \pm 0.73$ to $2.06 \text{ mm} \pm 1.51$ and in z-axis from $3.1 \text{ mm} \pm 0.96$ to $3.71 \text{ mm} \pm 1.03$ for the difference of the SIPS in y-axis from $0.43 \text{ mm} \pm 0.2$ to $0.53 \text{ mm} \pm 0.28$ and in z-axis $1.33 \text{ mm} \pm 0.71$ to $1.55 \text{ mm} \pm 0.59$. Statistics did not identify any differences of positioning variability between tested conditions. Discussion From the results we can conclude that our tested conditions have no influence on the variability of posture, defined by six parameters of the back surface. Therefore, it is optional and may be up to preference if 3d back shape analysis is performed in a standardized foot position or closed eyes. The data of natural position variability can help to objectively identify effects of aids and supporting tools in order to optimize human posture. Contact meike.bohlmann@tum.de

CHANGES OF POSTURAL STABILITY DURING A REPEATED KARATE KICK TASK IDENTIFIED BY MEANS OF SUPPORT VECTOR MACHINES

EEKHOFF, A., ARAGONÉS, D., HORST, F., SCHÖLLHORN, W.I.

Johannes Gutenberg University Mainz

INTRODUCTION Technique training in Karate is usually based on movement repetitions. Hundreds of repetitions within one training session are not uncommon. Alterations of kicking movements within 20 repetitions have been reported by Quinzi et al. (2015). Especially when analyzing kicks, the supporting leg is a relevant factor for the movement result. The aim of this study is to identify changes of center of pressure (COP) variables of the supporting leg when executing a frontal karate kick (mae-geri) during fatigue accumulation by means of support vector machines (SVM). METHODS Thirteen experienced (minimum brown belt) karate practitioners (4 women, 9 men) performed 9 training sets of 60 kicks. The period of rest between the sets was 90 s. Each set consisted of alternating subsets of 10 repetitions of each leg. All kicks were performed at a frequency of 1 kick/2 s at submaximal intensity without impacting a target. Subjects stood with each foot placed on different force platforms (Kistler, Switzerland, 1000 Hz). COP data of the supporting leg was determined, low-pass filtered (30 Hz) and then discrete values (direction dependent and independent ranges, velocities and traces, and angular data) were calculated. Classifications of subjects, sets within subjects and subsets within sets were performed by applying SVM with linear kernel. The leave-one-out method was used for cross-validation. RESULTS Mean classification rates are considerably higher than expected by chance. The mean subject classification rate (chance: 7.7 %) is 69.3 % and varies for individuals from 13.8 % to 98.1 %. SVM application on sets (chance: 11.1%) resulted in a mean classification rate of 22.9 % for the right kicking leg (left: 23.8 %). The first sets show the highest classification rates (right: 42.6 %, left: 40.6 %), but rates decrease until the sixth set (right: 12.6 %, left: 11.0 %). For later sets the values increase. Misclassification occurred mainly to temporally adjacent sets. The classification rates of the subsets (chance: 33.3 %) were 42.7 % (41.0 %) for the mean and 46.4 % (43.5 %), 39.7 % (37.9 %) and 42.0 % (41.5 %) for subsets 1, 2 and 3, respectively. DISCUSSION Results of subject classification underline the relevance of individuality in technique execution. The relatively high classification rates of the first set when compared to later sets might be an effect of fatigue, but also of familiarization. Although COP variables do not discriminate perfectly the different sets, a time dependency is shown. Within sets, fatigue mainly has an effect on postural stability between the first and the

remaining subsets. REFERENCES Quinzi F, Camomilla V, Di Mario A, Felici F, Sbriccoli P (2015). Int J Sports Physiol Perform. Epub ahead of print. CONTACT eekhoff@uni-mainz.de

AGE DIFFERENCES IN POSTURAL CONTROL ANALYZED VIA A PRINCIPAL COMPONENT ANALYSIS OF KINEMATIC DATA

HAID, T.H., FEDEROLF, P.

University of Innsbruck

Introduction Postural control plays a major role in sports and in everyday life. It is achieved by coordinating the movements of all body segments. Age differences in postural control were observed, for example, as decreased stabilometric entropy (Kang et al. 2009) indicating reduced complexity of postural movements. However, what specific changes occur due to aging in the coordination or control of the postural movements remains unclear. In the current study, we hypothesized that aging leads to an altered coordinative structure of postural movements (H1); fewer movement adjustments (H2); or more irregular timing of these corrections (H3). Methods Twenty young (ages 20-30; 14 females and 6 males) and 20 older (55-70; 15 f, 5 m) volunteers performed a 100s-tandem stance. Their postural movements were quantified using 37 retroreflective markers captured at 240 Hz by an 8-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA, USA). The marker data was submitted to a principal component analysis. H1 was tested by comparing the subject specific relative variances (Federolf et al. 2013); H2 and H3 by comparing the number of zero-crossings $N(k)$ and the standard deviation of the time between zero-crossings $\sigma(k)$ of the k-th principal postural acceleration (Federolf, 2016). Results The first 12 principal movements explained over 98.5% of the total postural variance. The subject specific relative variances showed significant differences in the 2nd (lateral ankle sway; +3.4%; p=.035), 9th and 11th (both combined head-elbow strategies; -0.7% and -0.4%; p=.020 and p=.033) components. The older volunteers showed decreased N and increased σ in the postural acceleration quantifying lateral ankle sway (N2: -2.6%, p=.038; σ_2 : +20.7%, p=.028), upper body rotation (N5: -2.5%, p=.043; σ_5 : +6.4%, p=.022) and a coupled knee- and hip flexion (N6: -2.7%, p=.025; σ_6 : +8.1%, p=.016). Discussion Our results supported H1, H2 and H3. Relative variance quantifies how much specific movement components contribute to the overall postural variations. The principal postural accelerations represent the neuromuscular control of these movement components. Our results therefore suggest that aging changes the coordinative structure of the postural movements and leads to fewer and more variable adjustments in the neuromuscular control of some movement components. Our study uses a novel approach to investigate neuro-mechanical control, allowing to identify what aspects of postural movements are affected by age. We expect that these results will help focusing fall prevention exercises to better address age-related deficits. References Federolf P. et al., (2013). J Biomech. 46(15), 2626-33. OP-PM71 Injury Prevention & Rehabilitation

INJURY BURDEN IN FOUR SPORTS OF ADOLESCENT ELITE ATHLETES: A 52-WEEK PROSPECTIVE STUDY

VON ROSEN, P., FROHM, A., HEIJNE, A.

Karolinska Institutet, Department of Neurobiology, Care Sciences, and Society (NVS) Division of Physiotherapy, Huddinge, Sweden

Background: The injury burden of adolescent elite athletes is in most sports limited or unknown, due to lack of prospective long-term injury surveillance reports. Objectives: To describe injury patterns in terms of injury type, location, prevalence/incidence, recurrence, relative impact of injuries (severity grade), time to first injury in adolescent elite athletes, competing in handball, athletics, orienteering and cross-country skiing. Methods: 262 adolescent elite athletes (age range 15-19) were weekly, over 52 weeks, monitored using a web-based questionnaire. Results: In total, 290 injuries were identified, including 27.6% recurrent injuries. Female athletes reported significantly higher prevalence of injury ($P<.001$) and substantial injury ($P<.001$) than male athletes. The injury incidence rate and average weekly injury prevalence was for handball 4.7/1000 hours exposure to sports, 47.2%; athletics 4.1/1000 hours exposure to sports, 33.6%; orienteering 5.7/1000 hours exposure to sports, 26.0%; cross-country skiing 2.5/1000 hours exposure to sports, 21.1%. A higher proportion of severe injuries, defined as injuries resulting in absence from normal training for at least one month, occurred in handball (43.2%), orienteering (41.2%), athletics (38.4%) compared to cross-country skiing (12.5%). In addition, 16.2% and 7.7% of all injuries resulted in more than six months from normal training in handball and athletics, respectively. The average weekly prevalence of severe injury was 28.6% in handball, 17.6% in athletics, 8.9% in cross-country skiing and 8.2% in orienteering. Most injuries occurred in the lower extremity (78.7%). Knee injuries had the most serious injury consequences in handball players (severity score: 12.86) and injuries in the foot the most serious injury consequences in athletics, orienteering and cross-country skiing (severity score: 1.47-3.60). Handball players had a significantly ($P<.001$) shorter time to first injury, median 9 weeks, compared to athletes of other sports, median 20-41 weeks. Conclusions: An alarming high number of adolescent elite athletes are weekly injured, resulting in serious consequences regarding sports participation, training or performance level. The highest injury burden was found in handball and athletics. Directing preventive interventions on knee and foot injuries will target both the majority and the injuries with the most serious consequences.

SPORT INJURIES IN MOTORCYCLE WORLD CHAMPIONSHIP/MOTOGP: OUR EXPERIENCE IN A PRELIMINARY STUDY.

SCHIAVI, P., ZASA, M., POGLIACOMI, F., POLO, R., CECCARELLI, F.

university hospital of parma

Introduction. The authors report all the Clinica Mobile interventions for musculoskeletal traumas during the MotoGp World Championship 2013/2014. The Clinica Mobile is a medical service which follows all the races of the MotoGp World Championship to treat pilot for any pathology. We evaluated epidemiological and demographic data of each trauma and the short-term outcome of the patients. Methods. All the reports of orthopedic intervention during the 2013/2014 World Championship were collected. The authors distinguished 2 groups: traumatic events (A) and chronic musculoskeletal pathology (B). For each acute trauma were analyzed the following data: circuit, category of the pilot, type of competition (test/race), weather (wet or dry track), open/closed injury, site of trauma. An univariate and multivariate statistical analysis was performed on data to individuate the presence of risk factor of trauma. Results. 204 patients for injury and 176

patients for chronic musculoskeletal pathology were treated. In Group A were included: 51 open and 46 closed upper limb injury, 21 open and 34 closed lower limb injury. In 20 cases a fracture was diagnosed involving: acetabulum (1 pt), tibial diaphysis (1 pt), metatarsal bone (2 pts), heel (1 pt), foot phalanx (2 pts), proximal ulna (2 pts), distal radius (5 pts), metacarpal bone (3 pts), hand phalanx (5 pts). Nine patients were affected by a joint dislocation which interested following joint: gleno-humeral (2 pts) acromion-clavicular (3 pts), elbow (2 pts), metacarpal-phalangeal (2 pts). In 3 cases patients were treated for a mild traumatic brain injury and in 7 cases for spine injury. The distribution of acute trauma in the different category of pilot was as following: 91 cases in Moto3, 68 cases in Moto2, 45 cases in MotoGP. No single circuit resulted statistically significant as more dangerous. At statistical analysis the probability of acute trauma resulted higher with a wet track ($p=0.035$) and during the race ($p=0.028$). At multivariate analysis was identified as predictive factor for a higher risk for acute trauma the membership to Moto3 category ($p=0.041$). Discussion. Musculoskeletal traumas are one of the most frequent events during Motorcycle World Championship. The circuits have a similar rate of accident, instead the univariate analysis shows that the probability of injury is higher with a wet track and during the race. The multivariate analysis highlighted that the Moto3 category can be considered as a predictive factor for acute trauma.

THE HEALTH AND INJURY PROFILE OF AUSTRALIAN COMPETITIVE SURFERS

LYSTAD, R.P., SWAIN, M., BURGESS, A.

Macquarie University

Introduction Surfing is a popular and rapidly expanding sport worldwide. Its popularity notwithstanding, there is a scarcity of published data elucidating the health and injury profile of competitive surfers. The objectives of this study, therefore, were to describe the health and injury profile of Australian competitive surfers. Methods All registered participants at the Australian Surfing Titles (Coffs Harbour, August 2014), aged 18 years or older, were invited to complete an online survey administered via SurveyMonkey. The survey comprised 51 questions distributed across three sections, namely: (1) demographic information, including details about surfing activities; (2) health-related quality of life using the Short Form health questionnaire; and (3) surfing injury history. Descriptive statistics were used to describe the responses to the survey items. The injury incidence rate (IIR) per 1000 hours was calculated with a 95% confidence interval (CI) using standard methods. Injuries were classified according to the Orchard Sports Injury Classification System version 10, and presented as proportions by anatomical region and type of injury. Results The sample consisted of 228 (77% male) adult Australian surfers with mean age of 36.1 (sd 13.2; range 18-71) years and a mean body mass index of 24.7 (sd 2.7; range 17.3-31.3). The mean number of years of surfing experience was 20.0 (sd 14.0; range 1-55) years, while the mean number of hours of surfing per week was 9.1 (sd 6.8; range 0-50). The estimated overall IIR was 4.1 (95%CI 3.6-4.7) per 1000 hours of exposure. The most commonly injured body regions were the lower back, foot, knee, and ankle; while the most common types of injury were abrasion, laceration, muscle strain, and contusion. Discussion This is one of the largest studies of the health and injury profile of Australian competitive surfers conducted to date. It reveals that competitive surfers report similar health-related quality of life as the general population. Although the present study highlights a substantial injury problem in the sport, the estimated IIR is lower than that previously reported in competitive surfers in the United Kingdom (Nathanson et al., 2007). The present study also reveals a higher burden of lower back injuries compared to previous reports (Furness et al., 2015; Nathanson et al., 2007). Further efforts are required to prevent and reduce the burden of injuries in surfing. References Furness J, Hing W, Walsh J, Abbott A, Sheppard JM, Climstein M. ANALYSIS OF THE HAMSTRING MUSCLE ACTIVATION DURING TWO INJURY PREVENTION EXERCISES

MONAJATI, A., NACLERIO, F., LARUMBE-ZABALA, E., GOSS-SAMPSON, M.

University of Greenwich

Introduction: Hamstring injury is one of the most common injuries within football players (Woods, C., et al, 2004). Many hamstring exercises have been proposed to reduce the risk of hamstring strain injury in team sports (Arnason, A., et al, 2008; Goldman, Elliott F., et al, 2010). The aim of this study was to perform an electromyographic and kinetic analysis of two commonly used hamstring eccentric strengthening exercises; Nordic curl (NC) and Ball leg curl (BLC). Method: Muscle activation during a maximum isometric voluntary contraction of the knee flexors was measured and used as a reference value. Ten female football players performed 3 repetitions of both NC and BLC, whilst knee angular displacement and activation of biceps femoris (BF) and semitendinosus (ST) were monitored. Results: No significant difference was found between BF and ST activation. Additionally the activation of the ST was higher at the closest knee angles ($>40^\circ$) in NC compared to BLC ($p=.003$). Similarly, BF showed a non-significant trend ($P=0.06$) to produce a higher activation during NC [closest knee angles ($>40^\circ$)] in comparison to BLC. At the knee open angles ($<40^\circ$) no significant difference was observed between two exercises. Hamstring muscles activation during NC increased over the first 60° (100° to 40°) of knee flexion from 30% to 77% of MVIC and then decreased (from 77% to 27% MVIC) during the last 40° of knee flexion.. Conclusion: Overall, BF and ST showed similar levels of activation during both NC and BLC. Although the overall hamstring muscles activation during NC was higher than the observed during the BLC, the level of activation during the knee open angles (where majority of hamstring injuries occur) was similar. During NC, the degree of hamstring muscle activation is highly influenced by the range of motion, meaning, activation during the open ($<40^\circ$) and close ($>40^\circ$) knee angles are distinctly different. This needs to be taken into consideration when designing an injury prevention program. 1- Woods, C., et al. NEGOTIATING A CHALLENGING WALKING SURFACE DEMANDS GREATER VISUAL ATTENTION BOTH PRIOR TO AND DURING LOCOMOTION IN OLDER COMPARED TO YOUNG FEMALES

BAMPOURAS, T., HAY, A., DEWHURST, S.

University of Cumbria

Introduction Negotiating obstacles is an additional challenge during locomotion which may cause falls in older adults (Begg and Sparrow, 2000). Challenging environmental conditions such as uneven walking surfaces make necessary to rely on visual information for a successful passage. Gaze fixations with regards to targeted footfalls are known to differ between young and older individuals with older

giving more attention to footfalls and obstacle avoidance (Chapman and Hollands, 2006). The present study aims to determine how both young and older females extract information from the environment both prior to and during locomotion. Methods Six young (20 ± 2 years) and six older (73 ± 7 years) healthy females without visual, gait or balance deficits were presented with two 7 m walkways (even and uneven). The uneven walkway presented a variety of challenges replicating possible urban terrains including kerbs and angled pathing. Visual fixations were quantified using eye tracking equipment (Tobii Glasses 2). Duration, was defined as the total time spent fixating on any part of the walkway, and frequency, as the total number of fixations on any part of the walkway. Fixations duration and frequency were compared between age groups for each walkway and for both the pre-movement scanning phase (SCAN) and during locomotion (WALK). Due to the small sample size, Mann-Whitney U test was used for between group comparisons, with Holm-Bonferroni correction for repeated pairwise comparisons and presented as mean \pm SD. Results Results show that older adults had a significantly higher total fixation duration and frequency during both SCAN and WALK for the uneven walkway (SCAN duration, 696 ± 330 vs 1841 ± 778 ms; $p=0.024$, frequency: 3.5 ± 1.8 vs 8.5 ± 2.1 ; $p=0.024$, for young and older, respectively; WALK duration: 1365 ± 1804 vs 4534 ± 1643 ms; $p=0.024$, SCAN frequency: 9.8 ± 4.9 vs 21.3 ± 8.3 ; $p=0.03$, for young and older, respectively). There was no difference between the groups for the fixations on the even walkway. Discussion The more challenging walkway demanded greater visual attention from the older adults compared to the young both in preparation for walking and during. This suggests that more visual information is needed by the central nervous system of the older individuals, to both help plan and guide limb movement to allow successful negotiation of the obstacles presented. EFFECTS OF AEROBIC EXERCISE ON DTI PARAMETERS OF AMNESTIC MCI

TEIXEIRA, C.V.L., REZENDE, T.J.R., WEILER, M., NOGUEIRA, M.H., DALANEZE, V.C., JOAQUIM, H.P.G., TALIB, L., FORLENZA, O., SCRIPTORE, G., SILVA, M.P.F., FERNANDES, P.T., NECHIO, P.E., CENDES, F.

UNICAMP

Balthazar, M.L.F. Introduction: The cognitive changes in aMCI can be associated to the neurodegeneration of Alzheimer's pathology, such as white matter atrophy. Increasing evidence demonstrates that physical activity is an important modifiable factor not only for cardiovascular fitness, but also for brain health. Therefore, the aim of this study was to analyze possible effects of 6 months of aerobic training on structural connectivity of aMCI with CSF biomarkers. Methods: 19 aMCI subjects were diagnosed using the core criteria of the NIA/AA for MCI and presented positive CSF biomarker. All of them underwent MRI procedure, which data was required on a 3.0T MRI Philips Achieva scanner. They were divided into Aerobic group AG (who practiced aerobic exercise 3x/week for 6 months with a group at our institution) and control group CG (who were stimulated to practice physical exercise by themselves). Aerobic fitness was assessed by graded maximal exercise testing on a motor-driven treadmill. For WM analysis, we used the Tract-based-spatial-statistics (TBSS) method (<http://fsl.fmrib.ox.ac.uk/fsl/fslwiki/TBSS>) to compare the diffusion parameters maps (fractional anisotropy FA, medial diffusivity MD, radial diffusivity RD, axial diffusivity AxD) between times. Results: We found an increase in FA and AxD values for AG group after 6 months of intervention while CG had a decrease in those parameters, in corpus callosum, forceps major, corticospinal tract, inferior fronto-occipital fasciculus, inferior and superior longitudinal fasciculus and cingulum. In the same areas, AG presented a decrease in MD and RD values while CG showed increased values. Discussion: Our results showed a positive influence of aerobic intervention on DTI parameters. Higher FA values shows better WM integrity. While higher MD and RD values mean alterations in the membrane density and desmyelinization, respectively. Studies have reported positive relation between aerobic fitness and WM integrity in cognitive normal old (Tseng et al., 2013; Johnson et al., 2012; Marks et al., 2007), especially in the areas our study showed improvement. Also a negative relation between aerobic fitness and MD and RD (Song et al., 2002), corroborating to our results. Conclusions: 6 months of aerobic exercise have positive influence on DTI parameters. EXERCISE INDUCED AMELIORATIONS IN LOCOMOTION OF PATIENTS WITH ALZHEIMER'S DISEASE.

PEDRINOLLA, A.M., VENTURELLI, C., FONTE, D., MUNARI, M., GANDOLFI, D., RUDI, N., SMANIA, F.

University of Verona

Introduction: Alzheimer disease (AD) is the most frequent cause of dementia worldwide. Oxygen uptake and gait biomechanics are severely compromised in AD, likely affecting energy demand during locomotion. The literature, underline several exercise-induced positive effects in patients with AD. However, the effect of exercise training (ET) on the energy cost of walking (Cw) and gait biomechanics in AD are inconsistent. Therefore, the aims of this study were to determine potential AD-induced alterations in locomotion and to compare the effects of ET with respect to sham therapy (ST) on Cw and gait biomechanics in patients with AD. Methods: In seventeen patients with AD (77 ± 7 yrs) and 11 healthy old controls (OLD), Cw, and spatio-temporal gait parameters (velocity, stride, step, swing, stance, double and single support, cadence) were assessed by oxygen uptake measurement during walking, and GaitRite respectively. Cw, heart rate (HR), pulse of oxygen (VO₂/HR) were then calculated. Following, AD patients were randomly assigned to ET group (n=8) or ST group (n=9) that performed 72 treatment sessions, 3 times a week. ET included 90 min of aerobic and strength training. ST included cognitive stimuli. Baseline measurements (T0) were repeated (T1) after 6-month of treatment. Results: In comparison to the OLD group AD patients exhibited significant reduction of locomotion parameters (Cw +50.2%, Velocity -30.9%, Stride -17.4%, Step -18.4%, Single support -7.0%, Double support +33.2%, Stance +5.7%, Swing -9.2%, Cadence -12.2%). After ET the Cw was significantly improved (-13.3%), while differences in spatio-temporal gait parameters were negligible (-15.8%, $p=0.041$). In addition, both HR and VO₂/HR were significantly ameliorated (-8.7% and +15.7% respectively). At the contrary, changes in Cw, spatio-temporal gait parameters, HR, VO₂/HR after the ST were undetectable. Conclusion: Data from the current study demonstrates an AD-induced alteration in human locomotion. However, it appears that an ET program can reverse the progressive reduction in gait biomechanics, usually exhibited by patients with AD. Further benefits of ET were retrieved in the improvement of Cw, associated with enhancement of HR and VO₂/HR. The results of this study suggest that ET-induced

amelioration in locomotion of patients with AD are mainly caused by positive adaptations of central and peripheral components of the VO₂.

ACUTE EFFECTS OF PERTURBATION TREADMILL TRAINING ON GAIT AND POSTURAL CONTROL IN PATIENTS WITH PARKINSON'S DISEASE

STEIB, S.1, KLAMROTH, S.1, GÄBNER, H.2, WINKLER, J.2, ESKOFIER, B.3, KLUCKEN, J.2, PFEIFER, K.1

FAU Erlangen-Nürnberg (Germany)

Introduction Treadmill training is an effective therapeutic option in gait rehabilitation of Parkinson's patients (Mehrholz et al., 2010). Novel training paradigms have emerged, focusing on perturbations during treadmill walking (Reisman et al., 2010). In order to understand potential mechanisms of adding perturbations during walking, gait and balance adaptations to a single session of perturbed treadmill walking were investigated in individuals with Parkinson's disease (PD). Methods 39 PD patients (Hoehn & Yahr 1 to 3) performed a single session of 20 minutes treadmill walking. Participants were randomly allocated into two groups. The experimental group (n=19) walked on a treadmill prototype (zebris Medical GmbH, Isny, Germany) which constantly induced small three-dimensional tilting movements of the walking surface. The control group (n=20) walked on the same treadmill without perturbations. Outcomes included overground walking speed (10m walk test) and postural sway during quiet standing (30 seconds at 100Hz, pressure sensor matrix). Additionally, spatiotemporal gait parameters were recorded during treadmill walking using a treadmill-integrated pressure sensor matrix. Outcomes were measured repeatedly throughout the training session and after 10 minutes retention. Linear mixed models were used to analyze within- and between-group changes over time. Results The experimental group significantly increased overground walking speed after intervention compared to the control group ($p = .014$; $d = +0.41$). Gait variability during treadmill walking significantly decreased in the experimental ($p < .05$; $d = 0.33 - 0.48$), but not in the control condition. Effects were more pronounced if patients were able to walk without handrail support. Sway area increased with treadmill walking only in the control group ($p = .009$; $d = +0.49$). No other postural sway measures changed over time. Subgroup analyses revealed that in the experimental group more disabled patients demonstrated larger increases in overground walking speed ($p = .016$; $d = +0.40$) and stance phase symmetry ($p = .011$; $d = -0.42$). Conclusions A single session of perturbation treadmill training led to larger gait improvements compared to unperfused treadmill walking. Adaptations were mainly related to a reduction of gait variability. Postural control appeared to be minimally affected References Mehrholz J, Friis R, Kugler J, Twork S, Storch A, Pohl M. (2010). Cochrane Database Syst Rev (1), CD007830. Reisman DS, Bastian AJ, Morton SM. (2010). Phys Ther, 90 (2), 187–195.

SOMATOSENSORY TRAINING IMPROVES SENSORY INTEGRATION AND QUALITY OF LIFE IN INDIVIDUALS WITH MILD TO MODERATE PARKINSON'S DISEASE

GREGORY, T., WELMAN, K.E.

UNIVERSITY OF STELLENBOSCH

Introduction: Parkinson's disease (PD) presents proprioceptive processing and integration deficits, which cause postural control (PC) deterioration (Vaugoyeau et al., 2011). However, applying light touch improves postural sway (PS) in individuals with PD (Rabin et al., 2013). The aim was to determine whether an eight-week somatosensory training programme (SSTP) would influence joint position sense (JPS), sensory integration and Quality of Life (QoL) in individuals with PD. Methods: Thirty-seven individuals with idiopathic PD (67 ± 9 years; H&Y: 2 ± 1) were divided into two groups: somatosensory training (EXP; n = 24) and placebo group (PBO; n = 13). Joint position sense, sensory integration (mCTSIB) and QoL were assessed at baseline, pre- and post-intervention. For the mCTSIB, the Instrumented Sway tri-axial accelerometer was used to assess Jerkiness (JERK), Centroidal Frequency (CF) and Root Mean Square (RMS) during 4 conditions i.e. eyes open (EO), eyes closed (EC), both off and on a foam pad (+F). Joint position sense was tested by means of the Active Movement Extent Discrimination Apparatus (AMEDA) and QoL with the Parkinson's Disease Quality of Life Questionnaire Summary Index (PDQ-39 SI). Results: A treatment effect was found for EC+F ($p = 0.0002$) and a strong tendency for a treatment effect for PDQ-39 SI ($p = 0.06$). The EXP group improved in JPS ($p = 0.02$) and PDQ-39 SI ($p = 0.03$) after the eight weeks. Furthermore, the EXP group showed less EC+F JERK compared to PBO group after the intervention ($p = 0.002$). Conclusions: The study findings provide evidence that SSTP might improve JPS and sensory integration in individuals with PD, which may contribute to improve PC and QoL. References: Rabin E, et al. SPATIAL LEARNING IN HUMANS IN A REAL LIFE WATER MAZE

BOEHR, J.1, WRIGHT, P.R.1, GARTHE, A.2, KEMPERMANN, G.2, SCHULZ, H.1

1 Chemnitz University of Technology, 2 German Center for Neurodegenerative Diseases Dresden

INTRODUCTION The Morris water maze (MWM) represents the gold standard for testing spatial learning in laboratory rodents. To assess disease-related changes in spatial learning in humans, virtual water mazes have been developed. However, it has been shown that small-scale learning (e.g. looking at a monitor) is partly based on different functional brain systems than large-scale learning (navigation in real, complex settings) (Hegarty, 2006). This raises the question whether testing humans in a virtual task captures the essential aspects of spatial learning in the physical world. The aim of this study was to develop a "real" human water maze to evaluate the potential of mimicking an established test paradigm for laboratory animals and to prove the ecological validity of a virtual navigation task. METHODS 27 healthy subjects (age 22.6 ± 2.4 years) conducted the real water maze (RWM) as well as a virtual navigation task (VNT). The setup used for the RWM consisted of a circular swimming arena in a large lake, with a diameter of 18 meters. Subjects performed four trials to locate and remember an invisible target position using the available distant visual cues (e.g. trees, buildings). The process of spatial navigation in both the VNT and RWM was analysed by measuring established parameters such as latency and path length, but also by evaluating more advanced read-outs such as salience, number, and spatial distribution of re-used landmarks. RESULTS Both rodents and humans are using highly similar search and/or navigation strategies to find and remember an invisible target position. Irrespective of species-specific sensory and cognitive abilities mice and men use distant landmarks to navigate the arena. Quantitatively, the type of landmarks used (out of all cues available) appears to be comparable between species and independent of a cues salience. There is also evidence that presenting the water maze task as a computer setup does not change the importance of using a specific set of stable distant visual cues for efficient navigation. The correlation analysis between RWM and VNT is still in progress. DISCUSSION The presented study con-

firmed that the established water maze paradigm could be effectively applied to humans for studying spatial learning in a complex environment. Transferring the task into virtual reality preserves most aspects of spatial navigation. The specific roles of proprioceptive and vestibular inputs which are absent in the VNT remain to be identified. REFERENCES Hegarty M., Montello D.R., Richardson A.E., Ishikawa T., Lovelace, K. POLYMORPHISM OF MNSOD AND GPX GENES AND BIOCHEMICAL RESPONSE TO THREE-MONTH SWIMMING TRAINING

JÓWKO, E., SADOWSKI, J., GROMISZ, W., CIEŚLIŃSKI, I.

Faculty of Physical Education and Sport in Biala Podlaska

The aim of the study was to analyse the influence of antioxidant enzyme genetic polymorphisms, MnSOD Val9Ala and GPx Pro198Leu, on the response of biochemical parameters of the blood to three-month swimming training. Methods: The study included 52 Polish (Caucasian) male students of physical education, who participated in a three-month swimming training program (1.5 h/day; 4 days/week). Blood samples were drawn from the ulnar vein prior to and after the training period. The activity of superoxide dismutase (SOD) was determined in erythrocytes and serum, and the concentration of total glutathione (TGSH) and activity of glutathione peroxidase (GPx) were measured in whole blood. Moreover, lipid hydroperoxides (LHs), total antioxidant capacity (TAC) and creatine kinase (CK) activity were determined in serum, along with the lipid profile: total cholesterol (TC), triglycerides (TG), LDL (LDL-C) and HDL cholesterol (HDL-C). Genomic DNA was isolated from peripheral blood using QIAamp DNA Blood MiniKit (Qiagen, Germany). Genotyping was based on real-time PCR with TaqMan SNP assays. Results: The three month-training resulted in a decrease in LHs, TAC and GPx ($p<0.05$) and an increase in serum SOD and TC. The post-training decrease in LHs, GPx and CK turned out to be associated with Ala/Ala genotype of MnSOD Val9Ala polymorphism ($p<0.05$), whereas the decrease in TAC was observed in both Ala/Ala and Ala/Val genotype carriers ($p<0.05$). Moreover, Ala/Val genotype was associated with an increase in serum SOD, TC and LDL-C ($p<0.05$), and Val/Val genotype correlated with an increase in TGSH level ($p<0.05$). Val/Val genotype carriers presented with significantly higher pre-training activity of SOD in erythrocytes than individuals with Ala/Ala genotype ($p<0.05$) and showed higher post-training TGSH levels than Ala/Val heterozygotes ($p<0.05$). GPx Pro198Leu polymorphism exerted less pronounced effects on the post-training changes in biochemical parameters. No mutant homozygotes (Leu/Leu) were identified in the study group. Pro/Pro genotype correlated significantly with a decrease in LHs and GPx ($p<0.05$), and Pro/Leu genotype predisposed to a decrease in TAC ($p<0.05$). Furthermore, both genotypes were associated with an increase in serum SOD. None of the analysed genotypes exerted significant effects on the lipid profile. Conclusions: Three-month swimming training induces changes in oxidative stress parameters and lipid profile. These changes seem to be mainly associated with the presence of Val16Ala SOD2 polymorphism. Presence of minor (mutant) allele Ala, especially as homozygote, is associated with some beneficial training-induced changes, such as a decrease in lipid peroxidation and less pronounced muscle damage. In turn, Ala/Val genotype may predispose to some unfavorable changes in the lipid profile.

POLYPHENOL SUPPLEMENTATION IMPROVES CARDIOMYOCYTE RECOVERY AFTER MARATHON RUNNING: A DOUBLE-BLIND, RANDOMIZED, PLACEBO-CONTROLLED TRIAL.

SCHERR, J., HALLER, B., NIEMAN, D.C., LORENZ, E.S., BRAUN, S., WOLFARTH, B., HALLE, M.

Technical University Munich

Background: The increase of cardiac troponin (cTn) during and after strenuous exercise are known phenomena. Polyphenols have anti-inflammatory and anti-oxidative effects that may counteract cTn release and inflammation-associated alterations of the cardiovascular system. Objective: We investigated, whether supplementation with a polyphenol containing beverage has cardiomyocyte protective effects in marathon runners. Design: We examined the effects of polyphenol supplementation in 277 male marathon runners (42 ± 9 yrs.) in a randomized, double-blind and placebo-controlled manner with regard to levels of cTnT and inflammatory biomarker levels before a marathon race (V1 & V2), and immediately (V3), 24 (V4) and 72 hrs (V5) afterwards. Participants were asked to ingest ≥1 L (corresponding to ≥326 mg gallic acid equivalents of polyphenols) of the supplementation beverage per day. Data of 210 participants (105 verum group (V=polyphenol supplementation), 105 placebo group (PL=identically with V except for polyphenols)) were analyzed in the full analysis set. To evaluate kinetics of biomarkers, area under the curve (AUC) was calculated for each participant. Results: We observed no significant difference between V and PL regarding cTnT concentration from V2 to V5 (median [IQR]: AUC: V: 33.3[23.7-54.0] d \cdot ng \cdot L $^{-1}$ vs. PL: 42.4[24.9-59.0] d \cdot ng \cdot L $^{-1}$, $p=0.168$). However, there were lower areas under the cTnT curve from immediately to 72 hrs post-race in V (30.0[21.6-49.0] d \cdot ng \cdot L $^{-1}$) compared to PL 39.0[22.4-54.5] d \cdot ng \cdot L $^{-1}$ ($p=0.16$), becoming statistically significant after adjustment of immediately post-race values ($p=0.015$, $\beta=0.09$, SE = 0.03). Also AUC from 24 to 72 hrs post-race were significantly lower in V ($p=0.030$). This resulted in a clinically relevant higher number of participants with a cTn value above the upper reference limit (14 ng \cdot L $^{-1}$; and therefore being suspicious for myocardial injury) in the placebo group compared to the verum group in all post-race visits (immediately post: 91.4% vs. 82.9%, 24 hrs post: 30.5% vs. 24.8%, 72 hrs post: 5.7% vs. 4.8%). Conclusion: Supplementation with a polyphenolic mixture was linked to enhanced cardiomyocyte recovery after prolonged and strenuous exercise.

EFFECTS OF ALTITUDE TRAINING ON CHANGES IN HEMOGLOBIN MASS, VO2MAX AND BODY COMPOSITION IN ELITE ENDURANCE ATHLETES; IMPACT OF INCREASED ANTIOXIDANT-RICH FOOD INTAKE ON THE ADAPTATION RESPONSE

KOIVISTO, A.I., PAULSEN, G.I.3, BØHN, S.K.2, GARTHE, I.1, PAUR, I.2, TØNNESSEN, E.1, RAASTAD, T.3, BLOMHOFF, R.2

The Norwegian Olympic Sports Center

1: Norwegian Olympic Sports Centre, Oslo 2: Dept. of Nutrition, Institute of Basic Medical Sciences, University of Oslo 3: Dept. of Physical Performance, Norwegian School of Sport Sciences, Oslo, Norway INTRODUCTION Training at high altitude increases the production of

reactive oxygen and nitrogen species (RONs), which potentially induce cellular damage. As a countermeasure, athletes are recommended to increase antioxidant intake. However, RONS are important cellular signalling molecules, and high-dose single-antioxidant supplement intake may blunt responses to endurance training. Whether increased consumption of antioxidant-rich foods will affect training adaptations in a similar manner, is currently unknown. Thus, this study aimed to assess the effects of training at moderate altitude in elite endurance athletes and evaluate the impact of antioxidant rich foods on the adaptation response. METHODS Thirty-one national team endurance athletes (8 females, 23 males) were randomly assigned to antioxidant rich snack (AO, n=16) or placebo group (PL, n=15). During a 3-week training camp at moderate altitude (2340 m) athletes received daily eu caloric AO (smoothies, nuts, dried berries/fruit, dark chocolate) or PL snacks. Before and after the altitude camp hemoglobin mass (Hbmass), blood volume (BV), lean body mass (LBM) and fat mass (FM) were determined and fasting blood samples collected and analyzed for hemoglobin (hb), hematocrit, erythrocytes and ferritin. Additionally, VO_{2max} (treadmill) was assessed in 16 athletes (AO, n=10, PL, N=6). RESULTS Moderate altitude training induced increases in Hbmass (4.9 %, p<0.001), hematocrit (4.0 %, p=0.001), erythrocytes (5.0 %, p<0.001), and VO_{2max} (2.6 %, p<0.01), whereas S-ferritin was reduced (-16.5 %, p=0.001). Body mass, LBM, and FM remained unchanged. No significant differences were found between groups for any of the adaptation response parameters. Compliance in AO group was 95%. DISCUSSION Three-weeks of training at moderate altitude increased Hbmass and VO_{2max}, important physiological determinants for endurance performance in elite athletes. Increased consumption of antioxidant-rich foods (doubling AO intake) was well tolerated by the athletes and did not interfere with the adaptive responses to altitude training. Whether high intake of antioxidants from food modulated systemic redox balance and inflammation markers awaits further analyses. REFERENCES Elkington et al. 2015. ANTIOXIDANTS REDUCE THE GLYCOLYTIC RATE DURING SPRINT EXERCISE IN HUMANS WITHOUT IMPROVING PERFORMANCE

MORALES-ÁLAMO, D., GUERRA, B., SANTANA, A., CALBET, J.A.L.

Las Palmas University

Introduction: About 80% of the energy yield during a 30s-Wingate test is provided by the anaerobic energy metabolism (2/3 by the glycolysis and 1/3 by phosphocreatine and ATP). This generates a fast and great production of pyruvate which overwhelms the capacity of the pyruvate dehydrogenase (PDH), leading to the accumulation of pyruvate, which is rapidly converted to lactate by lactate dehydrogenase. Consequently, sprint exercise ends with high muscular lactate concentration, acidification and increased production reactive oxygen and nitrogen species (RONs), which have been historically associated with fatigue. These effects are accentuated when the sprints are performed in severe acute hypoxia. Antioxidants may influence PDH activity by reducing RONS effects. Thus, the aim of this study was to determine if antioxidants might alter the anaerobic energy production during sprints exercise by modifying PDH activity and mitochondrial efficiency. Methods: Nine volunteers performed a single isokinetic (100-rpm) 30s Wingate test in four trials while breathing normoxia (N) or hypoxic gas (H, P_O2=75 mmHg) preceded by the ingestion of a placebo (P) or antioxidants (A) (alpha-lipoic acid, vitamin C, and vitamin E), with a double-blind design. Muscle metabolites and PDH phosphorylation was determined in muscle biopsies taken before, at the end of the sprint. Results: Peak power output (PPO) was similar between conditions. Mean power output (MPO) was a 5% lower in H than normoxia (FIO₂ effect, P<0.05). Antioxidants did not influence significantly performance in any condition. The glycolytic rate was 23% higher in hypoxia than normoxia (P<0.05). Compared to placebo, antioxidant ingestion reduced the glycolytic rate by 38% (P<0.05). However, Ser293-PDH-E1alpha and Ser300-PDH-E1alpha phosphorylation, as index of PDH activation, decreased similarly between conditions, suggesting similar PDH activation, regardless of antioxidant ingestion. Discussion and conclusions: Antioxidants (alpha-lipoic acid, vitamin C, and vitamin E) decrease the glycolytic rate and the level of muscle acidification during sprint exercise without any impact on performance. This finding has two implications. Firstly, that muscle acidification does not limit performance during sprint exercise, even in severe acute hypoxia (when acidification and lactate accumulation are greater). Second, since VO₂ was not increased to compensate for the reduced energy yield by glycolysis. This study implies that antioxidants must increase the efficiency of the oxidative phosphorylation or the contraction coupling efficiency. Granted by DEP 2010-21866

OP-PM65 Cardiovascular Physiology

THE EFFECT OF LOWER BODY POSITIVE PRESSURE ON THE CARDIRESPIRATORY RESPONSE TO SUBMAXIMAL RUNNING EXERCISE.

STUCKY, F., UVA, B., KAYSER, B.

University of Lausanne

Alter-G is an anti-gravity treadmill facilitating walking and running in patients with lower limb problems, by applying a positive pressure on the lower body (LBPP). Apart from providing weight support, LBPP could translocate blood from the lower limb to the trunk. It is unknown if this phenomenon leads to a modification in the cardiorespiratory response to running exercise. Six healthy males (31±14.3 yrs, 167.7±4.5 cm, 68.8±4.8kg) performed three bouts of running at 9, 11, 13 and 15 km.h⁻¹ (5 min stages), at 0, 15 and 40 mmHg LBPP. Steady state cardiac output (CO) was estimated from thorax bio-impedance changes and heart rate; oxygen uptake (VO₂) was monitored breath-by-breath using a respiratory gas analyser. Blood pressure was monitored beat-by-beat with finger plethysmography. To monitor potential effects of pressure on the lower abdomen any changes in FRC were monitored with inspiratory capacity (IC) manoeuvres. While the increase of speed was accompanied by an increase in VO₂ in all conditions, increasing LBPP to 40 mmHg led to significant decreases in VO₂ (2274±475 vs 1961±320 vs 1365±418 ml.min⁻¹ at 15 km.h⁻¹ at 0, 15 and 40 mmHg, respectively (p<0.05)) and in CO (22.2±2.0 vs 19.7±1.7 vs 14.9±2.2 l.min⁻¹, respectively (p<0.05)). Mean arterial blood pressure (MAP) remained unchanged, while peripheral resistance increased with LBPP (4.7±0.3 vs 5.2±0.5 vs 6.6±0.9 mmHg.ml⁻¹ at 15 km/h at 0, 15 and 40 mmHg, respectively (p<0.05)), suggesting increased left ventricular afterload. Regardless the level of pressure, the relationship between CO and VO₂ remained linear and with similar slope for each subject with a mean r² of 0.88±0.07. For a given level of ventilation IC values remained constant, suggesting an unchanged thoracoabdominal breathing configuration in all conditions. Our findings suggest that LBPP reduces the cardiorespiratory load proportionally to the reduced metabolic demand resulting from the body weight support, but increases left ventricular work for a

given metabolic demand. Whether these results could be clinically relevant when designing rehabilitation programs using LBPP-type devices for bodyweight support for patients with cardiorespiratory disease remains to be investigated.

DYNAMICS OF ARTERIAL BAROREFLEX RESETTING AT EXERCISE ONSET IN UPRIGHT AND SUPINE POSTURE

BRINGARD, A.1,2, ADAMI, A.2,3, FAGONI, N.4, LADOR, F.5, MOIA, C.1,2, TAM, E.6, FERRETTI, G.1,2,4

University of Geneva

1: HUG (Genève, Switzerland), 2: UNIGE (Genève, Switzerland), 3: UCLA (Torrance, USA), 4: UNIBS (Brescia, Italy), 5 : HUG (Genève, Switzerland), 6 UNIVR (Verona, Italy) INTRODUCTION The concept of baroreflex resetting during exercise is well established, yet its dynamics is poorly understood. This can be investigated using close-loop procedures. The aim of this study was to identify possible temporal components of the mechanisms of baroreflex resetting during exercise transient, on the hypothesis that resetting does not necessarily start at exercise onset. Since cardiac filling pressure is higher supine than upright, we investigated both postures, expecting that the baroreflex operating point in supine posture is displaced with respect to the upright posture even at rest (Schwartz et al., 2013). METHODS Eleven young volunteers (8 women, 3 men), performed light exercise in upright and supine posture. Heart rate (HR) was continuously determined by electrocardiography, and beat-by-beat mean arterial pressure (MAP) was computed from pulse pressure profiles recorded non-invasively. Assuming HR versus MAP relationship, between the exercise onset and the minimum of MAP (MAPm), lying on the steep part of a baroreflex curve, this segment was modelled by linear regression. RESULTS Just before exercise start, HR was higher than at quiet rest, conversely to MAP. As exercise started, MAP fell in about 10 s to a minimum (MAPm) of 72.8 ± 9.6 mmHg upright and 73.9 ± 6.2 supine. HR consequently grew. Before attainment of MAPm, the slope of HR versus MAP relationship were -0.66 ± 0.16 and -1.04 ± 0.43 mmHg \cdot 1 min $^{-1}$, respectively upright and supine ($P < 0.05$). After MAPm, both HR and MAP increased toward exercise steady state. DISCUSSION As exercise started, HR grew while MAP fell, whence a negative linear relation between these two variables, until the attainment of MAPm. The slope of this segment corresponded to the slope of the HR vs MAP relationship at rest, obtained with different baroreflex procedures (Ogoh et al, 2005; Schwartz et al., 2013). Also, the slopes of this relationships were flatter upright than supine (Schwartz et al., 2013), indicating reduction of baroreflex sensitivity in the former case. Notwithstanding a potential feed-forward mechanism, exercise baroreflex resetting started after attainment of MAPm, which may be interpreted as a threshold value triggering baroreflex resetting. After MAPm subjects operated along different baroreflex curves. REFERENCES Ogoh S, Fisher JP, Dawson EA, White MJ, Secher NH, Raven PB (2005). J Physiol. 566, 599-611. TECHNOLOGY-ENABLED CARDIAC REHABILITATION THROUGH PATHWAY. DESIGN AND RATIONALE FOR THE INVESTIGATION OF ITS FEASIBILITY, CLINICAL EFFECTIVENESS AND COST-EFFECTIVENESS

CORNELISSEN, V.A., MOYNA, N.M., CLAES, J., BRIGGS, A., MC DERMOTT, C., CHOUVARDA, I., FILOS, D., FINLAY, D., DARAS, P., WALSH, D., BUDTS, W., MORAN, K., WOODS, C., BUYS, R.

KU Leuven - departement of Rehabilitation Sciences - department of Cardiovascular Sciences

Background Exercise-based cardiac rehabilitation (CR) favorable and independently alters the clinical course of cardiovascular diseases resulting in a significant reduction in all-cause and cardiac mortality. However, only 15-30% of all eligible patients participate in a phase 2 ambulatory program. Uptake rates of community based programs following phase 2 CR are even lower and adherence to long-term CR is extremely poor. Newer care models, involving programs that are delivered remotely such as telehealth programs, show considerable promise for increasing adherence. In this view, PATHway (Physical Activity Towards Health) is being developed and needs to be evaluated on feasibility and potential clinical benefit. Methods In a multicentre randomized controlled pilot trial, 120 patients (m/f, age 40-80yrs) completing a phase 2 ambulatory CR program will be randomized on a 1:1 basis to PATHway or usual care. PATHway involves a complex comprehensive, internet-enabled, sensor-based home CR platform. It consists of several modules with an exercise module as the core component. PATHway provides individualized heart rate monitored exercise programs (exerclasses and exergames) as the basis upon which to provide additionally a personalized, comprehensive lifestyle intervention program (managing exercise, smoking, diet, stress, alcohol use). The control group will receive normal care. Study outcomes will be assessed at baseline, 3 months and 6 months. The primary outcome is the change in active energy expenditure. Secondary outcomes include health-related fitness (cardiopulmonary endurance capacity, muscle strength, body composition), vascular health (vascular stiffness and endothelial function), cardiovascular risk score, health-related quality of life, patient satisfaction, healthcare costs and safety. Intervention feasibility will be assessed via participant and stakeholder debrief. Discussion This study investigates the feasibility of the PATHway system in supporting patients to maintain a physically active lifestyle, and investigates its short-term effectiveness on cardiovascular health. It has the potential to further extend the provision of poorly accessible, hospital-based rehabilitation programs to effective, cost-effective delivery models in the community. This project has received funding from the European Union's Horizon 2020 Framework Programme for Research and Innovation Action under Grant Agreement no.643491. PATHway: Technology enabled behavioural change as a pathway towards better self-management of CVD (www.pathway2health.eu/).

RESPIRATORY MUSCLE TRAINING AFFECTS PERIPHERAL VASCULAR FUNCTION

BISCONTI, A., DEVOTO, M., VENTURELLI, M., OLFERT, M., CHANTLER, P., ESPOSITO, F.

University of Milan Via Colombo 71, 20133 Milano, Italy;

RESPIRATORY MUSCLE TRAINING AFFECTS PERIPHERAL VASCULAR FUNCTION Introduction Changes in breathing patterns, that are influenced by respiratory muscle training (RMT)(1), may also affect the autonomic balance by decreasing sympathetic drive and improve vascular function (2). Therefore, the aim of this study was to evaluate the efficacy of RMT on vascular function, assessed by flow mediated dilation (FMD), in young healthy subjects. Our hypothesis was that RMT could ameliorate both lung functions and brachial-artery FMD without affecting sympathetic and parasympathetic neural drive. Methods Twenty-three physically active participants were randomly assigned to an RMT group (TG: age 27 ± 8 yrs, BMI 24 ± 4 kg·m $^{-2}$; RMT 3 times a week for 2 months, 15-30 minutes of progressive RMT assessed weekly) or to a sham group (SG: age 33 ± 11 yrs, BMI 24 ± 4 kg·m $^{-2}$; 3 times a week for 2 months of RMT-Placebo). Maximal inspiratory mouth pressure (MIP) and maximum voluntary ventilation (MVV) were utilized to assess the pulmonary effects of RMT. Heart rate variability (HRV, the ratio between low and high frequency: LF/HF) was utilized to assess the autonomic balance. Vascular function was determined by measuring vessel vasodilation (%FMD), normalized by the shear rate (FMD/SR). Results After 2 months of RMT, MIP and MVV increased significantly by 25% and 8%, respectively, while in the SG, MIP and MVV didn't change. In both TG and SG the chang-

es in LF/HF were negligible. However, vascular function improved significantly only in TG (FMD/SR TG = -31 % FMD/SR; SG = -4 % FMD/SR). Discussion Data from the current study indicate a positive effect of RMT on both pulmonary and vascular function. However, contrary to our hypothesis, these positive results seem not primarily induced by adaptations of the autonomic balance. Therefore, physiological factors other than the modulation of sympathetic and parasympathetic nerve activity, seem positively triggered by the RMT (3). OP-PM26 Cycling

EFFECTS OF AN ULTRA-ENDURANCE BIKE MARATHON ON THE HEART OF RECREATIONAL CYCLISTS

RUESSMANN, A.1,3, OTTO, C.1, LAWRENCE, J.B.1, RUESSMANN, T.3, MOSER, O.1,2

Ernst von Bergmann Klinikum Potsdam

1: UP (Potsdam, GER), 2: UAS (Gleichenberg, AT), 3: EvB (Potsdam, GER) Introduction In normotensive athletes ultra-endurance sports had no negative impact on arterial stiffness (Radtke et al., 2014). Even so, such competitions were associated with acute reductions in large artery compliance (Burr et al., 2012). The effects of an ultra-endurance bike marathon on heart wall motion still remains unclear. The aim of this study was to determine the effect of an ultra endurance cycle marathon on wall motion in recreational cyclists. Methods 8 healthy male recreational cyclists (age: 42.8±13.2yrs, VO_{2max}: 47.4±5.8ml.kg⁻¹.min⁻¹) were investigated by an isolated speckle tracking echocardiography (STE) at rest, within 30min, 2h and 12h after a 300km cycle marathon. One week prior the competition a maximum cycle ergometer exercise test was conducted to determine the exercise intensities during the cycle marathon retrospectively (Hofmann et al. 2010). Echocardiographic loops for STE-analyses were acquired after race and determined offline. Average longitudinal peak strain of apical four-chamber view, apical long axis view and apical two-chamber view were measured. Presented global longitudinal peak strain (GLPS) is averaged over all measured segments. Data are given as mean±SD and were analysed via Shapiro-Wilk normality test, ANOVA for repeated measurements and Tukey's multiple comparisons test. Results Mean exercise intensity during the competition was 53±18% of lactate turn point 2 (LTP2). No significant differences were found in GLPS over time ($p=0.21$). In comparison to resting conditions (-20.6±2.6%) no significantly reduced GLPS immediately (-19.7±2.7%; $p=0.38$), 2h (-20.9±1.7%; $p=0.51$) and 12h after the competition (-21.4±0.8%; $p=0.35$) was found. Discussion An ultra-endurance bike marathon seems not to cause cardiac stress with respect to wall motion abnormalities as a sign of cardiac fatigue and increased risk of arrhythmia in recreational cyclists. Further studies have to prove by larger trials including different durations, weather conditions, exercise intensities, courses during ride and especially in older aged groups. ADAPTIVE RESPONSES TO EXTREME LOADS DURING ULTRA-CYCLING EVENT.

ZELENKOVA, I.1, KORNEEV, P.1, GRACHEVA, M.1, ZOTKIN, S.1

I: Russian Olympic committee.

Introduction. Red Bull Trans-Siberian Extreme Race is the longest cycling race in the world: from Moscow to Vladivostok. During this race the subjects are pushing their limits for 21 days and are covering 9200 km of distance. This study represents an attempt to investigate the limits of the adaptive response of human bodies. Methods. Ten athletes (177 (175-183) cm, 82.4 (75.4-85.6) kg, body mass index 22.7 (22-22.8) kg/m², 34 (29-37) years old) participated in the study. Body composition (bioelectrical impedance analysis), total haemoglobin mass (tHb-mass) and blood volume (CO-rebreathing method, Bloodtec, Radiometer), pulmonary oxygen consumption (breath-by-breath, Cortex MetaMax), anaerobic threshold (AT) were measured in the laboratory. During the race monitoring of hydration status, heart rate monitoring (Bodyguard, Firstbeat) and rate of perceived exhaustion were performed. For rating sample characteristics, median and interquartile dispersion was used. Non-parametric Wilcoxon tests were applied for referencing bound samples. Significance level P was rated at 0.05. Results. Before the race athletes body mass (n=10) was 74 (69-78) kg. After the race there was a significant decrease in body mass, reaching 71 (70-76) kg ($p<0.01$). Fat mass was the key factor causing body weight deterioration from 10.9 (9.5-12.9) kg to 8(5.8-9.2) kg: the decrease was 4 (5-2)% ($p<0.01$). Most pronounced two athletes demonstrated decrease: SH decrease of 12% and FE decrease of 8 %. There was no significant dynamics in muscle mass. tHb-mass in group was 999 (931-1054) g. The highest values were demonstrated by IM, EF, KI: 14.4 g/kg, 14.3 g/kg and 14.0 g/kg respectively. No significant decrease was observed. Decrease in maximal heart rate from 180 (177-189) bpm to 172 (160-178) bpm and heart rate on anaerobic threshold from 165 (159-172) bpm to 144 (137-145) bpm were observed. During the race the mean heart rate decrease was demonstrated by all athletes: from 145 (142-156) bpm to 131 (117-140) bpm despite increase in difficulty of path profile ($p<0.05$) The most pronounced reduction was observed with DR and SH: 20% and 19% respectively. At maximal aerobic power (MAP) the workload was 380 (345-403) W and 299 (272-336) W at AT and after race the workload at maximal aerobic power was 348 (314-387) W and 260 (253-294) W at AT. The maximal decrease we found in FE - 21%. Discussion. Pronounced fatigue developed in all athletes within the race duration. It was characterized by heart rate and workload reduction at MAP and AT. tHB-mass test accurately predicted race winners and precisely described aerobic capacity parameters. Such extreme workloads are hard to model within laboratory conditions, therefore further research of human body adaptive responses should be undertaken.

PHYSIOLOGICAL DEMANDS OF SIMULATED OFF-ROAD CYCLING COMPETITION

SMEKAL, G., VON DUVILLARD, S.P., HÖRMANDINGER, M., MOLL, R., POKAN, R.

University of Vienna

Introduction: Only limited empirical evidence is available to assess the physiology of competitive off-road cycling (COMP). Earlier studies investigating energetic demands of mountain bike (MB)-cycling were often based on heart rate (HR) and blood lactate (BLa) measures. Only few papers are available dealing with power output (PO)-and respiratory gas measures during COMP. However, the workload-pattern of COMP limits the utility of HR and BLa measures since BLa is slowly removed from blood and rather may reflect high intensity periods while HR has been shown to be influenced by psychological components. PO measures represent exertion of force expended by lower limbs and not overall physical demands of COMP requiring recruitment of additional muscle mass stabilizing against gravity and vibration. Considering these limitations the aim of our study was to describe COMPs via the combination of BLa measures and real-time measures of PO, HR and respiratory gas parameters. Methods: 24 male competitive cyclists performed our COMP and also laboratory tests (LabT). From LabT study parameters data were determined at maximal load and 2 ventilatory thresholds (VT1, VT2). A high-performance athlete (HPA) was used to demonstrate COMP on high level. The COMP-trail was a rocky, hilly single trail with many roots and stones (four identical laps, entire distance of ~24.348 km). Results: During the COMP, athletes achieved a mean oxygen uptake ($\dot{V}O_2$ COMP) of $57.0 \pm 6.8 \text{ ml.kg}^{-1}.\text{min}^{-1}$ vs. $71.1 \text{ ml.kg}^{-1}.\text{min}^{-1}$ for the HPA. The POCOMP was $2.66 \pm 0.43 \text{ W.kg}^{-1}$ and 3.52 W.kg^{-1} for the HPA. We further analyzed POCOMP, $\dot{V}O_2$ COMP, HRCOMP in relation to corresponding variables of LabTs. Mean POCOMP was 61.9% of POVT2 and 47.2% of POmax, whereas $\dot{V}O_2$ COMP was 112 % of $\dot{V}O_2$ VT2 and 88 % of $\dot{V}O_2$ peak and HRCOMP was 102 % of HRVT2 and 90% of HRmax. POCOMP, $\dot{V}O_2$ COMP and HRCOMP were compared to corresponding variables at the VT2 of LabT. LabT variables correlated with racing time (RTCOMP) and POCOMP ($P < 0.01$ to < 0.001 ; $r = 0.59$ to -0.80). Discussion/ Conclusion: The study resulted in following findings: During COMP high oxygen costs exist probably influenced by the high muscle mass simultaneously working. POCOMP turned out to be lower when compared to $\dot{V}O_2$ COMP, likely caused by phases of low force production (downhill phases) and also by the high mass performing COMP at this selective MB-trail. Data determined from LabT might be utilized to describe semi-specific abilities of MB-athletes and cannot be transferred to MB-cycling. Data originating from COMPs might be useful when designing MB-specific training. THE INFLUENCE OF TRAINING AND CADENCE ON GROSS EFFICIENCY IN YOUNG ELITE CYCLISTS

BALLAK, S.B., DE KONING, J.J., NOORDHOF, D.A.

Sportcentrum Papendal

Sport Science & Innovation Papendal, Sportcentrum Papendal, Arnhem, The Netherlands MOVE Research Institute Amsterdam, VU Amsterdam, Amsterdam, The Netherlands Background: Successful road cycling requires energy preservation for the last and decisive part of the race. Therefore, high cycling efficiency during the majority of the race increases the chance on a good result. Gross efficiency (GE), considered as a key determinant of cycling performance, is the ratio between mechanical power output and metabolic power input (I), expressed as a percentage. Cadence is a factor that influences GE [1], therefore, determining a cyclist' most efficient cadence and using this cadence during racing may preserve energy during the bulk of the race. As training status also influences GE [2], changes in training status during the season may result in an altered GE and most efficient cadence during submaximal cycling exercise. Currently, the change in GE and most efficient cadence have not been investigated in young elite athletes during the preparation phase of the season. Therefore, the goal of this study was to determine GE and the most efficient cadence during submaximal cycling exercise of a group of young elite cyclists in the winter and in the spring. Methods: To investigate GE and the most efficient cadence, respiratory data (Cosmed Quark CPET) were collected in six young elite male road cyclists (18.5 ± 1.9 yrs), at five different cadences (70, 80, 90, 100, and 110 RPM), while cycling 6 min for each RPM at 4 W/kg (Iode, Excalibur Sport). Repeated measures ANOVA was used to determine differences in GE between cadences, while a post hoc analysis was then conducted to identify the significant differences between groups. Results: GE at 70 and 80 RPM (23.4 ± 0.6 and 23.5 ± 0.3 %) was significantly higher ($p < 0.05$) than GE at 90, 100 and 110 RPM (22.7 ± 0.4 , 22.1 ± 0.6 and 21.2 ± 0.5 %). Four cyclists were most efficient at 80 RPM and two cyclists at 70 RPM. Although the data of the first testing period have been collected, the data of the second testing period (which consists of an identical testing day as the first and an additional day to determine $\dot{V}O_2$ max using an incremental test) have to be collected in a few months' time. Conclusion: These talented young cyclists are almost as efficient as world-class cyclists [3]. Whether GE and most efficient cadence change after a winter training period will be determined in the coming months. References 1. Ettema, G. and H.W. Loras, Efficiency in cycling: a review. GROSS EFFICIENCY DURING FLAT CYCLING IN LABORATORY AND FIELD CONDITIONS

NIMMERICHTER, A., HASELSBERGER, K., PRINZ, B.

University of Applied Sciences Wiener Neustadt

Introduction Gross efficiency (GE) is described as the ratio of mechanical work accomplished to the metabolic energy required to do that work and is considered as important determinant of cycling performance. Only a few studies examined GE in field conditions and Bertucci et al. (2012) reported GE to be 10% lower in laboratory compared to field conditions when cycling at freely chosen cadences. Previously it was shown, that cadence (60 vs. 90 rpm) and terrain (flat vs. uphill) affect GE in field conditions (Nimmerichter et al. 2015). The aim of this study was to compare GE at controlled power output and cadence during laboratory and field cycling. Methods Thirteen trained cyclists (mean \pm SD: age 24 ± 5 years; stature 177.4 ± 6.3 cm; body mass 67.6 ± 7.8 kg) performed an incremental ergometer test to determine maximal power (402 ± 39 W), $\dot{V}O_2$ max (68.3 ± 4.2 mL/min/kg) and the first ventilatory threshold (VT: 180 ± 19 W). On two separate days the participants performed two trials of 6-min in a seated position on level ground cycling (1.5%) at 90 rpm at an exercise intensity of 90%VT (162 ± 20 W) in laboratory and field conditions. Power output was measured with an SRM professional power crank. To simulate the gradient in laboratory conditions, the bicycle was mounted on an indoor trainer (TACX Elite) and was fixed on a treadmill. Oxygen uptake was measured breath-by-breath with a portable gas analyser (MetaMax3B, CORTEX). Gross efficiency was calculated as GE (%) = work rate/energy expenditure*100. Energy expenditure was calculated using the formula of Brouwer (1957). Paired samples t-tests were used to compare GE, $\dot{V}O_2$ and power output between laboratory and field cycling. The level of significance was set at $p < 0.05$. Results There were no significant differences between laboratory and field conditions for power output (163 ± 21 W vs. 167 ± 22 W; $t_{12} = 1.88$; $p =$

0.09), GE ($18.6 \pm 1.2\%$ vs. $18.8 \pm 1.9\%$; $t12 = 0.29$; $p = 0.77$) and VO₂ (2.54 ± 0.37 L/min vs. 2.61 ± 0.43 L/min; $t12 = 1.41$; $p = 0.25$). Discussion As both, power output and cadence affect GE, the results of the present study indicate the importance to control these variables to determine GE in laboratory and field conditions. In contrast to a previous study where significant differences were reported at freely chosen cadences (Bertucci et al. 2012), this was not found under controlled conditions. Although effects of terrain on GE were reported in a previous study (Nimmerichter et al. 2015), there were no interactions between terrain and cadence, which suggests, that the present findings would also apply to uphill cycling in laboratory and field conditions. DIFFERENCES IN SHORT TERM PARASYMPATHETIC REACTIVATION IN MALE AND FEMALE CYCLISTS; PRACTICAL IMPLICATIONS FOR PREDICTING AND MONITORING TRAINING STATUS IN CYCLISTS

LAMBERTS, R.1,2, TAM, N.2, DAVIDOWITZ, K.J.2

1 Stellenbosch University; 2 University of Cape Town

Differences in short term parasympathetic reactivation in male and female cyclists; practical implications for predicting and monitoring training status in cyclists Introduction The measurement of parasympathetic reactivation after exercise to monitor changes in training status has gained popularity over the last few years (Plews et al., 2013). Recently, Lamberts et al showed that short term parasympathetic reactivation after the LSCT (a submaximal cycling test) is an accurate predictor of cycling performance (Lamberts, 2014). In this study 50 male cyclists were tested, but no female cyclists. Therefore the main aim of this study was to determine if parasympathetic reactivation patterns and their relationship with cycling performance are the same in female and male cyclists Methods Twenty trained female cyclists (4.8 ± 0.3 W/kg) and 50 trained male cyclists (5.1 ± 0.6 W/kg) were recruited for this study. All cyclists performed, after familiarisation, a LSCT followed by a peak power output (PPO) and 3 days later, a LSCT followed by a 40km time trial (40km TT) test. Short term parasympathetic reactivation (LnRMSSD60s) was captured as part of the LSCT and correlated to PPO, maximal oxygen consumption (VO_{2max}) and 40km TT time. Results Strong relationships were found between PPO & LnRMSSD60s in male ($r = 0.93$; $p < 0.0001$) and female ($r = 0.85$; $p < 0.0001$) cyclists, while slightly weaker relationships were found between VO_{2max} & LnRMSSD60s in male ($r = 0.71$; $p < 0.0001$) and female ($r = 0.63$; $p < 0.0001$) cyclists and 40km TT time & LnRMSSD60s in male ($r = -0.83$; $p < 0.0001$) and female ($r = -0.63$; $p = 0.003$) cyclists. Although similar slopes were found in male and female cyclists, the y-axis intercept was significant different in all three (PPO, VO_{2max} and 40km TT) performance parameters relationships with LnRMSSD60s ($p < 0.0001$). Discussion Although similar strength relationships were found between LnRMSSD60s and cycling performance parameters in male and female cyclists, different y-axis intercept were found between male and female cyclists. This finding indicates that different regression formulas need to be used when predicting and cycling performance parameters from short term parasympathetic reactivation measurements. Introduction: Surface anthropometry is widely used to assess and monitor athletes due to its strong relationship with sporting success. Furthermore, some measures are frequently used for talent identification in certain sports. Recently, 3D body scanning has emerged as a promising alternative to traditional surface measurements, offering greater accuracy and precision. However, various steps in the 3D data collection process and analysis can potentially introduce error. Therefore, assessing the reliability and validity of the 3D body scanning (3D) technology is required to ensure best practice for its use in the assessment of anthropometric variables. Methods: Physical measurements (PM) were collected using both traditional ISAK protocols and 3D body scans on 30 highly trained young male athletes (age 15.8 ± 1.7 y, body mass 62.9 ± 15.1 kg, height 174.0 ± 7.9 cm). Digital data analyses of the 3D scans were carried out in duplicate by 3 trained technicians. Interclass correlation coefficients (ICC) and relative technical error of measurements (%TEM) were calculated to assess the reliability of the 3D analyses between technicians, and also between the 3D and PM data. Pearson correlation and a paired sample t test ($p \leq 0.05$) were also conducted. Results: There was no significant difference for intra-retest reliability (ICC: 0.97 – 1.00) and inter-rater reliability for the 3D analyses (ICC: 0.63 – 1.00) or between each technicians 3D data analyses and the PM (ICC: 0.47 – 1.00). 3D intra-tester %TEMs ($\leq 1\%$) showed agreement for height and 4 body lengths. Inter-tester %TEMs ($\leq 1.5\%$) showed agreement for height and 5 body lengths between 3D data analyses and PM. The correlation analyses revealed moderate to strong but statistically significant Pearson correlation coefficients (range: 0.67 – 0.99) for all variables. Results of the paired t tests were significant for several variables, indicating a significant difference between the 3D and PM. Discussion: This study shows that there is evidence for the repeatability of 3D measurements when assessing height, breadths, and several limb lengths and girths. Even though, 3D scans can easily be reviewed post-collection as many times as needed, it cannot exactly replicate the techniques used for PM (i.e. ISAK protocols). Therefore, a combination of both digital and physical methods should be considered. References: Daniell, N. (2008). Kinanthropometry X, 39-54. New York, NY. FAT PATTERNING DIFFERENCES IN MALE AND FEMALE PERSONS: APPLICATION OF A HIGHLY ACCURATE AND PRECISE ULTRASOUND TECHNIQUE

STÖRCHLE, P.1, SENGEIS, M.1, MÜLLER, W.1

1: Medical University of Graz

Introduction Body composition influences both health and physical performance. Particularly in weight-sensitive sports, underweight and body composition disturbances can cause serious medical problems and can lead to severe performance setbacks [1]. For investigating body fat and subcutaneous adipose tissue (SAT) patterning in athletes, highly accurate and precise measurement methods should be applied. Diagnostic ultrasound (US) fulfills these criteria and also enables measurements in the field. The aim of this study was to examine the sex specific fat distribution differences at eight standardised sites used in this novel US method. Methods Measurements were carried out according to the standardised measurement protocol of W. Müller et al., 2016 [2]. The used sites in this protocol were: upper abdomen (UA), lower abdomen (LA), erector spinae (ES), distal triceps (DT), brachioradialis (BR), lateral thigh (LT), front thigh (FT) and medial calf (MC). 24 subjects (12 males and 12 females) were examined. In order to cover a wide range of SAT thicknesses the BMI ranged from 18.6 to over 40 kgm⁻². For evaluating the US images, a semi-automatic tissue contour detection and measurement algorithm was used (FAT software, rotosport.com). Results The five sites UA, LA, LT, FT, and MC showed significant differences between men and women in this group ($p < 0.05$), whereas ES, DT, and BR did not. In men, UA and LA contributed 51% to the sum of the eight fat thicknesses, whereas in women it was only 34%. In women, all three sites on the leg: LT, FT and MC (women: 26%, 12% and 8%; men: 15%, 8% and 5%, respectively) showed significantly higher SAT values. Mean value of the total sum of SAT was 85 mm in the men's group (mean BMI 26.8 kgm⁻²) and 117 mm in the women's group (mean BMI 24.6 kgm⁻²). Discussion The results obtained in this group show the pronounced SAT thickness differences at the eight sites chosen for the standardised fat patterning analysis in individuals and between a group of men and a group of women. LT, a site that has not been used in preceding studies, was found to be a fat depot site which is more pronounced in women than in men. In further studies, the differences between males and females should be investigated in larger groups. This measurement technique can also be applied for SAT studies in various groups of athletes and also in overweight persons. This method [2] provides a sensitivity for fat patterning studies not reached by any other method before. References [1] Müller, W., Maughan, R. J. (2013). BJSM, 47(16), 1001–1002. Introduction As training methods have become more sophisticated, each athletics group has become specialized, modifying its typical physique imperatives away from general morphological norms¹. However, the influence of total and regional body composition on swimmers aerobic capacity remains to be better clarified. The aim of this study was to analyze the influence of total and regional body composition on swimmers aerobic profile. Methods Eleven male (18.0±4.0 years of age, 180.2±6.8 cm in height and 71.8±9.5 kg in body weight) and five female swimmers (16.8±3.6 years of age, 166.2±5.5 cm in height and 61.1±9.8 kg in body weight) underwent the following evaluations: 1) Maximal tethered swimming force (Fmaxtethered), which consisted of two 30 seconds maximal efforts in tethered apparatus (Cefise®) with a 10 minutes rest interval to maximum and mean force determination (Fmax and Fmean)² and 2) a incremental test with a conventional load system tied to the swimmer with increments of 5% per minute (range 30–100% of Fmean). Oxygen uptake was assessed by an automatic and portable system (K4b2 Cosmed, Italy) for direct breath-by-breath analysis of pulmonary gas exchange, which was attached to the swimmer by a snorkel with a tri-dimensional valve (Aquatrainier®). Maximum oxygen uptake (VO_{2max}), respiratory compensation point (RCP) and gas exchange threshold (GET) were determined. Body composition was assessed by dual-energy X-ray absorptiometry method (DXA). Correlations were analyzed using Pearson's coefficient, $p \leq 0.05$ was adopted. Results Lean mass of the upper limb (LM_UL, 6741.9±1573.1 g) was significantly correlated to VO_{2max} (3423.0±601.9 ml·min⁻¹; $r=0.83$, $p<0.01$), RCP (3046.2±588.7; $r=0.80$, $p<0.01$) and GET (2214.8±455.0 ml·min⁻¹; $r=0.81$, $p<0.01$). The same was observed between lean mass of the lower limb (LM_LL, 20146.5±3844.4 g) and VO_{2max} ($r=0.81$, $p<0.01$), RCP ($r=0.79$, $p<0.01$) and GET ($r=0.67$, $p<0.01$) and between total lean mass (LM, 56852.8±10125.7 g) and VO_{2max} ($r=0.81$, $p<0.01$), RCP ($r=0.79$, $p<0.01$) and GET ($r=0.66$, $p<0.01$). VO_{2max} and RCP was not correlated to body fat (BF), only GET was correlated to BF_UL (16.0±8.6%; $r=-0.73$, $p<0.01$), BF_LL (19.6±8.1%; $r=-0.67$, $p<0.01$) and total BF (17.0±6.8%; $r=-0.66$, $p<0.01$). Discussion This study highlight that body composition plays an important role in swimming metabolic demand. The higher the physiological demand (respectively VO_{2max}, RCP, GET), the higher the influence of body composition. Tethered swimming may represent a useful method for aerobic assessment and regional body composition analysis seems relevant as the relationship between upper limb body composition and aerobic profile of the swimmers was always higher compared to total and lower limb. BODY COMPOSITION AND MENSTRUAL CYCLE IN ENDURANCE-TRAINED FEMALES. A PILOT STUDY

DELGADO, B., CASTRO, E.A., CUPEIRO, R., BARBA, L., BARRIONUEVO, E., PEINADO, A.B.

Technical university of Madrid

Introduction The association between menstrual cycle and body composition (BC) in healthy sedentary women has been widely studied (Elliot et al., 2015; Marsh and Jenkins, 2002); however, few studies have evaluated the relation between the different menstrual cycle phases and BC in athletes (Wojtys et al., 2015). Therefore, the aim of this study was to assess the influence of the menstrual cycle phases on BC variables in endurance-trained females. Methods Six endurance-trained females (body mass index 18.4 kg/m²); aged 36.67±4.46 years, participated in this study. BC variables were measured by bioelectrical impedance (OMRON BF 306W analyzer, OMRON HEALTH-CARE Co., Ltd, Ukyo-ku, Kyoto, Japan), at three phases of the menstrual cycle: Early Follicular Phase, (EFP), Midfollicular Phase (MFP) and Luteal Phase (LP). One-way ANOVAs with repeated measures were used to analyze differences among menstrual cycle phases and BC variables. Results No significant differences were observed for body weight, fat mass and lean body mass percentages, water or impedance among phases ($p>0.05$). Discussion Differences between menstrual and follicular phases for weight and fat free mass, as well as between the follicular and luteal phase for weight, has already been reported for sedentary women (Gleichauf and Roe, 1989). However, our results did not show differences in BC throughout the cycle in trained females. Although our data are preliminary, our outcomes are in agreement with other findings in female athletes (Marsh and Jenkins, 2002; Teixeira et al., 2013). Suggesting a different BC behaviour

throughout the menstrual cycle in trained women compared with healthy non-athlete females. More data are needed in order to elucidate the specific interaction between sex hormones changes and BC variables when studying endurance-trained women. References Elliot SA, et al. (2015). COMPENSATORY CHANGES IN HABITUAL PHYSICAL ACTIVITY IN RESPONSE TO AEROBIC EXERCISE UNDER WEIGHT STABLE CONDITIONS

DRENOWATZ, C.1, SHOOK, R.P.2, HAND, G.A.3, BLAIR, S.N.1

1: University of South Carolina (Columbia, SC, USA), 2: Iowa State University (Ames, IA, USA), 3: West Virginia University (Morgantown, WV, USA)

Introduction. A high total daily energy expenditure (TDEE) is generally associated with better long-term weight management. Many participants in exercise-based interventions, however, display a less pronounced increase in TDEE than what could be expected from the exercise program. The present study examined differences in habitual physical activity (PA) between compensators and non-compensators participating in an aerobic exercise program that targeted an increase in TDEE, while maintaining body weight. Methods. A total of 40, previously sedentary adults (65% male, 31 \pm 7 years) provided valid measurements at baseline and 3-month follow-up. Body weight was measured at baseline and at the beginning of every exercise session to ensure participants maintained their body weight. TDEE, exercise energy expenditure as well as time spent sedentary, in light PA and moderate-to-vigorous PA (MVPA) was measured with a multi-sensor device over a period of one week at each measurement time. Compensation was determined based on the difference in TDEE between BL and follow-up relative to energy expenditure during exercise; participants whose change in relative energy expenditure was less than exercise energy expenditure were classified as compensators. Results. Compensation was observed in 21 participants, while 19 increased their TDEE beyond the exercise energy expenditure. There was no significant association between compensation and the amount of exercise (i.e. number of exercise days, exercise duration, and exercise energy expenditure). Exercise participation was associated with an increase in MVPA on exercise days in both groups ($p<0.01$) but the increase was more pronounced in non-compensators (84 \pm 23 min/d vs. 62 \pm 32 min/d). Compensators displayed a significant decline in light PA (-37 \pm 29 min/d, $p<0.01$), while the reduction in sedentary time was non-significant. In non-compensators sedentary time declined significantly (-80 \pm 42 min/d, $p<0.01$), while light PA did not change significantly. Non-compensators further significantly increased MVPA at the expense of sedentary time on non-exercise days (31 \pm 8 min/d, $p<0.01$). Discussion. Given the limited amount of time spent in supervised exercise during a specific intervention, non-exercise behavior is a crucial aspect in the success of exercise-based interventions. In addition to compensatory adaptations on exercise days, the present study emphasizes the role of PA on non-exercise days. Participants, therefore, need to be encouraged to increase their MVPA outside any supervised exercise session while reducing sedentary time.

OP-PM30 Training Methods in Soccer

WARM-UPS WORK! EXAMINING THE TIME-COURSE OF CHANGES IN MUSCLE TEMPERATURE AND CONTRACTILE FUNCTION FOLLOWING THE PRE-MATCH WARM-UP IN SOCCER AND THE USE OF PASSIVE HEATING

MARSHALL, P.W.M., CROSS, R., LOVELL, R.

Western Sydney University

Background We were interested in examining the time-course of changes in quadriceps muscle contractile function and voluntary drive around a soccer specific warm-up, and how any changes contributed to measures of rate of force development as an experimental measure of muscle power. Moreover, considering the links between muscle temperature (Tm) and mechanisms of power output, we examined the effect of a 'cool-down' period commensurate with that observed in the EPL prior to match-play on measures used. Finally, we tested whether a passive heating garment applied after the warm-up would have any effect on measures we performed. Methods Ten amateur soccer players performed two experimental sessions that involved performance of a modified FIFA 11+ soccer specific warm-up, followed by a 12.5 minute rest period where participants were required to either wear normal clothing or a passive electrical heating garment was applied to the upper thigh muscles. Assessments around the warm-up and cool down included measures of maximal torque, rate of torque development, vastus lateralis muscle temperature (measured at a depth of 4cm), and electrically evoked measures of quadriceps contractile function and voluntary activation (10Hz and 100Hz doublet stimulation of the femoral nerve). Results Tm was increased after the warm-up by $3.2 \pm 0.7^\circ\text{C}$ ($p<0.001$). Voluntary and evoked rates of torque development increased after the warm-up between 20 to 30% ($p<0.05$), despite declines in both maximal voluntary torque and voluntary activation ($p<0.05$). Application of a passive heating garment in the cool-down period after the warm-up did not effect variables measured. While Tm was reduced by $1.4 \pm 0.4^\circ\text{C}$ after the rest period ($p<0.001$), this value was still higher than pre warm-up levels. Voluntary and evoked rate of torque development remained elevated from pre warm-up levels at the end of the cool-down ($p<0.05$). Conclusion The soccer specific warm-up elevated muscle temperature by 3.2°C and was associated with concomitant increases of between 20 to 30% in voluntary rate of torque development, which seems explained by elevations in rate dependent measures of intrinsic muscle contractile function. Application of a passive heating garment did not attenuate declines in muscle temperature during a 12.5-minute rest period.

AN EVALUATION OF THE RESISTANCE TRAINING PROGRAMMES IN AN ELITE SOCCER ACADEMY AND IT'S EFFECTS ON THE DEVELOPMENT OF ISOMETRIC STRENGTH

BROWNLEE, T., O'BOYLE, A., MORGANS, R., MORTON, J., ERSKINE, R., DRUST, B.

Liverpool John Moores University, Liverpool Football Club

INTRODUCTION Muscular strength is a desirable attribute in soccer players of all ages. The aim of this study was to evaluate the training completed by English Premier League soccer players in an academy over an 8-week period and to determine whether such training

increased isometric strength compared to a control group. METHODS Training for 184 elite soccer players from under 9 (U9) to under 21 (U21) was recorded over an 8-wk period. Data was examined to establish distribution of training time in soccer training, matches, non-resistance training athletic development activities and resistance training. From that group 155 elite and 93 control participants completed two isometric mid-thigh pull tests 8-wks apart. Isometric strength was expressed as both absolute and allometrically scaled (force * body mass 0.66). RESULTS Total training time progressively increased between the U9 (268 ± 25 min/wk) and U14 (477 ± 19 min/wk) age groups with only a small proportion of training time ($3 \pm 18\%$) consisting of training focussed on solely improving physical attributes. Total training time was then subsequently reduced from the U14 to the U15 (266 ± 77 min/wk) age groups, with no differences in training duration for any groups between U15 and U21 ($P > 0.05$). When the U15 to U21 squads (the only players who completed resistance training) were compared no difference in session duration was observed ($P > 0.05$). No main effect for peak isometric force (PF) between elite (1617.10 ± 611.15 N) and control (1535.69 ± 624.83 N) groups was present ($P = 0.087$). For allometrically scaled force (RF) a main effect was noted with the elite cohort (118.29 ± 21.96 N) being stronger than controls (109.69 ± 27.91 N) though no interaction between group and maturity status was observed ($P = 0.167$). Following 8 weeks of training no changes were seen in either group for PF (at 8 wk elite group 1580.12 ± 632.55 N; control group 1496.38 ± 555.51 N) or RF (elite group at 8 wk, 119.12 ± 23.43 N; control group at 8 wk, 110.89 ± 25.75 N) ($P > 0.05$). DISCUSSION These data examine training practices and isometric strength throughout an English Premier League soccer academy compared with a matched control group. They suggest that training practices evaluated here do not elicit increases in isometric strength. This is likely a result of the focus of training time on technical development. This data can provide practitioners with baseline isometric strength data and training data for comparisons across teams.

DEVELOPMENT OF STRENGTH AND BALANCE ABILITIES DURING ONE COMPETITIVE SEASON IN HIGH LEVEL FEMALE FOOTBALL PLAYERS OF DIFFERENT AGE GROUPS

ROTH, R., DONATH, L., ZAHNER, L., FAUDE, O.

Universität Basel

Introduction: Isokinetic assessment of thigh muscle strength is frequently applied to assess the risk of injury. Similarly, trunk muscle strength and a well-developed dynamic balance are considered beneficial with regard to sports performance and injury prevention. The aim of the present study was to assess leg and trunk muscle strength as well as dynamic balance in high-level female football players of different age groups over the course of a competitive season. Methods: 45 female soccer players of a high-level Swiss football club (under-16: N=19; age = 15.0 (SD 0.7) years; body mass = 54.6 (5.8) kg; under-18: N=15; age = 16.8 (0.6) y; body mass = 59.9 (8.0) kg; body fat = 18.4 (8.8)%; adult players: N=11; age = 21.2 (2.4) y; body mass = 61.1 (6.1) kg) participated. 26 (58%) of these players were tested twice (under-16: N=10; under-18: N=10; adults: N=6), at the end of the pre-season (November 2014) as well as at the end of the second leg of the season (May 2015). Hamstrings (H) and quadriceps (Q) strength was measured on an isokinetic device (IsoMed 2000) at a speed of 60°/sec, 240°/sec and -30°/sec (eccentric). H:Q-ratio was calculated at 60°, 240° and -30°/240° (Croisier et al., 2003). Ratios between flexion/extension and rotation were calculated for trunk strength measures. Dynamic balance performance was assessed by means of the Y-balance test. Results: Quadriceps strength in the preferred leg was higher in all age-categories for flexion (60°, under-16: +11% ($p=0.004$); under-18: +10% ($p=0.004$); adults: +10% ($p=0.007$) and extension (i.e. 60°, under-16: +4% ($p=0.31$); under-18: +7% ($p=0.09$); adults: +3% ($p=0.27$)) as compared to the non-preferred leg. H:Q-ratio also showed higher values in the preferred leg. Trunk strength and flexion-to-extension-ratios rose with age (under-16: 1.59 (0.28); under-18: 1.68 (0.21); adults: 1.86 (0.14)). Balance performance showed no differences between age groups and legs ($p>0.75$). An increase from pre- to post-season was found for knee extension peak torque (60°, preferred leg: +12% ($p=0.001$); non preferred leg: +10% ($p=0.08$)) in the under-16 players. Discussion: Our results show an inconsistent development in leg and trunk strength over age categories. However, players showed only small differences from pre- to post-season. H:Q ratios as well as the balance score developed differently in preferred and non-preferred leg. Whether strength and balance imbalances are potentially harmful cannot be clarified by our data. However, in order to prevent injuries and to detect maldevelopment timely, regular strength and balance assessment is advisable. References: [1] Croisier, J.-L., et al. (2003). IES 11(1): 61-62.

THE DEVELOPMENT OF A STANDARDISED PROTOCOL FOR MONITORING HEART RATE RECOVERY IN SOCCER PLAYERS

ORME, P.1,2, ANDERSON, L.1,2, MORGANS, R.1, MORTON, J.P.2, DRUST, B.1,2

1:Liverpool Football Club (Liverpool, UK) 2:Liverpool John Moores University (Liverpool, UK)

Introduction Physiological monitoring during the recovery process following elite soccer performance has been an area of considerable interest over recent years. The aim of this study was to develop a standardised exercise protocol for use in the calculation of heart rate recovery (HRR) that can be integrated into a training strategy used by an elite team. Furthermore, this study attempted to evaluate the reliability of the HR response to the protocol as well as compare the protocol to specific physical loads completed during the recovery period following soccer match play. Methods Three exercise protocols (1-6x60m 6ms 10:20s; 2-6x80m 5ms 16:14s; 3-6x60m 5ms 12:8s) were tested for reliability of HR response and suitability with regards to soccer training loads. Nine male competitive soccer players (Mean \pm SD: age 17 ± 0.6 years, height 1.7 ± 0.9 m, body mass: 63 ± 9.0 kg) took part in the study. All subjects completed one trial of each protocol on each of 5 data collection days (3 familiarisation trials and 2 testing sessions). Trials completed on each data collection day were separated by 30 min of seated rest. HR and GPS data was collected throughout all trials (duration, total distance, peak speed, %MAXHR, HRR at 1 min post exercise). Data were analysed using standard error of measurement (SEM) and coefficient of variation (CV) for reliability assessment and by the use of paired t-tests to compare the physical loads completed in the protocol and by players during actual recovery training sessions. Results There were no significant differences ($P<0.05$) between previous soccer recovery activities completed in training (duration- 3min, distance- 399m, peak speed- 4.7ms, %MAXHR- 74%) and the exercise protocols developed in this study (duration- 4min, distance- 406m, peak speed- 5.3ms, %MAXHR- 86%). All protocols elicited a %MAXHR above 80% (protocol 1-82.5%, protocol 2-85.5%, protocol 3-89.5%). CV and SEM were lower for both HRR and %MAXHR for protocol 2 (HRR CV=9.9%, HRR SEM=2.14% - %MAXHR CV=2.57%, %MAXHR SEM=2.19%) compared with protocol 1 (HRR CV=21.99%, HRR SEM=5.74% - %MAXHR CV=4.08%, %MAXHR SEM=3.36%) and 3 (HRR CV=40.41%, HRR SEM=10.41% - %MAXHR CV=2.62%, %MAXHR SEM=2.33%). Discussion This study developed a protocol (6x80m 5ms, 16:14s) that is suitable for use as a real world monitoring tool during the recovery period following soccer match play. The developed protocol presented CV and SEM data to suggest that this protocol is suitable for use to detect changes in the HR response. Contact p.orme@2009.ljmu.ac.uk

THE EFFECT OF STATIC STRETCHING ON MUSCLE RECOVERY FOLLOWING COMPETITIVE SOCCER MATCHES

POOLEY, S., SPENDIFF, O., ALLEN, M., MOIR, H.

Tottenham Hotspur FC

Introduction Static stretching (SS) is a recovery intervention often used in elite football for assisting in the reduction of muscle soreness post-exercise, and in research as a control for comparing alternative recovery interventions. However, its effects on elite young footballers has received little attention, and therefore the aim of this study was to assess the effects of static stretching on muscle recovery following competitive soccer matches in elite young footballers. **Methods** Participants used in this study were recruited from a professional football academy from the Premier League. Participants were male (16 ± 1 years) and of elite standard. Using a controlled cross-over design, participants completed a total of 6 competitive soccer matches followed by one of two recovery interventions (static stretching or passive recovery). The recovery interventions were conducted immediately following completion of competitive soccer matches. The static stretching protocol was administered comprising 7, 15 second stretches on lower body muscles whilst the passive recovery protocol comprised 10 minutes passive seating. Assessments used to measure muscle damage were taken before, within 30 minutes after, and 48hours post match and consisted of muscle oedema, Creatine Kinase (CK) assessment, countermovement jump (CMJ) height and perceived muscle soreness. To maintain control, players were excluded from individual games if they failed to complete a minimum of 80% of the competitive soccer match. **Results** When comparing the effects of recovery interventions over time, results showed that competitive soccer matches had a significant effect on markers of muscle damage, with almost all indicators showing significant differences for pre and immediately-post competitive match for recovery interventions, with only gastrocnemius oedema assessment showing no significant difference. Additionally, significant differences between pre- and 48 hours post-exercise assessments were found in perceived soreness, CK values and CMJ height. When comparing the effects of recovery interventions between conditions, the only difference observed was between CK which demonstrated improved levels of recovery in the static stretching group at 48 hours following exercise. **Discussion** The findings from this study demonstrate that competitive soccer matches provide strenuous exercise, inducing muscle damage which may have detrimental effects on future performance. This is demonstrated by the reduction in CMJ performance and elevation in CK and muscle soreness at 48 hours post-exercise. Furthermore, there is limited evidence to suggest that a static stretching protocol would assist in the reduction in muscle damage post-exercise, with only CK showing improved effects. The improved effects of static stretching on CK are unclear, however may be linked to the idea that static stretching assists in the removal of muscle oedema following exercise. Additionally, it may be possible that due to the elite standard of participants, they have a heightened level of CK removal post-exercise.

Oral presentations**OP-PM42 Recovery Modalities****EFFECT OF TWO RECOVERY STRATEGIES ON PERFORMANCE RECOVERY: COLD-WATER IMMERSION VS WHOLE-BODY CRYOTHERAPY.**

ABAÏDIA, A.1,3, LAMBLIN, J.3, DELECROIX, B.1,3, LEDUC, C.2, MC CALL, A.4, NÉDÉLEC, M.2, DAWSON, B.5, BAQUET, G.1, DUPONT, G.1,3,4

Introduction Cold-water immersion and whole-body cryotherapy are two commonly used strategies to accelerate recovery following muscle-damaging exercise. Some studies have shown a positive effect of both strategies on accelerating the recovery kinetics (Ingram et al., 2009; Ferreira-Junior et al., 2015). However, to our knowledge, no study has yet compared these two strategies in direct competition with each other. The purpose of this study was therefore to investigate which recovery strategy; cold-water immersion versus whole-body cryotherapy was more effective at enhancing the recovery kinetics following a muscle-damaging exercise. **Methods** In a randomized cross-over design, ten subjects performed a muscle-damaging exercise protocol: 5 sets of 15 single leg eccentric contractions for the hamstring muscle. Immediately following the exercise, subjects were either, immersed in cold-water (10 minutes at 10°C) or exposed to whole-body cryotherapy (3 minutes at -110°C). The recovery kinetics were assessed immediately, 24h, 48h and 72h after the muscle-damaging exercise. Specifically, the recovery protocol consisted of measuring; creatine kinase, hamstring maximal force, countermovement jump height, perceived muscle soreness and perceived recovery. **Results** A very likely (99% and 97%) moderate effect was found in favour of cold-water immersion for one-leg (Effect Size=-0.63; 90% CI=-1.38 to 0.13) and two-leg countermovement jump (ES=-0.68; 90%CI=-1.43 to 0.08) 72h after exercise respectively. The perceived muscle soreness was moderately lower 48h after exercise in the cold-water immersion condition (ES=0.68; 90% CI=-0.07 to 1.44). Perceived recovery was moderately improved 24h after the exercise in the cold-water immersion group (ES=0.62; 90% CI=-0.13 to 1.38). Trivial and small effects of condition were found for the other outcomes. **Discussion** According to the findings in the present study, cold-water immersion was more efficient to accelerate recovery kinetics compared to whole-body cryotherapy. Specifically, recovery was enhanced for one and two-leg countermovement jump 72h post-exercise. Cold-water immersion also showed a greater ability to reduce perceptions of muscle-soreness and improve the level of perceived recovery. In regards to muscle strength indices, there was no difference in recovery between both strategies. References Ferreira-Junior JB, Bottaro M, Vieira A et al. (2015). THE EFFECTS OF TWO DIFFERENT CRYOTHERAPY INTERVENTIONS ON MARKERS OF RECOVERY FOLLOWING A 26.2 MILE TRAIL RUN

WILSON, L., COCKBURN, E., PAICE, K., SINCLAIR, S., FAKI, T., DIMITRIOU, L.

Middlesex University

Introduction Following strenuous exercise, it is common for athletes to experience symptoms of muscle damage, inflammation, oxidative stress and fatigue (Appell et al., 1992). The use of cryotherapy as a recovery strategy is becoming increasingly popular as a means to try and minimise the negative impact of strenuous physical activity on subsequent exercise performance (Leeder et al., 2012). Therefore, this

study aimed to assess the effects of whole body cryotherapy (WBC) and cold water immersion (CWI) on markers of recovery following a bout of prolonged endurance exercise. Methods Thirty one endurance trained males (mean age 39.4 ± 7.9 years; height 1.77 ± 0.07 m; mass 77.7 ± 9.05 kg) completed a 26.2 mile trail run (average completion time 229.3 ± 23.4 minutes). Participants were randomly assigned to a CWI (10 min at $8^\circ \pm 0.5^\circ\text{C}$), WBC (1 x 3 and 1 x 4 min separated by 15 min at $-85^\circ \pm 5^\circ\text{C}$) or placebo group. Ratings of perceived muscle soreness, changes in muscle function, and perceptions of training stress were recorded before exercise, immediately after completion of the assigned intervention and at 24 and 48 hours following completion of the trail run. Self-reported sleep quality data was also recorded for a week before, and a week after completion of the trail run. Results Exercise resulted in significant increases in muscle soreness immediately, and 24 hours following the trail run. Significant decreases in peak knee extensor torque, maximal voluntary isometric contraction (MVIC) and counter-movement jump (CMJ) height were recorded immediately, and 24 hours post exercise. Perceptions of training stress were significantly increased immediately after exercise but returned to baseline by 24 hours post. Self-reported measures of sleep quality did not alter significantly at any time point. Despite significant main effects for time across all dependent variables except sleep quality, there were no significant differences between groups at any time point. Discussion These results suggest that cryotherapy (CWI or WBC) applied immediately following strenuous endurance exercise is no more effective than a placebo intervention for improving these specific markers of recovery in endurance trained athletes. PRE- OR PERCOOLING BY ICE SLURRY INGESTION TO IMPROVE CYCLING TIME TRIAL PERFORMANCE IN THE HEAT

LEVELS, K., VAN OVERBEEK, B., VAN DE WESTELAKEN, L.

Vrije Universiteit Amsterdam, MOVE Research Institute Amsterdam (Amsterdam, The Netherlands)

Pre- or percooling by ice slurry ingestion to improve cycling time trial performance in the heat Introduction The ingestion of ice slurry has become a popular way of cooling to improve endurance exercise performance in the heat. Consuming ice slurry can take place before exercise (precooling) or during exercise (percooling) and it has been shown that both methods can be beneficial for performance (Bongers et al., 2015). However, at this moment it is still unclear which regime should be preferred: pre- or percooling. Therefore, the aim of this study is to compare the effect of precooling and percooling by ice slurry ingestion on performance during a 30-km cycling time trial in the heat. Methods Ten experienced, trained cyclists (age: 27 ± 9 years, body mass: 77 ± 8 kg, VO_{2max}: 58 ± 4 ml/kg/min) performed one maximal incremental exercise test, one 30-km familiarisation time trial and two experimental 30-km cycling time trials in the heat ($29.9 \pm 0.5^\circ\text{C}$, relative humidity: $38 \pm 7\%$). The cycling time trials were preceded by the Lamberts and Lambert Submaximal Cycling Test (LSCT: Lamberts et al., 2011) as a warm-up. The participants ingested 7.5 g/kg body mass ice slurry during the LSCT (PRE) or during the cycling time trial (PER). Power output (PO), rectal temperature (Tre), mean skin temperature (Tsk), heart rate (HR), rating of perceived exertion (RPE), thermal sensation (TS) and thermal comfort (TC) were measured. Results Finish time of the time trial did not differ between conditions (PRE: 2752 ± 133 s, PER: 2739 ± 176 s; P=0.65). In line with this, PO was similar (PRE: 257 ± 36 W, PER: 263 ± 43 W; P=0.39). A statistical trend was observed towards a difference in pacing pattern between PRE and PER (interaction-effect: P=0.08), displayed by a higher PO towards the end of the time trial in PER. Mean HR during the time trial was similar for PRE and PER (P=0.27). Precooling did not result in a lower Tre at the start of the time trial (PRE: $37.9 \pm 0.3^\circ\text{C}$, PER: $37.9 \pm 0.3^\circ\text{C}$; P=0.66) but the increase in Tre during the time trial was smaller in PER than in PRE (P=0.008). Tsk and RPE were similar during the time trial for both conditions (P=0.93 and P=0.83, respectively) whereas TS and TC during the time trial were higher for PRE than for PER in the last 10 km. Discussion No difference was observed in performance during a 30-km cycling time trial in the heat between precooling or percooling. Therefore, the moment of ice slurry ingestion, either before or during a cycling time trial, appears to be irrelevant. References Bongers C, Thijssen D, Veltmeijer M, Hopman M, Eijsvogels. ACUTE EFFECTS OF FOAM-ROLLING ON JUMP HEIGHT AND SOFT TISSUE STIFFNESS

BAUMGART, C., KÜHNEMANN, M., HOPPE, M.W., FREIWALD, J.

University of Wuppertal

Foam-rolling is frequently used during warm-up and regeneration procedures for self-myofascial release [1]. However, the acute effects on performance and potentially underlying soft tissue properties are not fully understood. Therefore, the study aimed to evaluate the acute effects of foam-rolling on jump height and soft tissue stiffness of the lower extremities. Twenty male active subjects (26.9 ± 2.6 years, 181.6 ± 6.8 cm, 80.4 ± 9.1 kg) were randomized to execute the following three interventions: 2x30 repetitions of foam-rolling (FR) on the thigh and calf (BLACKROLL, Bottighofen CH), 10 min of ergometer cycling (EC), and controls (CO). Before as well as 0, 15, and 30 min after each intervention, three countermovement jumps were performed on a force plate (Kistler 9287BA, Winterthur CH). Soft tissue stiffness was measured on two points (M. rectus fem., M. gastrocnemius med.) of both legs by myomechanography (MyotonPRO AS, Tallinn EST). Data were analyzed using a two-way repeated measures ANOVA (time x intervention) as well as one-way repeated measures ANOVA with post-hoc Bonferroni correction. Pearson correlation coefficients were used to investigate relationships between changes in the jump height and stiffness. A significant main interaction (time x intervention) was found in jump height (p<.001, eta²=.81) and stiffness of M. rectus fem. (left: p=.002, eta²=.74, right: p=.008, eta²=.67). Thereby, jump height increased only after EC (34.8 ± 3 vs. 36.4 ± 3 cm, p=.001) and decreased thereafter as in FR and CO. Stiffness of M. rectus fem. decreased after FR (left: 266 ± 24 vs. 260 ± 27 N/m, p=.01; right: 268 ± 32 vs. 260 ± 33 N/m, p=.004) and return to pre-values afterwards. However, the increase in stiffness of M. rectus fem. after EC was not significant (left: 265 ± 28 vs. 270 ± 31 N/m, p=.17; right: 270 ± 33 vs. 275 ± 34 N/m, p=.12). The Pearson correlation coefficient between the changes in jump height and stiffness of M. rectus fem. after all interventions was .40 (p=.002). Soft tissues properties were altered after foam-rolling. In contrast to a traditional warm-up on a cycling ergometer, the jump height did not increase and the soft tissue stiffness of the thigh decreased after foam-rolling. Therefore, the isolated use of a foam-roller as a warm-up procedure before explosive activities seems to be questionable. Future studies have to show if the decrease of the stiffness is caused by fascial, muscular, and/or other soft tissues. [1] Schroeder AN, Best TM. Is self myofascial release an effective preexercise and recovery strategy? A literature review. Current sports medicine reports. 2015;14(3):200-208.

THE EFFECT OF FOAM ROLLING ON RECOVERY BETWEEN TWO 800-M RUNS

DAMICO, A.1, MATTHEWS, T.2, WOOD, R.2, PAOLONE, V.2

1: Salem State University (Salem, MA, USA), 2: Springfield College (Springfield, MA, USA)

Introduction With the increased popularity of foam rolling as a means of recovery, it is important to establish the exact manner in which the practice is useful. Therefore, the purpose of this study was to examine the impact of foam rolling on recovery between two 800 m runs. Methods Sixteen male middle distance runners (mean \pm sd; age, 20.5 \pm .5 years; 800 m run time, 145.2 \pm 1.8 seconds) participated in the study, using a randomized, crossover design. The subjects completed two 800 m runs on a treadmill, separated by a 30 min rest, during which time a foam rolling protocol or passive rest period was performed. The speed of each run was as fast as possible. Subjects had access to speed controls, but were blinded to the actual speed. Blood lactate concentration and VCO₂ were measured prior to and following each run. Stride length, running economy, 800 m run time, and hip extension were measured during each run. Results VCO₂, stride length, running economy, 800 m run time, and hip extension were not significantly different between conditions ($p > .05$). For blood lactate, no statistical interaction was found between condition and time ($p > .05$). Discussion Foam rolling between two 800 m runs separated by 30 min performed by trained male runners does not alter recovery and subsequent performance. These findings are in contrast to investigations utilizing longer periods of time between exercise bouts, such as 24, 48, or 72 hr, and measures of strength and power (Macdonald et al., 2014; Pearcey et al., 2015). Our research was limited to the influence of foam rolling on short-term recovery in 800 m runners. The length of the rest interval and the type of athletic event may determine the efficacy of foam rolling towards an athlete's recovery. References Macdonald GZ, Button DC, Drinkwater EJ, Behm DG. ROLLER MASSAGE DOES NOT ALTER EVOKED PAIN PERCEPTION OR CONTRACTILE PROPERTIES

DOEWELING, A.1, CAVANAUGH, M.T.2, HOGDSON, D.D.2, QUIGLEY, P.J.2, WHITTEN, J.H.2, YOUNG, J.D.2, BEHM, D.G.2

1: Ruhr-University Bochum, Germany (Department of Training & Exercise Science), 2: Memorial University of Newfoundland, Canada (School of Human Kinetics and Recreation)

Introduction Foam-rolling (FR) and roller massage (RM) have become a common practice with warm-up or recovery from exercise. It is believed to promote soft-tissue extensibility, improve muscle function, and reduce pain. However, it is not known if RM directly alters muscle properties. Therefore, the aim of this study was to determine if RM has an immediate effect on evoked contractile properties and sensation of evoked pain. Methods In a randomized repeated-measures design ($n = 12$) the acute effects of three different RM interventions on evoked pain perception (PP / i.e. pain visual analog scale (VAS) with evoked twitch and submaximal and maximal tetanic stimulation of the dominant calf muscles), maximum voluntary isometric contraction (MVIC) force and evoked contractile properties (twitch and tetanic maximum force, time to peak force, half relaxation time and rate of force development) were investigated. The interventions consisted of 3 x 30s bouts of 1) heavy rolling massage (7/10 perceived pain) on the stimulated calf, 2) heavy rolling massage (7/10) on the contralateral limb and 3) light rolling (<1/10) on the stimulated calf (Control). Testing was conducted prior to the RM intervention as well as 1 and 5 min after the intervention, respectively. Results A two-way repeated measures ANOVA revealed no statistically significant main effects or interactions (roller massage intervention x testing) regarding PP, MVIC and evoked contractile properties. Discussion This data suggests that a single bout of RM had no effect on evoked or voluntary contractile properties. Furthermore, evoked twitch and tetanic pain remained unaffected by RM. Based on the present and prior research; RM may not predominately affect muscle properties nor reduce all types of pain.

OP-SH13 Sociology: Development

SPORT-FOR DEVELOPMENT: ARE WE CROSSING BORDERS IN RESEARCH?

SCHULENKORF, N.1, FRAWLEY, S.2, SUGDEN, J.3, FUJAK, H.4, SIEFKEN, K.5

1-4 UTS (Sydney, Australia), 5 Medical School Hamburg (Germany)

Introduction Over the past decade, the field of sport-for-development (SFD) has received significant attention from practitioners and researchers around the world. We have seen a strong proliferation of sport-based projects that aim to contribute to developmental outcomes such as economic development, social inclusion, cultural cohesion, healthy lifestyles, fair education, and gender equity (Coalter, 2013; Schulenkorf & Adair, 2014). In this paper, we critically analyse the research context of SFD by asking the question: Where is SFD research undertaken, by whom, and are researchers crossing borders? Methods Building on project information listed on the established SFD platform of the Swiss Academy for Development (sportanddev.org) and the comprehensive integrative review of SFD literature that was recently published by Schulenkorf, Sherry and Rowe (in press), we conducted a content analysis that investigated the geographic representation of SFD projects around the world; the home-location of the researchers involved in SFD studies; and any joint research projects in which international researchers have been 'crossing borders' to cooperate with local researchers. Findings First, by February 2016 a total of 639 organizations are involved in SFD programs all over the world (see sportanddev.org); however, a large majority of projects are implemented in Africa, Latin America, Asia and the Middle East. Second, the significant majority of the total 383 researchers that contributed to published SFD studies are based in Europe (37%), North America (36%), and Australia/New Zealand (19%), and much of SFD research is being undertaken in the "home countries" of these researchers. Third, local contributors from low- and middle income countries were significantly under-represented in the research teams, with less than 10% of journal articles noting their inclusion. Discussion The geographical contexts of study location and research authorship present an interesting paradox: Although the majority of SFD projects are carried out in LMICs, a staggering 90% of SFD research authors are based in high-income countries. This suggests that there is a clear practitioner-scholar divide in SFD. Moreover, only a minority of academics is 'crossing borders' for their research work and, perhaps most alarmingly, for their research engagement with local actors in the field. We conclude that hundreds of SFD projects in LMICs are therefore not benefitting from any kind of research engagement or academic support. In addressing these issues, research capacity building exercises should be promoted that strengthen the integration of—and collaboration with—academics in LMICs to improve their research access, skills, and/or opportunities. References Coalter, F. (2013). Sport for Development: What Game Are We

Playing? London: Routledge. Schulenkorf, N., & Adair, D. (Eds.). (2014). Global Sport-for-Development: Critical Perspectives. Basingstoke: Palgrave Macmillan.

A COMPARATIVE STUDY ON THE ROLE OF ATHLETIC AND COMMUNITY SPORT IN SOCIAL DEVELOPMENT

GHAFOURI, F., GHAEDI, A.

Allameh Tabatabai University,

The aim of this study was to examination and compares the role of athletics and community sport on social development indicators (social welfare, personal, health, social health and social Justice) from the perspective of sport Professionals and Managers. Instrument was, 50-item questionnaire in four indicators of social development. Of 235 questionnaires 65% returned to the researchers. A Construct factor analysis was conducted to establish validity of the measurement scale, followed by ANOVA to examine and compare the role of athletic and community sport on development indicators by occupation. The results showed that in social welfare, role of athletic sport ($M= 3.47$, $SD = .47$) was more than role of the community sport ($M= 3.34$, $SD = .52$). In personal and social health, Unity and social solidarity, Social Justice, the role of community sport was greater than the role of athletic sport. In total of 4 Dimensions, role of community sport ($M= 3.49$, $SD = .48$) was more than role of athletic sport ($M= 2.34$, $SD = .46$). Discussion: The results suggest that both types of sport have great role on social development indicators. However, in most of indicators, role of community sport is greater than athletic sport. This finding is consistent with results of, Ekholm (2013) that showed sport had an important role on prevent and reduce crime and social deviations. The results are also in consistent with Sugden (2006), who showed sport had an important role in forge a community spirit in the face of social ills, promote peace and conflict resolution, prevention of cultural violence and building social structure. Sport is an activity which has great potential to development. According to the results, sport is generally considered as a tool for development of society. However, more comprehensive type of sport, community sport, has greater effect on social indicators. Nickolson et al (2013) showed that the role of sport organizations, generally greater than non-sport organizations in some social indicators like, attachment, social integration, reliable alliance, guidance, and opportunity for nurfurance. The present study compared the role of two sectors within sport organizations in social indices. The results include an important message for governments; although athletic sport may bring political prestige for you, community sport can bring personal prestige for majority of people you lead! Additionally, they will be able to play their role in making of modern and healthy community. References: Ekholm, D. (2013). Sport and crime prevention: individuality and transferability in research. ADULT SPORT PARTICIPATION IN THE U.S. AS CULTURAL CAPITAL

STEMPEL, C.

California State University, East Bay

Stempel, C.11: CSUEB (Hayward, California, USA) Introduction Dominant class adults in the U.S. participate more in competitive and fitness sports than middle/working class counterparts. More study is needed on cultural capital processes of sport participation, lifestyle divisions between the culturally and economically dominant classes, and where sport fits in the field of high status practices (Bourdieu, 1984; Stempel, 2005; Thrane, 2001; Veenstra, 2010). We test these questions by exploring relationships between participation in 3 types of sporting activities (fitness, competitive, attending elite sporting events) and participation in 3 types of high culture practices (residual, hegemonic, scholastic). Methods Data from the Survey for Public Participation in the Arts is analyzed using logistic and linear regression. Building on Bourdieu's focus on the volume and structure of capital we test a mapping of class lifestyles that fits the U.S. Key hypotheses are: 1. Dominant class occupations will lead participation in all 3 types of sports. 2. Fitness sport participation will be highest in the culturally dominant occupations. 3. Attending sporting events and sport omnivorosity (does all 3) will be highest in the economically dominant occupations. 4. All sport practices will be most weakly associated with the residual/tradional high culture. 5. All sports, particularly fitness sport, will be most strongly associated with scholastic high culture. 6. Hegemonic high culture will also be strongly associated with attending sporting events and participation in all 3 sports. Results Results generally confirm hypotheses. Discussion Sport participation is a neglected, but leading indicator of changes in the structure of cultural capital processes labeled 'omnivorism.' Contra interpretations that emphasize democratization, the patterns better fit emphases on moral individualism and personal responsibility related to neoliberalization, and a remasculinization of culture (Burstyn, 1999; Hall & Lamont, 2013; Lizardo & Skiles, 2012; Wacquant, 2009). THE ROLE OF FUNDING WITH INCLUSIVE PHYSICAL ACTIVITY PROGRAMS

WRIGHT, E.M., STEMPEL, C., HAFT, N.

California State University East Bay

Introduction We report on a study on non-governmental organizations providing socially marginalized youth opportunities for sport and physical activity in Oakland and San Francisco, California. We contextualize the study in terms of the growing privatization and adult organization of youth sports and recreation (Coakley, 2014; Messner, 2009), and an increasing emphasis on 'competitive kid capital' (Levey Friedman, 2013) among the dominant classes in the U.S. In this context we wonder how intentionally inclusive play leaders are envisioning the role of sport and physical activity in the lives of marginalized youth and how they have organized their programs to foster their goals. Methods We conducted semi-structured, in-depth interviews with leaders of 5 organizations serving marginalized youth. Interviews were analyzed using a comparative case study framework focusing on how organizational leaders developed their programs, including how their vision of sport and the role of sport has evolved; challenges they have overcome to sustain their program; challenges they are currently facing; and current practices that foster inclusivity. Results We found that programs had a variety of starting places, visions, motivations, and initial pathways. Securing ongoing funding is a primary challenge that shapes program goals and structures,

and organizational practices and routines. Analysis of current challenges includes managing tensions between maintaining inclusivity and pressures to focus on high performance sport; serving a population being dispersed by gentrification; and meeting the demands of funders for evidence of program effectiveness. Discussion These findings are discussed relative to the existing literature and frameworks on inclusive programming (e.g. Donnelly & Coakley, 2002). Further, we specifically highlight the role of grants and funding opportunities for inclusive sport/physical activity organizations and how these shape available programs. We discuss adapting to funders' definitions of program success and possibilities for using research to build a network of support for increased public funding. We conclude with this observation that research evaluating program effectiveness is a great need of organizations offering sport and physical activities for marginalized groups. OP-SH23 Statistics

BELIEVES AND ATTITUDES AMONG YOUTH AND PROFESSIONAL FOOTBALL PLAYERS REGARDING INJURY PREVENTION

ZECH, A., WELLMANN K.

University of Jena

Introduction Although injury prevention strategies can be successfully promoted among team coaches and physiotherapists (Junge et al. 2011) it is still unknown which of these measures are generally accepted and regularly used by athletes. The objective of this study was to collect first data on perceptions on injury mechanisms and risk factors as well as used prevention strategies among professional and youth football players. Methods The study was a cross-sectional survey among professional and youth football players in one German high-level football club. 139 youth (n=115) and professional players (n=24) between age 13 and 35 years completed a standardized questionnaire. It included categories with history of injuries and perceptions regarding the influence of intrinsic and extrinsic factors on lower extremity football injuries. Athletes were also asked to report which of several prevention strategies they regularly use for injury prevention. Pearson's Chi-Square test was used to test whether these injury rates, perceptions on potential risk factors and preventive measures were differently distributed between teams or between injured and non-injured players. Results The response rate of returned questionnaires was at 98%. 84.2% of respondents reported a previous injury in the lower extremities. Most injuries of players between U17 and the first team occurred at the ankle joint whereas the younger teams (U16 and U15) reported more injuries at the thigh / groin. 47.5% of respondents believed that physical contact with other players is a risk factor for lower extremity injuries, followed by physical fatigue (38.1%), environmental factors (including equipment, 25.9%), muscle impairments (25.7%) and previous injuries (21.7%). The majority of respondents consider injury prevention important or very important. 91.5% of all players declared regularly to use stretching exercises in order to prevent injuries. About half of all respondents (54.0%) perform specific warm up exercises and one third (33.1%) specific strength exercises. External measures used regularly by players are taping (27.3%), shoe insoles (27.0%) and bracing (11.5%). Conclusions The results show that athletes in general are positively disposed towards injury prevention. Nearly all athletes perform stretching in order to prevent injuries although no scientific evidence exists for this measure. Thus, effective transfer measures are needed to promote use of research evidence in football practice. GAME STYLES IN FIELD SPORTS: DEFINING AND MEASURING IT

NORTON, K., HEWITT, A., GREENHAM, G.

University of South Australia

Introduction 'Game style' is a term commonly used by coaches, sports scientists, performance analysts and media to refer to patterns of play in team sports. Despite these pervasive references there is not a definition for game style and consequently it is not possible to measure game style. Team sports are dynamical systems and we can quantify how players interact in various contextual environments and circumstances. These interactions, particularly successful, dominant or recurrent patterns, are important in forming a game style and play a part in our perceptions of game style. This study proposes a definition of game style and an initial framework of variables that can be measured and used to describe game style. Methods The game style framework is based on metrics within five key moments of play: (1) Established Attack, (2) Transition from Attack to Defense, (3) Established Defense, (4) Transition from Defense to Attack, and (5) Set Pieces. If variables can be reliably measured and assigned to one of these moments then they can be used to categorise game style in sports. The total number of variables is potentially unlimited. We trialed the system in several sports in 2015-16 using multiple games per team and multiple measurements within each moment (a total of 12 performance variables). The variables measured were compared among 6 teams in the competition to calculate z-scores. They were then combined for a single z-score within each moment, reflecting the relative strength or weakness of that moment within games. ANOVA can then be used to determine differences among teams within each moment. Results Our working definition of game style was: 'the characteristic playing pattern demonstrated by a team during games. It will be regularly repeated in specific situational contexts such that measurement of variables reflecting game style will be relatively stable. Variables of importance are player and ball movements, interaction of players, and will generally involve elements of speed, time and space (location)'. Game style plots of the 5 moments were generated following 14 games in an elite football competition. These allowed visual and statistical comparisons that highlighted a team's typical play pattern and game style. Discussion Our game style assessment system and plots have practical applications for coaches and practitioners when evaluating efforts to create or compare game styles. Importantly, they allow performance analysts to: (1) categorise and monitor game styles over time, across leagues and age groups, (2) compare against benchmark performances of top teams, and (3) produce evidence of dominant and weaker elements of a team's game style in invasion-based field sports that can also be used to model training drills.

THE INFLUENCE OF CONTEXTUAL FACTORS AND PLAYER CHARACTERISTICS ON MATCH ACTIVITY PROFILE IN PROFESSIONAL AUSTRALIAN FOOTBALL

COUTTS, A.J., SULLIVAN, C.J., CIANCIOSI, M., BILSBOROUGH, J., KEMPTON, T.J.

University of Technology, Sydney (UTS)

Introduction Match activity profiles in Australian Football (AF) have been shown to vary between individuals and throughout the season. Indeed, factors such as playing position, the opponent, individual player characteristics, player interchange, skill involvements, the environment, match score and competition scheduling have been shown to independently influence match activity profile. However, previous studies have failed to control, or account for the interactive effects of these contextual factors when interpreting player activity profiles. Therefore, this study used multi-level, mixed-modelling to examine the independent effects of match contextual variables and player characteristics on match activity profile in professional AF. Methods Global positioning system (GPS) and technical performance measures were collected from 35 players competing in the Australian Football League over two seasons to provide 327 individual matches. The GPS data were categorized into relative total distance (m/min) and relative high-speed running distance (HSR m/min, >14.4 km/h). Each match was classified according to season phase, location, recovery length, opposition strength, match result, win/loss margin, environmental temperature, skill involvement and objective performance rating. Individual player fitness was obtained from a 2-km maximal run time-trial conducted prior to the start of the competition seasons. Two separate multi-level, mixed-models were constructed to examine the influence of match-related and individual player characteristics on relative total and HSR distances. Results Higher player fitness (i.e. time-trial performance), increased interchange, away games, and stronger opposition increased HSR m/min and m/min. Matches following short recovery cycles were associated with greater HSR m/min distances. Players who had greater objective performance scores also had greater m/min but not HSR/min. Conclusions A complex interplay of match contextual and individual player characteristics affect match activity profiles in professional AF players. These results underline the importance of considering the effects of match scheduling (i.e. location, recovery period), opponent, playing tactics and individual fitness and performance characteristics when interpreting match activity data in professional AF. SEARCHING TACTICAL PATTERNS IN SOCCER GAME PLAY BY UNSUPERVISED MACHINE LEARNING

LESER, R., HOCH, T., TAN, X., MOSER, B., BACA, A.

Centre of Sport Science

Location systems in game sports provide a wealth of data, which is capable of reconstructing game play from a tactical point of view. Precise position measurements up to 50 times per second/player during an entire soccer game enable in-depth analyses of individual and collective game behavior. Small-sided games (SSGs) are used in soccer training to simulate specific game situations. By the given constraints (smaller pitch size, lower number of players) SSGs are used to provoke intended player behavior with a higher rate than it occurs in the full-size game. Due to these properties SSGs are also suited to analyse successful/unsuccessful tactical patterns in a reasonable framework. The research described in this paper aims to identify behavioral patterns in soccer SSGs based on the players' positional data. The approach is demonstrated by a 3vs2-SSG (3 attackers playing versus 2 defenders), which is often used in soccer training to acquire collective and individual goal scoring skills against a shorthanded opponent. Based on expert information the SSG is temporally segmented and for each defined key moment and temporal phase a couple of parameters are derived from the position data. Statistical methods (e.g., the laplacian score for feature selection) reduce the high-dimensional parameter space to a manageable number of variables. This resulted in the 3vs2 analyses in 9 parameters describing the shot and the assist (last past) situations. For each of the two situations unsupervised pattern recognition was performed by spectral clustering. For the shot as well as for the assist situation three different patterns were identified. The goal ratios for the assist patterns range from 0 to 29%, the goal ratios for the shot patterns from 8 to 24%. By a fuzzification of the quantitative parameters into linguistic variables the outcome of the pattern recognition process becomes understandable and interpretable for experts like coaches. The results give evidence that the most efficient assist is a middle distance to goal pass from the side to the centre, whereas rear-faced passes are far more successful than forward-faced passes (47 to 8% goal rate). Shots with the highest success rate are performed from a middle distance to the goal in the centre of the field. The findings of our study give data-based hints for successful tactical principles in soccer, which are likely valid also for the 11-a-side game. For the 3vs2 test case we can support the common coaches' assumption that ball possession at the wing moves the defenders to the side, which creates space in the centre field. This enables opportunities with the highest goal scoring probability.

IDENTIFYING TACTICAL PATTERNS IN SOCCER GAME PLAY BY MEANS OF AN EXPLANATORY COMPUTATIONAL MODEL

HOCH, T., LESER, R., TAN, X., BACA, A., MOSER, B.A.

Software Competence Center Hagenberg

Introduction The tactical analysis of player behaviour in team sports like association football is of great interest. The increasing availability of position data allows for an in-depth analysis of tactical behaviours of individual players (Leser et al., 2015). The high complexity of player interactions, however, makes the assessment of individual tactic skills based on time-continuous position data difficult. Methods We address the problem of designing an explanatory computational model for player assessment by fusing fuzzy human-like knowledge related to tactical behaviour with unsupervised feature extraction based on time-continuous position data from a tracking system. Our hierarchical model architecture consists of two layers. The first layer provides an abstract representation of the time domain via temporal segmentation of the data into game-situation specific temporal phases. Conceptually the coarsened view on the time domain is modelled via a Markov chain where transitions between states represent meaningful events. In a second step we then identify different behaviour patterns hidden in the data with unsupervised machine learning techniques. The main focus of this layer is to provide the trainer with a qualitative description of the key differences of the behaviour patterns based on key performance indicators. We show how to reduce the high dimensionality of the input space using unsupervised dimensionality reduction methods and how to provide a meaningful explanatory model for the trainer using natural language expressions. Results and Discussion We illustrate our approach by means of three different kinds of small-sided games in association football with increasing complexity. Starting with a 1vs1 situation with low complexity, we show the principals of our modelling approach. Next we show that for 3vs2 and 5vs5 situations our approach is able to identify the underlying dynamical patterns of player interactions. With the multifactorial statistical analysis, as presented in this paper, we are able now to present the complex interaction between the automatically selected measurement variables in a qualitative way that is

suitable for the trainer. Reference Leser, R., Moser, B., Hoch, T., Stögerer, J., Kellermayr, G., Reinsch, S. & Baca, A. (2015). Expert-oriented modelling of a 1vs1-situation in football. International Journal of Performance Analysis in Sport, 15 (12), 949-966.

FUNCTIONAL SEMANTICS EMBEDDED IN THE ASSESSMENT OF SELF ORGANIZATION IN SOCCER

LOPEZ-FELIP, M.

University of Connecticut

Introduction To date, much of the research on coordination dynamics in team sport has benefitted from concepts and tools from Dynamical Systems Theory (DST). However, while DST provides suitable techniques for modeling living systems, it makes no direct claims about their status nor provides a theoretical basis for understanding the principles of their behavior. The aim of this study was to develop a method of analysis to measure the self-organization of teams based on a recently developed ecological ontology of perception and action in soccer [1]. This framework applies DST to the functional semantics of the game, where, for example, self-organizing behaviors in the defensive team are defined by the relations between the position of the possessor of the ball relative to the goal as a function of time. Method Twenty-two elite soccer players from La Liga played a practice game during a training session. Player position data were collected via GPS (10 Hz) for an entire match (two halves of thirty minutes). We analyzed the degree of synchronization in the defensive team in terms of the Kuramoto order parameter (cluster amplitude) r , (high synchronization = 1) by measuring location data (x,y coordinates on the pitch) over time [2]. Results Team synchronization was measured in 4 blocks of 5 minute time-epochs. For block 1 ($r = 0.978 \pm 0.014$); block 2 (0.962 ± 0.033); block 3 (0.981 ± 0.026); and block 4 (0.968 ± 0.046). However, while mean synchronization across blocks was fairly consistent, $F(1, 8) = 0.22$, $p = 0.65$, the overall degree of synchronization ranged between 0.84 and 0.99. To account for this drastic changes we compared our synchronization time series of all blocks to corresponding events in the match. Visual inspection of these time series revealed five instances when r decreased by more than 0.20. These dramatic decreases in the defensive team's synchrony corresponded with scoring opportunities of their opponent. Discussion Our analysis by means of the Kuramoto order parameter revealed that the synchronization measure was able to distinguish between periods of low and high group synchronization. Using this approach as a foundation, we are building a preliminary model that captures systematic changes in coordination between defensive players at the local (one-on-one) and global (team-wide) scales—quantifying breakdowns in the stability of the defensive team's coordination and showing how they anticipate scoring opportunities for an opponent. This approach promises to address gaps in this literature by taking DST measures related to group coordination and synchrony and integrating them with measures that capture the functional, qualitative aspects of the game. IS-PM13 Physical activity and brain vascular function

DEHYDRATION AND EXERCISE – CEREBROVASCULAR CONTROL AND ORTHOSTATIC TOLERANCE

RICKARDS, C.

University of North Texas Health Science Center

Exercise represents a physiological stressor that challenges the maintenance of cerebral blood flow and oxygenation as a result of increased metabolic demand (cerebral and systemic), elevated perfusion pressure (arterial pressure), changes in arterial PO₂ and PCO₂, dehydration, and heat stress. These interrelated factors play a role in the regulation of cerebral blood flow and oxygenation during exercise, and can also affect subsequent tolerance to orthostasis following the exercise bout, particularly when combined with post-exercise hypotension. In particular, dehydration due to environmental/situational conditions (heat stress, lack of adequate hydration fluids, exercise intensity and duration) or purposeful dehydration (fluid restriction for weight loss) can further exacerbate the exercise-induced impairments in cerebral blood flow regulation, placing the athlete at greater risk of orthostatic intolerance. The modality (aerobic vs. resistance) and duration (endurance vs. sprint) of exercise influences the magnitude of dehydration, the timing and magnitude of cerebral blood flow impairment, and risk of subsequent orthostatic instability. This presentation will explore the independent and combined effects of exercise (aerobic and resistance), dehydration, and heat stress on cerebral blood flow and cerebral oxygen regulation, highlighting recent advances in the examination of cerebral oxygen metabolism, and regional cerebral blood flow responses. The implications of these responses on the risk of orthostatic intolerance will be examined. Knowledge gaps in this field of investigation will be presented, and future research directions will be discussed.

EXERCISE, CEREBRAL BLOOD FLOW AND PERCEIVED EXERTION IN TYPE 2 DIABETES PATIENTS

VAN LIESHOUT, J.J.

Academic Medical Centre, University of Amsterdam, Netherlands & School of Life Sciences, University of Nottingham, United Kingdom

Reduced exercise tolerance in type 2 diabetes mellitus (T2DM) patients is incompletely understood, and has been attributed to cardiac impairment and impaired muscle metabolism. Physical activity by T2DM patients markedly improves the impaired insulin action, but unfortunately these patients also perceive sustained aerobic exercise to be considerably more strenuous than healthy, non-diabetic people. This, in turn, sets a limit to the effectiveness of physical activity as a preventive life-style factor for this patient population. In this talk I will review ideas about the role of brain blood flow (BBF) control during exercise in their physiological limits of performance. When the brain is activated, as during exercise, an increment in BBF enhances cerebral oxygenation. The cerebral hyperperfusion in the early phase of exercise may be an important precaution because BBF declines in the later stages of exercise, mainly by the dominant negative effect of progressive hypocapnia on BBF. Brain function deteriorates when its oxygenation is reduced by more than 10% from the resting

level. In contrast, skeletal muscles tolerate oxygen desaturation down to 10%. In healthy exercising subjects a progressive reduction in cerebral oxygenation precedes development of so-called central fatigue. Debate continues on whether the subsequent reduction in cerebral oxygenation in the later stages of exercise could play a role in the development of central fatigue with reduced motor drive to working muscles. A key focus of the lecture will be on how in T2DM an inability to increase cardiac output sufficiently may interfere with the normal increase in BBF in response to exercise with consequences for maintaining brain oxygenation. j.i.vanlieshout@amc.uva.nl

IS-PM14 Achieving and maintaining a large weight loss: The role of exercise

EFFECTS OF EXERCISE ON APPETITE REGULATION

ROSENKILDE, M.

University of Copenhagen

The body weight of human beings is defended by a host of compensatory responses after a diet-induced weight loss. The biological responses range from changes in both long term and short term hormonal regulators of appetite to the efficiency of storage and utilization of energy, such that weight regain is biological predisposed in the weight reduced. In the context of human evolution and survival mechanisms opposing a negative energy balance seems logical. However, in response to an bout of endurance exercise where energy is expended and energy balance must be acutely negative, a biological reverse pattern in markers of appetite is immediately observed favoring suppression of appetite, a phenomena known as exercise-induced anorexia. Despite this immediate suppression of appetite habitual exercise is not regarded as an effective weight loss strategy. Whether this transient suppression in hormonal markers of appetite persists when exercise becomes habitual is not well described in the literature. Here the physiological regulation of appetite in response to exercise is reviewed.

EXERCISE, OBESITY AND CARDIOMETABOLIC RISK: DOES EXERCISE INTENSITY MATTER?

ROSS, R.

Queen's University

Although progress has been made to elucidate the effects of exercise as a strategy for reducing obesity and related cardiometabolic risk, the specific exercise exposures required to achieve optimal benefit continue to be the source of considerable uncertainty and debate. Implicit within current guidelines for physical activity and health is the observation that 75 minutes of weekly high intensity exercise is equivalent to 150 minutes of lower intensity exercise. Consequently the guidelines suggest that there are no added health benefits of high intensity exercise other than the shorter time frame needed to expend the appropriate amount of energy. In other words, the benefits of engaging in high intensity exercise are attributed to the greater amount of energy expenditure per unit time, and do not relate to intensity per se. The scientific committee report from which current guidelines were developed recognized that many unanswered issues exist in response to the question of how much of what type of activity is appropriate for a given health outcome and acknowledged that future investigations need to evaluate the effects of exercise intensity at fixed amounts of energy expenditure. In this presentation emerging evidence regarding the separate effects of exercise intensity and amount on cardiorespiratory fitness and related cardiometabolic risk factors will be considered. Major gaps in knowledge will be identified and the quality of evidence upon which exercise intensity has independent effects will be scrutinized. Finally, the inter-individual response for selected cardiometabolic risk factors in response to standardized exercise will be considered.

A ROLE FOR EXERCISE AFTER WEIGHT LOSS FROM GASTRIC BYPASS SURGERY

COEN, P.M.

Florida Hospital

Obesity predisposes an individual to type 2 diabetes (T2D), cancer, and cardiovascular disease and places a massive strain on healthcare providers. Bariatric surgery is the most effective therapeutic option for obesity and provides significant weight loss and diabetes remission to a larger percentage of patients. However, the long term efficacy for bariatric surgery is not clear and there is evidence that weight regain and T2D relapse are problems for some patients. Exercise is also a therapeutic option for obesity that greatly improves metabolic health including peripheral insulin sensitivity and is important for maintenance of weight loss following diet induced calorie restriction. Recent evidence indicates that following significant weight loss, bariatric surgery patients remain relatively sedentary. Recent studies also indicate that exercise is a feasible and clinically effective adjunct therapy for bariatric surgery patients leading to additional improvements in metabolic health. We extend these recent findings to hypothesize that exercise is likely a critical factor for long term weight loss maintenance and lasting remission of T2D in bariatric surgery patients. We will draw on evidence from exercise and diet induced calorie restriction studies which support this hypothesis. Finally, we will outline the future studies needed to generate evidence for contemporary exercise guidelines for this unique patient population.

OP-BN13 Running Biomechanics 2

MECHANICAL WORK EXPLAINS THE HIGH METABOLIC COST OF SHUTTLE RUNNING

PAVEI, G.1, MONTE, A.2, NARDELLO, F.2, MINETTI, A.E.1, ZAMPARO, P.2

1. Università degli Studi di Milano; 2. Università degli Studi di Verona

Introduction Shuttle running (SR) is a common activity in field sport (e.g. soccer and basket) and differs from linear running (R) by the presence of accelerations, decelerations and changes of direction (CoD). Previous studies have shown that the metabolic cost (C , $J \text{ kg}^{-1} \text{ m}^{-1}$) of SR is up to 7 times larger than in R and that the difference decreases by increasing the SR length (Zamparo et al. 2014). The work done by muscles to accelerate the body centre of mass (BCoM), the external work (W_{ext}), and the work to accelerate limbs with respect to BCoM, the internal work (W_{int}), have been previously shown to account for most of the cost of locomotion (Minetti et al. 1993). The aim of this study was to calculate the mechanical work in SR to understand the determinants of its larger metabolic cost compared to R. Methods Twenty trained males (22.6 ± 2.4 years, 77.6 ± 9.9 kg, 1.82 ± 0.06 m) performed SR (5+5 m with a 180° CoD) at low, moderate and maximal speed; three trials were performed for each speed. The 3D position of 18 markers was recorded by 14 Vicon cameras at 100 Hz in order to compute the BCoM trajectory and the related values of W_{ext} , W_{int} and total work ($W_{tot} = W_{ext} + W_{int}$). Based on the C vs. v relationship reported by Zamparo et al. (2015) in SR over this same distance (5+5 m with a 180° CoD), metabolic cost was estimated as $C = 11.94 \cdot v_{mean} - 12.82$. Results In the speed range analysed (2.0 - 3.5 m s^{-1}) mechanical work ($J \text{ kg}^{-1} \text{ m}^{-1}$) increased linearly with speed, $W_{ext} = 1.388 + 0.337 \cdot v_{mean}$ ($P < 0.001$); $W_{int} = -1.002 + 0.853 \cdot v_{mean}$ ($P < 0.001$); $W_{tot} = 1.329 \cdot v_{mean}$ ($P < 0.001$, $n=180$) where v_{mean} is mean speed (m.s^{-1}). Locomotion efficiency (W_{tot} / C) was $19.7 \pm 2.4\%$ when considering, as in R, only positive work; when including also negative work, efficiency became 21.3%. Discussion Mechanical work in SR is larger than in R; this supports its role as a determinant of the increased C , particularly when considering that elastic energy in SR is much lower than in R, as witnessed by the obtained efficiency (within the 'just' muscle efficiency range). SR shows two acceleration and deceleration phases, where the work done to accelerate the limbs with respect to the BCoM is largely involved. At high speeds W_{int} values are equal to W_{ext} values and thus could not be neglected in the mechanical analysis. Moreover, braking can be substantial in SR, thus the analysis of mechanical work performed by muscles to move BCoM and limbs should consider both positive and negative work in order to better understand the determinants of the metabolic demand in SR. TIME-CONTINUOUS KINEMATIC ASSESSMENT OF THE DIFFERENCES BETWEEN BAREFOOT AND SHOD GAIT

LAMB, P., ADHIA, A., BUTTON, B.

University of Otago

To protect the calcaneus at ground contact during barefoot walking and running, humans tend to plantarflex the ankle to prepare for a forefoot strike (Lieberman et al., 2010). Accordingly, the literature has shown that several other kinematic parameters are also adjusted during the gait cycle to achieve the forefoot strike. The kinematic variables reported in the literature, however, are chosen at discrete events in the gait cycle to allow statistical analyses (Tam et al., 2016). The purpose of the current study was to test the hypothesis that discrete mediolateral ankle and knee angle values characterize the differences between barefoot and shod gait completely. Thirty-eight participants walked and ran for 30 s at two leg length normalized speeds ($M = 1.78 \text{ m/s}$, and 2.53 m/s , respectively) in shod and barefoot conditions. Data were collected at 100 Hz using a ten-camera Vicon system. Ankle and knee Cardan angles were calculated in Visual3D. Statistical parametric mapping (SPM; Pataky, 2010) was used to assess the differences in knee and ankle flexion throughout the gait cycle when walking and running shod compared to barefoot. The t statistic was computed at each time frame, forming a single t' trajectory. The significance of the t' trajectory was assessed by computing a critical t threshold that smooth Gaussian trajectories would reach in only alpha=5% of many repeated experiments. Our results confirm that the following discrete values reported in the literature (Franklin et al., 2015) were contained within the time frames at which the t' trajectory exceeds the $p=0.05$ threshold: increased knee flexion at ground contact and decreased ankle dorsiflexion at ground contact when barefoot for walking and decreased knee flexion during stance and early swing as well as decreased dorsiflexion at ground contact when barefoot for running. Additionally, knee flexion was reduced during the swing phase, plantarflexion onset was earlier in late stance, which also lead to earlier dorsiflexion in early swing when walking barefoot; during running the ankle was less dorsiflexed during stance, but more dorsiflexed during early swing when barefoot. The SPM analysis showed that the differences between barefoot and shod gait are not solely key events such as foot strike. None of the discrete variables from the literature persisted to be significantly different for less than 10% of the gait cycle with many persisting longer than 20% of the gait cycle. This suggests that discrete variables may have limited sensitivity in biomechanics without associated exploratory analysis using tools such as SPM. References Franklin S, et al. (2015). ACUTE EFFECTS OF MINIMAL SHOES OR BAREFOOT INTERVENTION ON FOOT STRIKE PATTERN WHEN RUNNING IN NORMAL RUNNING SHOES AGAIN

DOLENEC, A., RADJ, P., STROJNIK, V.

University of Ljubljana, Faculty of sport

Introduction Most recreational runners use rearfoot strike pattern when running in shod conditions (de Almeida et al., 2014). Switching from rearfoot strike to forefoot strike increase lower limb loading and should be done gradually (Ridge et al., 2013). There is lack of data what happens with foot strike pattern when runners experience short barefoot or minimal shod intervention and switch back to normal running shoes. Therefore, the aim of this study was to analyse acute effects of minimal shoes or barefoot conditions on foot strike pattern when running in normal running shoes again. Methods Nineteen subjects (age = 33.5 ± 6.7 years, height = 173 ± 9 cm, mass = 73.5 ± 13.9 kg), randomly divided into two groups participated in this experiment. Subjects in the group1 ran barefoot, while subjects in the group2 ran in minimalistic shoes (Altra, model Zero Drop The ONE). Both groups got information about forefoot strike pattern and were encouraged to use it. The initial and the final state of the foot strike patterns was measured in classic running shoes. Protocol of the

experiment was described in details in Dolenec et al. (2015). Results Only the group 2 changed the foot placement on the ground significantly ($p = .028$). 38% of the subjects in this group changed foot placement on the ground from the heel strike to the forefoot strike in all 18 analyzed steps. Still half subjects in the group 2 did 90 % of all steps with heel strike pattern. Discussion Only subjects in the group 2 significantly changed to forefoot strike pattern when using normal running shoes again. This was rather surprising since barefoot running force runners to switch from rearfoot to forefoot strike pattern (Lieberman et al., 2010) and consequently it was expected that barefoot running might play an important role for switching from rearfoot strike to forefoot strike pattern. Fatigue might play an important role on our results since barefoot running represents higher lower limb loading than shod conditions (Paquette et al. 2013) and consequently higher fatigue than minimalist shoes with certain cushioning properties. Due to high fatigue, subjects of group 1 might rather choose comfortable rearfoot strike than high demanding forefoot strike when running in shod conditions again. THE RUNNING BIOMECHANICS AND ECONOMY OF SOUTH EAST ASIANS: WE DO NOT ALL RUN THE SAME

HÉBERT-LOSIER, K.1, LUSSIANA, T.2, TEE, C.C.L.1

1: National Sports Institute of Malaysia (Kuala Lumpur, Malaysia), 2: Université de Franche-Comté (Besançon, France)

Introduction There are numerous running biomechanical and physiological studies; however, few of these involve well-trained South East Asian (SEA) runners. Knowledge on the biomechanical and physiological characteristics of SEA runners and how these differ from non-SEA runners could inform on exercise prescription and the potential for cross-ethnic study inference. Hence, our aims were to compare the biomechanics and running economy of well-trained long-distance runners from SEA to those from outside of SEA (non-SEA). **Methods** Seventeen SEA distance runners were matched based on sex, age, and running performance level to seventeen non-SEA runners. Baseline anthropometric and running history characteristics were collected first. Thereafter, running economy and biomechanics were assessed for all subjects ($n = 34$) running on a treadmill at 10, 12, and 14 km/h using a metabolic cart and an 8-camera 3D motion system, respectively. Data were analyzed using mixed effects models that considered group (SEA vs. non-SEA), speed (10, 12, and 14 km/h), and group-speed interaction effects. **Results** The SEA runners were shorter, lighter, and had smaller body mass indexes. Despite similar weekly mileage, race performance, and ratings of perceived exertion during the economy test, SEA runners were significantly less economical than non-SEA runners at the three examined speeds (10-12%). The SEA runners employed shorter and quicker steps, striking the ground closer to their center of mass and more frequently with their midfoot or forefoot (55%) than non-SEA runners (5%). The former group also exhibited less hip and knee extension at push-off. **Discussion** Despite similar performance levels, our SEA runners were less economical than non-SEA runners and demonstrated different movement patterns. The SEA runners relied on a higher cadence to compensate for their smaller stature. The footstrike and push-off mechanics of SEA runners were also remarkably dissimilar from non-SEA runners, suggesting differences in muscle recruitment patterns and foot-ground interactions. Previously published research in the field has mainly focused on Caucasian or East African runners; but based on our current findings, the generalization across ethnic groups may not apply. Exercises that focus on the leg extensors and horizontal force application might benefit the running performance of well-trained SEA runners. Contact Kim Hébert-Losier, PT, PhD: hl.kim@isn.gov.my

HEAD FLEXION IN OLDER ADULTS DURING WALKING HAS NO EFFECT ON GAIT PATTERN

DEWHURST, S., MASLIVEC, A., BAMPOURAS, T.M.

University of Cumbria

Introduction Older adults are known to adopt a greater head flexion during walking when compared to young adults (Marigold and Patla 2008). Although head flexion may provide a better visual field during locomotion, stability could be threatened. Buckley et al. (2005) reported that head flexion is destabilising in older adults during quiet standing, however the effect head flexion has on gait stability has not been examined. The purpose of the study was to investigate whether gait patterns differed between a naturally adopted head position and an instructed fixed head position, at different walking intensities, in young and older adults. **Methods** 15 young (23 ± 4 years) and 16 older (76 ± 6 years) healthy females walked along a 9m flat walkway at three different walking intensities (slow, comfortable and fast) under two head positions (natural and fixed (focusing on an eye level visual target)). Gait parameters (step length, double support time, step time and gait stability ratio) were recorded using Optopjump, while head angular displacement in the sagittal plane was assessed using 2D video analysis. A mixed design ANOVA was performed for each variable, with age as a between-subject factor and walking intensity and head position as within-subject factors. **Results** While walking with natural head position, older adults displayed greater head flexion at all walking intensities ($p < 0.05$) when compared to young. With regards to walking intensity, older adults had greater head flexion during slow walking compared to comfortable ($p < 0.01$) while young showed no difference between walking intensities. The fixed head position reduced the head flexion at all walking intensities ($p < 0.05$) in the older group, but not in the young. Modifying the head position between natural and fixed position had no effect on gait variables at any of the walking intensities. **Discussion** The greater head flexion seen in older adults when walking at different walking intensities, appeared to have no effect on gait patterns. Findings suggest that head flexion may be a behavioural adaptation to increase the feeling of stability due to a greater footfall visibility however this adaption does not appear to affect gait stability. **References** Marigold DS, Patla AE.
